2. Of 6 rabbits treated with a lipid-metaprotein preparation, 2 showed very slight transient increases of titer, one showed fluctuation of the previously constant Kahn titer in an elevated range, 2 showed primary diminution and

secondary elevation of titer, most marked in the Kahn but also evident in the other flocculation tests; one, after a previously negative reaction, showed a definite rise of titer, evident in all tests and comparable to that seen in the rabbit injected with flocculate from human syphilitic serum.

3. Of 2 rabbits treated with heated autogenous serum, both exhibited elevation of the Kahn titer during the first five weeks.

4. Two rabbits were treated with aqueous extract of rabbit tissues. One showed no definite serologic change. The other showed a rising Kahn titer but was found to have a splenic lesion, possibly a granuloma due to the injected lipids.

5. Two rabbits were treated with a lipid extract of rabbit tissues; one showed a very slight transient increase of titer, most evident in the Kahn test, and the other exhibited an incidental lesion, *Echinococcus* cyst, which is believed to have affected the serologic results.

6. Two rabbits were treated with a peptic metaprotein from "lipid free" rabbit tissues, and each showed a transient increase of titer most evident in the Kahn test but of doubtful proportions.

CONCLUSIONS

While the evidence brought forward may not be entirely convincing, it is compatible with, and is best explained by, the conception that reagin is a closely related group of antibodies and not a single chemically constant compound, and that, while the primary serologic change in syphilis may be the formation of antibodies to *T. pallidum*, the potential or actual occurrence of positive or doubtful reactions with lipid antigens in the absence of syphilis results from the formation of antibodies to the "ubiquitous lipid," either from some other infectious agent or from the tissues of the host, dependent upon the liberation of lipid haptens and protein derivatives capable of activating them.

VITAL CAPACITY STUDIES IN THE AGED

ISIDORE MILLER, M.D., NEW YORK, N. Y.

SINCE 1846 the estimation of the vital capacity has been used as a measure of respiratory efficiency. Various standards and tables have been set based on occupation, weight, surface area, standing height, sitting height, and chest circumference. These standards were needed for comparison, since differences were found in the ability of men with the same vital capacity to resist dyspnea. In 1846 Hutchinson¹ in his work with the spirometer used the standing height as the standard of comparison, the vital capacity varying directly with the standing height. Peabody and Wentworth² also used standing height measurements; they divided people into three groups, according to height, and made average vital capacity readings for each group. Dreyer³ and West⁴ used surface area standards in their work. Dreyer³ divided people into three groups, based on physical fitness. His vital capacity figures varied from high in the active athlete and laborer group to low in those with sedentary occupations. Training, sex, and occupation all played a part in the vital capacity.

Most of the work with vital capacity has been done on adults. Observations made on the aged have been only incidental and were based on relatively few cases. Hutchinson¹ found an increase in vital capacity with age up to 30 years, and a definite decrease after 50 years. Loomis⁵ stated that with advancing years the vital capacity decreased with tolerable regularity, about 1.5 cubic inches each year. He reported that a healthy adult exhaled about 1,340 cubic inches of carbonic acid per hour; in men between 60 and 80 years the amount fell to 930 cubic inches, and in very old men it diminished to 670 cubic inches. Charcot⁶ found that the functions of the respiratory apparatus were weakened in old age, the amount of the carbonic acid exhaled decreased, the number of inspirations increased, and the vital capacity of the lungs was reduced. Myers⁷ studied the vital capacity of 88 women and 118 men, 66 years of age and over. The average vital capacity in men decreased with age from 74 per cent to 53 per cent; in women it decreased from 52 per cent to 44 per cent. Pratt⁸ studied the influence of age on the vital capacity of 100 normal men in the second to the eighth decade of life. He reported a maximum capacity in the third decade, after which it slowly decreased. Bowen⁹ studied the vital capacity of 184 people between 15 and 85 years, of whom 64 were over 50 years. He found the greatest drop between 50 and 60 years. Lemon and Moersch⁹ stated that age had little effect before 50 or 60 years, and only a variable effect after that age. The decrease in vital capacity, if present, accompanied the decrease in physical fitness occurring at this period of life. The decrease was due not so much to age as to the degenerative changes and to the changes in height and weight which occurred in this age group. Levy¹⁰ reported his studies

on the vital capacity of 110 men and 71 women, 60 to 94 years of age. In men the average vital capacity decreased from 2,980 c.c. at 60 to 65 years to 2,350 c.c. at 86 to 94 years. In women the average vital capacity decreased from 1,985 c.c. at 60 to 65 years to 1,460 c.c. at 86 to 92 years.

TABLE I

AGE	NUMBER OF MEN	AVERAGE VITAL CAPACITY	
		C.C.	PERCENTAGE OF NORMAL
40-44	4	3,150	79
45-49	7	3,200	80
50-54	50	3,000	75
55-59	73	3,000	75
60-64	126	2,900	72.4
65-69	168	2,750	70.6
70-74	171	2,700	70.2
75-79	100	2,650	69.2
80-84	36	2,600	68.8
85-89	6	2,500	68.1
90-94	3	2,400	62

The vital capacity studies in this report were made on 744 men, 40 years of age and over. These men were inmates of the New York City Farm Colony, a home for the aged. The test was done in the afternoon hours, between meals, and in the different dormitories, which are situated on the ground floor and on the second floor. The men rested on the side of their beds for thirty minutes to rule out any possible dyspnea which might be due to walking or to climbing the one flight of stairs. Each man was given three trials at the spirometer, and the highest figure was taken as his normal. Weight and sitting height determinations were made on each man. The vital capacity readings were compared with the weight and sitting height, and the tables of Myers⁶ were used to determine the percentage of normal.

Table I gives the average vital capacity and percentage of normal by five-year periods. There is a decrease in the average vital capacity from 3,150 c.c. at 40 to 44 years to 2,400 c.c. at 90 to 94 years. The decrease in percentage is from 79 to 62. The average vital capacity of the group as a whole was 2,780 c.c., 71 per cent of normal. Our determinations agree closely with those of Levy.¹⁰

DISCUSSION

Vital capacity is the sum total of tidal, supplemental, and complemental air; it is the maximum expiration of air as measured by a spirometer after the deepest inspiration. The vital capacity decreases with advancing age. The decrease is due to physiologic conditions that occur in the aging body. Degenerative changes are the most important. The lung tissue becomes less elastic, the thoracic cage is more fixed, and the muscular power diminishes.

Pulmonary pathology decreases the vital capacity. In 5 patients with pulmonary fibrosis and silicosis, the average vital capacity was 2,040 c.c., 50 per cent of normal. The figures for this group would have been lower if we had included several men whose attempts to do the test were not accurate. The first attempt at the spirometer brought on an attack of coughing and dyspnea, and further trials had to be abandoned. In 27 men with bronchiectasis the average

vital capacity was 2,130 c.c., 55 per cent of normal. Pulmonary tuberculosis (30 men) and pulmonary emphysema (31 men) gave a similar picture, an average vital capacity of 2,400 c.c., 62 per cent of normal. The patients with pulmonary tuberculosis had the productive type of lesion, with involvement of one or both apices or upper lobes.

Blood pressure variations had no effect on vital capacity with the exception of the group, with a systolic pressure of 200 mm. and over. This group had an average vital capacity of 2,400 c.c., 62 per cent of normal. Seventy men with heart murmurs, systolic murmurs at either the mitral or aortic areas, and 27 men with auricular fibrillation had normal vital capacity readings. Physical examination revealed no evidence of decompensation in these cases.

Vital capacity studies to be of use must be interpreted correctly. A single reading is not as accurate as a series of readings; a fall in vital capacity is important. A normal vital capacity does not denote the absence of pulmonary pathology; a low vital capacity is of significance. A vital capacity of 90 per cent and over is considered normal.¹¹ With a vital capacity of 80 to 90 per cent, work can be done, but any increased strain will produce dyspnea. With a reduction in vital capacity to 40 to 70 per cent, only light work can be done, and a slight increase in effort will produce dyspnea. With a vital capacity of 40 per cent or less, patients are usually dyspneic even without effort. Of the 744 patients 40 years of age and over, 11 per cent had a vital capacity of 90 per cent and over; 45 per cent had readings between 70 and 90 per cent; 43 per cent had readings between 40 and 70 per cent; and 2 per cent had readings under 40 per cent. It can be concluded that the older age group can do light or moderate work, but an increase in effort would produce dyspnea.

CONCLUSIONS

1. Vital capacity determinations were made on 744 men, 40 to 94 years of age. There was a decrease in vital capacity from 3,150 c.c. (79 per cent of normal) at 40 to 44 years to 2,400 c.c. (62 per cent) at 90 to 94 years. The vital capacity for the group as a whole was 2,780 c.c. (71 per cent). The causes of the decreased vital capacity are loss of elasticity of the pulmonary tissue, the lessened mobility of the thoracic cage, and diminished muscular power.

2. Pulmonary fibrosis, pulmonary tuberculosis, pulmonary emphysema, and bronchiectasis gave vital capacity readings below normal for their age groups.

3. Compensated heart cases gave normal vital capacity readings. Lowered figures were found in men with blood pressure of 200 mm. and over.

4. A normal vital capacity does not denote the absence of pulmonary pathology; a low vital capacity is significant.

PULMONARY ASPERGILLOSIS*

J. M. DONALDSON, JR., M.D., C. J. KOERTH, M.D., AND
R. G. McCORKLE, M.D., SAN ANTONIO, TEXAS

ALTHOUGH mycotic infections of the lungs have been recognized for decades, they are still very interesting and unusually hard to diagnose because of their relative rarity. Hughes Bennett in 1842 reported the first case on record. Cases of pulmonary aspergillosis reported in the nineteenth century were made by Virchow, Dieulafoy, Chantemesse, and Widal.¹

The species of the genus *Aspergillus* are predominantly saprophytic, but some are quite pathogenic. Because of its omnipresence, universal infection would undoubtedly occur were not the vast majority of this genus nonpathogenic.

Aspergillosis is produced by a moldlike fungus with a basal stem and stalk supporting a spore-bearing head. This organism seems to have a definite affinity for the pulmonary system,^{2, 3} although other organs may be attacked, especially the kidneys of experimental animals.

An interesting side light on this disease is given by C. W. Dodge:

The natives of Watusi make use of the pathogenicity of some species of *Aspergillus* in an interesting way, according to Mattlet (1924). When they wish to wreak vengeance on some one, they exhume a corpse of a person recently dead of a pneumomycosis, remove the lungs, desiccate them, and mix the powder in a banana beer. Evidently the *Aspergillus* is not killed by this process, and the recipient wastes away with the Aspergillosis, without suspecting the cause.²

CASE REPORT

H. B. G., a white male, aged 40 years, a bookkeeper by occupation, who first came under observation on April 22, 1940, had a productive cough and fever. In August, 1939, he began to run an elevated temperature, and developed a yellow tinge of the skin. He had had a cough for several years, and two months before the present examination he had noticed pain in the chest. X-ray examination (Fig. 1) of the chest on August 6, 1939, revealed

*From the Woodmen of the World War Memorial Hospital, San Antonio.
Received for publication, March 8, 1941.

numerous scattered areas of infiltration throughout the middle and upper lobes of the right lung, especially marked in the first and second interspaces, while the mediastinum was displaced to the right. The left lung showed scattered infiltration throughout the entire upper lobe and the upper half of the lower lobe. Diffuse fibrosis was present throughout the left lung, especially marked in the upper lobe. Both hilar shadows were increased in density, while numerous circumscribed areas of rarefaction were present in both lung fields. Pulmonary tuberculosis was diagnosed from this x-ray picture, although the sputum was negative for tubercle bacilli. The patient entered the Texas State Tuberculosis Sanatorium on October 18, 1939. Many sputum examinations before entrance to the Sanatorium were negative for tubercle bacilli, as were numerous ones made during his six months' stay at this institution.

Fig. 1.—X-ray examination on Aug. 6, 1939, revealed numerous scattered areas of infiltration throughout the middle and upper lobes of the right lung. Areas of infiltration were present throughout the left upper lobe and the upper part of the lower lobe. Numerous areas of rarefaction were present in both lung fields.

Lipiodol injection of the bronchial tree revealed evidence of the presence of bronchiectasis, while a tentative diagnosis of cystic disease was made from the scattered areas of rarefaction observed in the x-ray examination.

The patient's family history was irrelevant. When a small child, he had measles, mumps, pertussis, and chickenpox. In 1918 he had influenza, and on one or two occasions since that date he has had repeated attacks. He had malaria in 1923 and a transient attack of asthma in August, 1938.

In an effort to determine the possible etiology of the asthmatic attack, the patient was referred to the allergist, Dr. B. H. Reinarz. He reported the patient to be sensitive to the following allergens: *Inhalants*, wool, mohair, and sterile mycelia. *Foods*, beef, corn, lamb, mutton, pork, veal, chocolate, goat's milk, and cow's milk.

Physical examination of all systems was negative, except as will be noted. There was blanching and thickening of the mucous membrane throughout the nose, with haziness of the sinuses, that of the left maxillary being especially marked.

Inspection of the chest showed the thorax to be poorly nourished, with all the bony landmarks prominent. There was a yellowish tinge to the skin. Decreased expansion was observed over the upper half of each hemithorax, there being a more marked restriction of expansion on the left. Increased tactile fremitus was present over the upper lobe of the left lung. Impaired resonance was elicited upon percussion of the right chest from the apex to the second rib anteriorly, and from the apex to the spine of the scapula posteriorly. Impaired resonance was present over the anterior portion of the left chest from the apex to the fifth rib, and from the apex to the angle of the scapula posteriorly. From auscultation the presence of harsh breath sounds was noted over the apex of the right lung anteriorly and posteriorly. The whispered voice was increased in intensity over the same area, but no râles were present. Increased intensity of the breath sounds was noted from the left clavicle to the fourth rib anteriorly, and over the suprascapular region posteriorly. Fine and medium moist râles were observed in these same areas.

Fig. 2.—X-ray examination on April 22, 1940, showed some clearing of the infiltration in both lungs since the last examination. Fibrosis was marked in both lung fields.

X-ray examination on April 22, 1940 (Fig. 2) revealed a decrease in the degree of the infiltration observed in the right lung on previous examination. Fibrosis was still marked especially in the middle and upper lobes. The mediastinum was displaced to the right. There had been slight clearing of the infiltration in the left lung. Scattered areas of rarefaction were still present in both lungs.

The urine was negative, except for an occasional pus cell; the erythrocyte count was 3,930,000; the leucocyte count was 7,000; the hemoglobin 85 per cent (Dare); polymorphonuclear leucocytes 65 per cent; lymphocytes 20 per cent; monocytes 10 per cent; eosinophiles 5 per cent; Kahn test negative; sedimentation^{6, 7} rate 5.5 per cent, 14.5 per cent, 43 per cent; Weltmann's coagulation band 8. Ten sputum specimens were negative for tubercle bacilli. Cultures of the sputum on Sabouraud's glucose agar resulted in a growth of *aspergillus*, whose cultural characteristics are as follows: Milk coagulated, then liquefied; broth, large whitish surface colony; Sabouraud's and Krinsky's agar, tough, dull, yellowish-white growth; carrot

Fig. 3A.—Slide culture of the aspergillus showed mycelial strands from which branched stalks bearing conidia clustered about the conidiophore.

Fig. 3B.—Higher magnification of the slide culture revealed the structural arrangement of the spore-bearing stalk.

infusion agar, colonies small, round, and spinose; gelatin stab, white, cottonish surface growth. Acid but no gas was formed in dextrose, saccharose, maltose, and lactose.

Microscopic examination revealed a gram-negative nonacid-fast organism, exhibiting a branching mycelium with a basal stem and a stalk which terminated in a bulbous enlargement or conidiophore around which were clustered numerous conidia (Figs. 3A and 3B). The conidia ranged in size from one-third to one-half the size of an erythrocyte.

Intravenous injection of one-half of a forty-eight-hour agar slant culture of the aspergillus caused the death of a grown rabbit in three days. Post-mortem examination of the rabbit showed large hemorrhagic areas throughout both lungs, liver, and spleen, with petechial hemorrhages present in the cortex of the kidneys. Cultures from the various organs were planted on Sabouraud's agar, and a pure culture of the organism was recovered from the spleen.

From these findings a diagnosis of pulmonary aspergillosis was made, and the patient was placed upon iodide therapy. Potassium iodide was given orally in increasing doses until 40 drops were given three times daily. The patient's symptoms have disappeared after nine months' treatment and he has gained 45 pounds in weight.

COMMENTS

It has often been emphasized that aspergillosis has a distinct relationship to certain occupations. This is most commonly observed among bird fanciers¹⁰ and pigeon stuffers¹¹ who feed the birds from their own mouths. This occupation affords a double hazard in the infected birds and the contaminated grain. Other occupations in which there is prolonged exposure to grain dust, such as occurs in farming, milling, threshing, and sponge cleaning afford ample opportunity for infection with this organism.^{1, 3} It is likely that often repeated massive dosage is the chief factor in the pathogenesis of this disease. Asymptomatic cases have been found upon routine examination of iron miners in certain localities.

The concomitant occurrence of aspergillosis and other pulmonary diseases has prompted many investigators to advance the theory that aspergillosis does not occur in man unless the local or constitutional resistance is lowered. "Secondary aspergillosis" has been reported to complicate pulmonary tuberculosis, primary carcinoma,^{9, 13} and other pulmonary conditions. Lowering of the general resistance by such diseases as uncontrolled diabetes, carcinoma, dysentery, and enteritis predisposes to the infection of the lungs with aspergillosis.

Lapham⁴ in 1926 reported ten cases of primary aspergillosis which she divided into two groups, the wet or parenchymatous and the dry or interstitial types. However, the classification most often employed recognizes a superficial and a deep form. In the superficial type aspergillary catarrh and bronchitis are included. The deep type produces necrosis, and caseation of the lung tissue occurs. This organism shows a high⁴ and constant virulence for laboratory animals. Large doses of the spores intravenously cause death of the animal in one or two days. The lesions produced by this massive infection showed only hemorrhagic and necrotic areas. Smaller doses cause death of the animal in a week or ten days. In studying these tissues Henrici noted that tubercles resembling those produced by tuberculosis resulted.⁵

The onset of the disease is insidious and may be manifested only by cough, asthmatic attacks, and anorexia. Later the cough is increased and the sputum

becomes tenacious and may be dotted with black specks¹⁴ which are conidia. Night sweats, an evening rise in temperature, loss of weight, and hemoptysis occur as the disease progresses. Massive hemorrhages may be the first symptom that causes the patient to seek medical advice. In the asthmatic type progressive dyspnea is a distressing symptom. Pleurisy may be the most outstanding symptom as the patient relates his history.

Cavitation and destruction of the lung tissue are slow, and the course is protracted. However, when mixed infection of the diseased tissue occurs, the progression of the disease may be much more rapid.

As with other pneumomycoses, there is no characteristic x-ray picture. Involvement of the bases and hilar regions is most common. Limitation of the involvement to these areas is by no means constant.¹⁶ Increased hilar shadows with radially distributed increased markings are said to be one of the earliest pictures presented by this disease. The x-ray may resemble bronchopneumonia in the early stage of resolution.³

Physical examination may reveal limited expansion of the chest, most marked on the side with the greater degree of involvement. Coarse and fine râles may be observed upon auscultation over the bases or hilar areas.

Diagnosis of aspergillosis must be made only when all other possible etiologic factors are ruled out. The finding of the aspergillus organism in the sputum is not sufficient evidence for making such a diagnosis. Culturing the organism, the reproduction of the lesion by means of animal inoculation, and the reisolation of the fungus are important factors in clinching the diagnosis. The presence of agglutinins in the patient's serum and positive skin reaction to stock or autogenous vaccines are additional aids in the diagnosis, although their value is questioned by some authorities.

In the treatment of pneumomycoses in general, a multitude of agents have been used. The same is true of the treatment of aspergillosis. The time-honored remedy employed in the condition is potassium iodide;¹² other medicaments often used are the inhalation of ethyl iodide,¹ neoarsphenamine intravenously, intramuscular bismuth, sodium iodide intravenously,¹⁵ and the roentgen ray. Of course, the presence of concomitant pulmonary tuberculosis contraindicates the use of iodides. It is easily seen that there is no "specific" drug.

SUMMARY

1. Pneumomycosis should be considered in any patient with pulmonary symptoms.

2. A case of pulmonary aspergillosis was presented with a discussion of the mode of infection, pathology, symptomatology, x-ray picture, diagnosis, and treatment.

THE PERCUTANEOUS POTENCY OF PROGESTERONE*

R. R. GREENE, M.S., M.D., AND S. C. HARRIS, M.S.
CHICAGO, ILL.

IT HAS been known for some time that estrogens and androgens are absorbed through the skin of the experimental animal and produce systemic effects.¹⁻³ Various workers have made clinical observations demonstrating that the same effect is obtained in the human being.^{1, 9-12} Unfortunately, both estrogens^{1, 2} and androgens^{7, 8} are much less potent when given percutaneously in an ointment than when given parenterally. Investigations on the percutaneous effectiveness of progesterone are limited to a statement by Zondek that in the rabbit it is less effective by this route than by subcutaneous injection.²

After parenteral administration progesterone is relatively rapidly absorbed, metabolized, and excreted. It resembles estrone or testosterone in this respect. The estrogens and androgens, however, may be given parenterally in the esterified forms (e.g., estradiol dipropionate and testosterone propionate) which are relatively slowly absorbed and have a prolonged effect. Thus the patient may be given adequate therapy with treatment at infrequent intervals. Progesterone, however, has no active esterified form; consequently, the patient should be treated frequently, probably every day, to obtain the best clinical response. The indications, if any, for progesterone therapy and the inadequacy of the dosages commonly employed are not pertinent to this discussion.

Since percutaneous application of progesterone would be a convenient method for daily treatment, it was decided to investigate the percutaneous potency of progesterone. A quantitative procedure such as this was not

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, and the Department of Gynecology, St. Lukes Hospital, Chicago.
Received for publication, March 10, 1941.

feasible in the human being; accordingly, the rabbit was used. We realize, of course, that skin absorption of progesterone is not necessarily the same in the rabbit as in the human being. Therefore, the results obtained in the rabbit can only be considered as indicative of what might happen in the human being.

PROCEDURE

Thirty-seven virgin immature rabbits were used in this study. All were primed with 0.002 mg. estrone on the first and third days of the experiment. Five animals were given no further treatment and served as controls. The remaining animals were given progesterone* daily, starting on the fifth day. All animals were killed on the tenth day. The uteri were dissected out, weighed, fixed in Bouin's fluid, and prepared for microscopic study. The progesterone-treated animals were divided into eight groups (Table I). One group was treated parenterally, and the remainder were treated percutaneously. The substance for parenteral administration was applied to an area on the back from which the hair was clipped.

TABLE I

TREATMENT (DAILY DOSE)	NO. OF ANIMALS	AVERAGE BODY WEIGHT (GM.)	AVERAGE UTERINE WEIGHT (GM.)	MCPHAIL RATING (AVERAGE)
Control (primed)	5	667	0.364	0
Subcutaneously 0.1 mg. (oil)	5	683	0.862	2.6
Percutaneously 0.1 mg. (oil)	2	630	0.383	1.0
Percutaneously 0.3 mg. (oil)	4	654	0.456	1.25
Percutaneously 0.6 mg. (oil)	4	694	0.765	2.37
Percutaneously 0.1 mg. (alcohol)	5	684	0.561	1.4
Percutaneously 0.2 mg. (alcohol)	5	763	0.590	1.6
Percutaneously 0.4 mg. (alcohol)	5	549	0.995	3.0
Percutaneously 0.6 mg. (alcohol)	2	653	1.697	4.0

In all cases the progesterone was given in 0.1 c.c. of solvent. Alcohol was used as well as oil for percutaneous application, since it has been demonstrated that both estrogens and androgens are more potent when applied percutaneously in this solvent.^{2, 6, 7}

The progestational responses of the uteri were graded according to the histologic method of McPhail.¹³

RESULTS

The mean uterine weights and progestational responses, as well as the treatment details for each group, are presented in Table I.

The number of animals in each group is adequate for an estimation only of the potency of progesterone when given by different methods. It is obvious, however, that in an oil solvent progesterone is not very effective by the percutaneous route. With 0.1 mg. the uteri were not significantly larger than those of the castrate controls, and histologically they showed only slight stimulation. The effect was only slightly greater with 0.3 mg., and even 0.6 mg. produced uteri which were smaller and had a lower histologic rating than 0.1 mg. parenterally.

*The progesterone used in this study was furnished by Schering Corporation.

The alcohol solvent definitely increased the effectiveness of the percutaneous progesterone. However, even in this solvent the percutaneous route was less effective than the parenteral, 0.1 and 0.2 mg. both produced smaller uteri and lower histologic ratings than did 0.1 mg. parenterally. However, 0.4 mg. percutaneously produced a somewhat greater effect than 0.1 mg. parenterally.

DISCUSSION AND SUMMARY

These data indicate that progesterone is less effective by the percutaneous route than by the parenteral method. With oil as the solvent it is less than one-sixth as potent. With alcohol as the solvent it is less than one-half, but more than one-fourth, as potent percutaneously as parenterally.

Any clinical application of these data must rest on the assumption that skin absorption of progesterone is the same in man as in the rabbit. The validity of this assumption can only be tested by clinical experience. Assuming, however, that the skin of the human being would react in a manner similar to that of the rabbit, it is obvious that very large doses of progesterone would have to be given to obtain a satisfactory clinical response.

THE DETERMINATION OF THE DOSAGE-MORTALITY RATIO OF PENTOTHAL SODIUM WITH SULFANILAMIDE*

PAUL H. LORHAN, M.D., GRETCHEN GUERNSEY, M.D., AND
ALBERT E. PUGH, M.A., KANSAS CITY, KAN.

WITH the increasing use of sulfanilamide in the fields of medicine and surgery, the anesthetist is frequently called upon to administer an intravenous anesthetic, particularly pentothal sodium (sodium ethyl 1-methyl butyl thiobarbiturate), to a patient who has been receiving sulfanilamide (para-aminobenzenesulfonamide) or one of its derivatives. Adriani¹ has suggested that the sulfanilamide-barbiturate sequence may be unwise in human therapy.

In his experiments on rats previously treated with 0.5 to 1.0 Gm. per kilogram of sulfanilamide, a dose which Nelson² describes as fatal for rabbits, susceptibility to anesthetic doses of the barbiturates was increased. The thio-barbiturates were the worst offenders in this respect.

The present study was undertaken with the purpose of determining whether the toxicity of pentothal sodium is increased by previous administration of sulfanilamide in therapeutic doses (0.15 Gm. per kilogram per day). The above dose agrees fairly well with that recommended by Long and Bliss,³ who used 0.11+ Gm. of sulfanilamide per kilogram for human therapy.

The animals used were white Wistar strain rats, between the ages of six weeks and three months, weighing approximately 150 Gm. Sulfanilamide was prepared by dissolving the crystals in sterile distilled water to make a 1 per cent solution. Intraperitoneal injections of 0.15 Gm. of sulfanilamide per kilogram of body weight were then made daily for seven days. On the eighth day pentothal sodium (2.5 per cent solution) was given intraperitoneally to eight groups of 10 rats each, each group receiving a different dose. The doses ranged from 50 to 110 mg. per kilogram. As a control eleven groups of 10 rats each were given 40 to 140 mg. per kilogram of pentothal sodium, having had no previous treatment with sulfanilamide.

Computations of the $L. D_{.50}$ were carried out according to the method of Bliss,³ using the equation $\log L. D_{.50} = \bar{x} + s(5 - \bar{y})$ for the determination of the logarithm of the median lethal dose, and the equation $V(\log L. D_{.50}) = s^2 \left(\frac{(5 - \bar{y})^2}{(wxy)} + \frac{1}{S(w)} \right)$ for the standard error of deviation.

From the data in Table I the log of $L. D_{.50}$ for pentothal sodium alone, and for pentothal sodium with sulfanilamide has been computed, with their standard

*From the Hixon Laboratory for Medical Research and the Department of Anesthesia, University of Kansas Medical School, Kansas City.

Received for publication, March 10, 1941.

errors. Graph 1 shows the computed curves for pentothal sodium and pentothal sodium with sulfanilamide.

TABLE I
TOXICITY OF PENTOTHAL SODIUM AND OF PENTOTHAL SODIUM SUBSEQUENT
TO SULFANILAMIDE THERAPY

NO.	PENTOTHAL SODIUM		PENTOTHAL SODIUM WITH SULFANILAMIDE (15 MG.)	
	DOSE IN MG.	NUMBER OF RATS DEAD/TOTAL	DOSE IN MG.	NUMBER OF RATS DEAD/TOTAL
1	40	0/10		
2	50	1/10	50	0/10
3	55	1/10		
4	60	1/10	60	1/10
5	65	2/10		
6	70	3/10	70	2/10
7	75		75	3/10
8	80	3/10	80	4/10
9	90	5/10	90	6/10
10	100	6/10	100	7/10
11	110	9/10	110	9/10
12	140	10/10		
	L.D. ₅₀	84.85 ± 4.00		85.2 ± 6.56

Dosage Mortality Curves

Graph 1.

RESULTS

By the above method the median lethal dose (L. D.₅₀) for pentothal sodium was computed to be 84.85 ± 4.00 mg. per kilogram. This result is in fair agreement with that of Pratt and his co-workers,⁵ who found the M. L. D. for pentothal sodium in rats to be 80 mg. per kilogram, although they do not state how they arrived at this figure. The median lethal dose (L. D.₅₀) for pentothal

sodium in rats which had previously received therapeutic doses of sulfanilamide was calculated to be 85.21 ± 6.56 mg. per kilogram. By comparison of these median lethal doses (L. D.₅₀) there is no significant difference in the toxicity of pentothal when given to rats which have received therapeutic doses of sulfanilamide.

CONCLUSION

These data justify the conclusion that sulfanilamide in therapeutic doses does not increase the toxicity of pentothal sodium given subsequently to white rats, does not render the animals more susceptible to the effects of pentothal sodium, nor do the two drugs exert synergistic action, at least of a harmful nature, with this dosage.

IMMUNITY STUDIES OF CRYPTOCOCCUS HOMINIS (TORULA HISTOLYTICA) IN MICE*

C. L. HOFF, M.D., CHICAGO, ILL.

A REVIEW of published reports (see references†) demonstrates that a mild form of hypersensitivity, usually revealed by skin reactions, occurs in patients infected with torula. Tests for serum antibodies are inconclusive. This study was undertaken to determine evidence of immunity against torula in a highly susceptible animal, such as the white mouse.

MATERIALS AND METHODS

The *Cryptococcus hominis* strain used for the study was isolated in 1935 from a patient with torular meningitis. Growth on glucose agar was abundant in forty-eight hours at 37° C. Cultures from slants of this medium were suspended in normal saline, and the concentrations were estimated with a hemocytometer. Other methods for standardization of suspension were unsatisfactory. The suspensions were heated for fifteen minutes at 100° C. The torula were killed by two to four minutes' exposure to this temperature. Aqueous

*From the Henry Baird Favill Laboratory, St. Luke's Hospital, Chicago.

†Submitted in partial fulfillment for the degree of Master of Science, Department of Pathology, Northwestern University, Chicago.

Received for publication, March 12, 1941.

extracts were obtained by Berkefeld filtration of old cultures (two and a half months) in peptone broth and synthetic medium.* A concentrate of the synthetic medium was prepared by precipitation with four parts of acetone and reprecipitation from normal saline solution. The final volume was one-tenth that of the original filtrate. Serologic tests were made with torula treated by the Stoddard and Cutler method. To a flask containing a saline suspension of torula, 0.1N hydrochloric acid was added to a pH of 4. After the mixture digested for forty-eight hours at 10° C., the organisms were removed by centrifugation and washed free of acid. The torula were used as the agglutino-gen and the neutralized acid extract was used as the precipitinogen for the demonstration of serum antibodies.

DETERMINATION OF THE MINIMUM LETHAL DOSE

Each of 18 mice received 300,000,000 live torula intraperitoneally. This dose was established by preliminary experiments. All the mice died within twenty-five days; 40 per cent died in eleven days; 50 per cent in twelve days; 70 per cent in fourteen days. Using twelve days arbitrarily as the time limit, and 50 per cent as the number of mice killed with a dose of 300,000,000 torula, an arbitrary M.L.D. was obtained with a range of error of 11 per cent.

IMMUNITY FROM INJECTIONS OF DEAD TORULA

Twenty-three mice were immunized by twelve injections of 30,000,000 heat-killed torula at three-day intervals. The mice were then infected with live torula as was an equal number of control mice. All nonimmunized mice were dead in sixteen days, and the immunized mice in seventeen days. Twelve control mice and six immune mice were dead after eight days. On the tenth day the ratio was 18:10; on the twelfth day, 22:15. In the immunized group the death rate from the seventh to twelfth days was approximately 50 per cent that of the nonimmunized mice.

The gross pathology at post mortem did not differentiate the immune mice from the control mice. In the histologic examination of the immune mice, the lungs varied from complete susceptibility, represented by a massive hemorrhagic pneumonia, to a moderate degree of immunity, represented by patches of proliferated cells and thickening of the alveolar walls by hyperplasia of the septal cells. Immune changes observed in the brain were: fewer and smaller cysts, fewer torula, and single torula without cyst formation. Some brains had plaques of proliferated cells where the pial vessels course through the cortex. Occasionally there was proliferation of the endothelium of the choroid plexuses.

In experiments performed with rats, pairs of immunized and control rats were killed at seven-day intervals following the infecting dose. Thus the evolution of the lesions, as well as the character of the changes, could be observed. The histologic immune process early consisted of cellular proliferation of the septal cells of the lung, reticulo-endothelial cells of the spleen and the liver, and connective tissue growths in the omentum forming irregular focal regions of compact cellular tissue. As these changes progressed, foreign body giant

*Distilled water with 6 per cent ammonium lactate, 0.2 per cent dipotassium phosphate, and 0.5 per cent sodium chloride.

cells with torula appeared. Later, the fibrous tissue elements became more prominent, and loosely woven nodules of fibrous tissue in whorls with epithelioid cells formed. Langhans giant cells were numerous and in combination with the nodules resembled tuberculous foci. The immunity expressed itself mainly as a hastening of the stages of cellular proliferation with subsequent scar tissue reaction and disappearance of the torula.

IMMUNITY FROM INJECTION OF BROTH FILTRATE

The immunity obtained in these animals was comparable to that of the previous group, but less marked. Attempts to reveal soluble toxins gave negative results.

SENSITIZATION TO TORULA

Mice were infected with torula, each mouse receiving 25,000,000 organisms. After twelve, sixteen, and twenty days, tests for hypersensitivity by intradermal injections on the shaven abdomens gave no reactions. The test solutions were broth filtrate, filtrate of the synthetic medium, and the concentrate of the latter filtrate. Intratesticular injections also were reactionless. Skin tests on an immunized rabbit were likewise negative. Accordingly, either the time required for the development of sensitization was long or these animals were not susceptible to such a response to this strain of torula.

DETERMINATION OF HUMORAL IMMUNITY

Six intravenous injections of heat-killed torula were made in a rabbit at three-day intervals. One cubic centimeter of dilutions of immune and control sera was mixed with 1 c.c. of a suspension of torula prepared as described, and placed in a water bath at 37° C. The suspensions of torula were stable for four hours. At the end of one hour the agglutination titer was 1:180. After five hours it was 1:280, with 1:60 in the controls. Agglutination tests with three different control serums compared with saline controls proved there was no nonspecific agglutination.

SUMMARY

1. Injections of torula suspension killed by heat prolonged life and modified the histologic structure of the lesions in mice subsequently infected with torula.
2. No exotoxin or cutaneous hypersensitivity was demonstrated with this strain of torula.
3. Agglutinins were demonstrated in the serum of an immunized rabbit to a titer of 1:180.

THE EFFECT OF SPLENIC EXTRACTS FROM CASES OF ESSENTIAL THROMBOCYTOPENIC PURPURA ON THE PLATELETS AND HEMATOPOIETIC ORGANS OF RABBITS*

JEROME T. PAUL, M.D., CHICAGO, ILL.

THE relation of the spleen to the production of essential thrombocytopenic purpura has for some time been a subject of much dispute among investigators. In 1915 Frank¹ suggested that the spleen was responsible for the formation of an agent which exerts a destructive action upon the megakaryocytes of the bone marrow. The assumption that this toxin is capable of involving the bone marrow as a whole was proposed by Minot² in 1917. Kaznelson,³ who first removed the spleen in a case of essential thrombocytopenic purpura, believed that the thrombocyte reduction in the peripheral blood was brought about by an increased thrombolytic activity of the spleen. Torrioli and Puddu⁴ showed injury of the megakaryocytes in bone marrow cultures after the application of concentrated doses of splenic extracts from cases of essential thrombocytopenic purpura.

The recent investigations of Troland and Lee^{15, 16} demonstrate a marked depression of the circulating blood platelets in rabbits after intravenous injection of acetone extracts of splenic tissue taken from three patients operated on for essential thrombocytopenic purpura. In September, 1939, Pohle and Meyer⁹ reported that acetone extracts of the spleen from three patients with essential thrombocytopenic purpura produced no effect on the platelet levels of injected rabbits. Major and Weber⁷ injected extracts prepared from the spleens of two

*From the Department of Internal Medicine, University of Illinois College of Medicine, Chicago.

Received for publication, March 24, 1941.

patients with essential thrombocytopenic purpura. The splenic extract from one patient produced an increase in the blood platelet count, while the extract from the second patient caused a moderate fall in the platelet level. Tocantins¹² was unable to demonstrate the presence of platelet-destroying substances in the spleen and urine of three patients with thrombocytopenic purpura. Following the injection of 45 c.c. of an acetone extract of a thrombocytopenic spleen into a rabbit, Hobson and Witts³ reported a depression in the platelet count from 525,000 to 109,000 in thirty hours. Rose and Boyer¹⁰ record studies which are confirmatory of the work of Troland and Lee.^{15, 16} Because of the bearing of these experiments on the mechanism of the production of essential thrombocytopenic purpura, it seemed important to repeat them and to include in the study changes in the bone marrow and hematopoietic organs.

MATERIAL AND METHODS

Extracts were prepared from splenic tissue obtained from five patients with essential thrombocytopenic purpura and from six other control patients with splenic enlargement. Sufficient clinical and hematologic data are presented to establish the accuracy of the diagnosis of the cases.

CASE 1.—Patient With Essential Thrombocytopenic Purpura:

D. T., a white girl, aged 14 years, was admitted to the Illinois Research and Educational Hospitals on March 10, 1938, complaining of frequent attacks of epistaxis and excessive menstrual bleeding. Bleeding from the nose was first noticed in October, 1937, at which time she experienced a nosebleed which persisted for two days. Menstrual period in November, 1937, continued for nine days, and in December, for fourteen days.

Physical examination was essentially negative, except for numerous petechiae, especially over both lower extremities. The spleen was not palpable. Blood studies on entrance showed platelets 48,040, erythrocytes 3,680,000, hemoglobin 8.5 Gm., and a definite megakaryocytic increase of the sternal bone marrow. On March 19 the bleeding time was three minutes and the coagulation time (Howell's method) was ten minutes. There was no clot retraction at the end of twenty-four hours and the tourniquet test was positive. Blood studies on March 25 showed platelets 61,200, erythrocytes 2,930,000, hemoglobin 7.25 Gm., and megakaryocytic hyperplasia of the sternal bone marrow. Splenectomy was performed on April 11, 1938. The spleen weighed 157 Gm. Twenty-four hours after operation the platelet count was 72,300. The platelets increased progressively, and on April 18 (seven days after splenectomy) they numbered 386,400. Following splenectomy there has been no bleeding at any time.

CASE 2.—Patient With Essential Thrombocytopenic Purpura:

R. V., a white woman, aged 22 years, admitted to the Illinois Research and Educational Hospitals on June 24, 1938, had frequent attacks of epistaxis. Nasal hemorrhages commenced about Feb. 15, 1938, and usually persisted for about one-half hour. She continued to have two or three hemorrhages weekly up until June 1, when the attacks became more frequent and prolonged. Menstrual history was normal until June 12, 1938, and continued until July 1, with a marked increase in the bleeding. Physical examination revealed a moderate pallor of the skin and numerous bright red petechiae over chest, abdomen, back, and extremities. The spleen was palpable and the tourniquet test was strongly positive. Blood studies on entrance showed platelets 24,400, erythrocytes 2,400,000, hemoglobin 6.3 Gm., and marked increase of the megakaryocytes on sternal bone marrow examination. The coagulation time was five minutes and the bleeding time was eight minutes. There was no clot retraction at the end of twenty-four hours. Splenectomy was performed on June 30. The spleen weighed 270 Gm. Five hours postoperatively there were 136,200 platelets with many large forms. Twenty-four hours after splenectomy platelets numbered 185,400, and on July 11 (eleven days after surgery) the platelet count was 473,000.

CASE 3.—Patient With Essential Thrombocytopenic Purpura:

F. R., a white woman, aged 21 years, first entered the Illinois Research and Educational Hospitals on Dec. 5, 1938, complaining of frequent attacks of epistaxis, bleeding from the gums, vagina, and rectum. She was in good health until the latter part of October, 1938, when she first noted a small amount of bright red blood after defecation. Shortly afterwards she began to have frequent attacks of epistaxis. The menstrual period during the first week of November was very profuse and continued for eight days. Physical examination revealed numerous petechiae distributed over both lower extremities. The spleen was palpable, and the tourniquet test was markedly positive. Blood studies on entrance showed a platelet count of 29,740, erythrocytes 4,970,000, hemoglobin 13.6 Gm., and a megakaryocytic hyperplasia of the sternal bone marrow. The coagulation time was eight minutes and the bleeding time was ten minutes. There was no clot retraction at the end of thirty hours. Splenectomy was performed on Dec. 14, 1938. The spleen weighed 132 Gm. Twenty-four hours after operation the platelet count was 171,400, and on December 19 the platelets numbered 314,700. Bleeding subsided completely following the splenectomy.

CASE 4.—Patient With Essential Thrombocytopenic Purpura:

P. H., a white boy, aged 15 years, was admitted to the Illinois Research and Educational Hospitals on Sept. 12, 1939, complaining of epistaxis. Bleeding from the nose was first experienced in June, 1939, and was followed in a short time by persistent oozing of blood from the gums. Physical examination was essentially negative, except for numerous petechiae over the posterior aspect of the neck, cubital region, and chest. Blood studies on entrance showed platelets 40,000, erythrocytes 4,490,000, hemoglobin 13.0 Gm., and a definite megakaryocytic increase of the sternal bone marrow. The bleeding time was twenty minutes and the coagulation time was nine minutes. There was no clot retraction at the end of twenty-four hours. The patient remained in the hospital under observation for several months. During this time he had many severe attacks of epistaxis. Platelet counts as low as 11,000 were obtained. Splenectomy was performed on Dec. 21, 1939. The spleen weighed 290 Gm. Six hours after removal of the spleen the platelets numbered 76,000, and eight days postoperatively a count of 980,000 was obtained.

CASE 5.—Patient With Essential Thrombocytopenic Purpura:

B. P., a white girl, aged 17 years, was admitted to the Illinois Research and Educational Hospitals on July 26, 1940. She had severe epistaxis, bleeding gums, purpuric spots, and bruised easily since December, 1938. At the time of entrance she was pregnant approximately seven months. Physical examination revealed red, spongy gums. The liver was palpable and the tip of the spleen could be felt. The bleeding was controlled, and the patient was allowed to go into labor spontaneously on Sept. 29, 1940. The puerperium was afebrile and uneventful. Blood studies on admittance to the hospital showed platelets 100,000, erythrocytes 3,120,000, hemoglobin 9.8 Gm., and a myeloid erythroid and megakaryocytic hyperplasia of the sternal bone marrow. The bleeding time was twelve minutes, the coagulation time was nine minutes, and the beginning clot retraction occurred at the end of one and one-half hours. She was prepared for splenectomy by the administration of blood, and on Oct. 23, 1940, the spleen was removed. Twenty-three days postoperatively blood studies revealed platelets 200,000, erythrocytes 5,910,000, and hemoglobin 17.5 Gm. Since splenectomy there has been no bleeding from the nose or gums.

Splenic tissue obtained from six control cases was used in the preparation of extracts. They included a normal spleen and cases of congenital hemolytic anemia, splenic vein thrombosis, chronic lymphatic leucemia, aplastic anemia, and Banti's syndrome.

The method of extraction used in this investigation has been described in detail by Troland and Lee.^{15, 16} Suffice it to say that the macerated splenic tissue was placed in acetone. After a variable length of time the acetone was filtered off and then distilled. The sediment was dissolved in 100 c.c. of distilled water

and filtered. Extracts were stored in the refrigerator and injected within forty-eight hours after preparation. The type of acetone (commercial or reagent) used in the extraction seemed to have no influence on the results obtained. Table I contains the extracts prepared, type of acetone used in the extraction, weight of the splenic tissue, grams of the splenic tissue in a 20 c.c. dose of the splenic extract, and the length of time the tissue was allowed to remain in the acetone.

E. 11. Banti's syndrome	Reagent	250	18	50.0	25.0

In the present study the number of blood platelets was determined by the direct method. In some instances the indirect blood smear method was used to check the results obtained by the direct counts. The diluting fluid used consists of 0.6 Gm. sodium chloride, 0.2 Gm. sodium citrate, and 0.04 Gm. brilliant cresyl blue made up to 100 c.c. with distilled water. Blood was obtained from a stab wound of the marginal vein of the rabbit's ear. The blood was drawn to the 0.5 mark in a standardized erythrocyte pipette and diluted to the 101 mark with the platelet diluting fluid. After shaking for two minutes a certified counting chamber with improved Neubauer ruling was filled and allowed to stand for ten minutes. Counts were made with a high, dry (4 mm.) objective and a 12.5x ocular.

Normal rabbits, approximately 2 kg. in weight, were employed as the experimental animals. A new rabbit given no food for twelve hours previously was used for each experiment. Several control platelet counts were made prior to the injection of the splenic extracts. After administration of the extract, platelet counts were repeated every two to four hours for a period of twenty-four to forty-eight hours.

Bone marrow sections and bone marrow imprints, together with sections of the liver, lung, and spleen were obtained from seven animals. After injection of 20 c.c. of the extracts prepared from the essential thrombocytopenic purpura specimens, the rabbits were sacrificed at the maximal platelet count depression. Following the injection of a control extract (E. 7), the rabbit was sacrificed at the time interval required to produce maximal platelet drop with the essential thrombocytopenic purpura extracts. Specimens of the bone marrow, liver, lung, and spleen were also obtained from a normal untreated rabbit. Pieces of tissue were fixed in a solution of formaldehyde and in Zenker's fluid. After preparation of the sections they were stained by hematoxylin and eosin and Giemsa's stains.

On examination of the bone marrow sections the number of megakaryocytes per 1,500 nucleated bone marrow cells was determined. The bone marrow imprints were prepared by touching the cut end of the sternum to a glass slide. Each slide contained eight such touch smears of approximately equal size. In enumerating the megakaryocytes on the bone marrow imprints all megakaryocytes exclusive of the central portion of the imprint were counted. The central portion of the imprints were not included in the counts because of the deep stain which they assumed, preventing accurate cellular differentiation. The megakaryocyte counts of the imprints were determined by taking the average of eight imprints.

EXPERIMENTAL OBSERVATIONS

Splenic extracts prepared from the essential thrombocytopenic purpura specimens, Cases 1, 2, 3, 4, 5, will be designated as extracts (E) 1, 2, 3, 4, 5, respectively. After injection of 20 c.c. of E. 1, a depression in the platelet count was noted from the preliminary count of 500,000 to 325,000 within eight hours. Twelve hours after injection the platelet count was 450,000, and within twenty-four hours it had reached the preinjection level.

Injection of 20 c.c. of E. 2 produced practically the same result as that of E. 1. A depression in the platelets from the preinjection level of 492,000 to 315,000 was obtained within eight hours. Twenty hours later the platelet count was 440,000, and within twenty-four hours it reached the level determined prior to injection of the extract.

E. 3 differed from the previously mentioned extracts in that the maximal platelet depression was not reached until sixteen hours had elapsed. After injection of 20 c.c. of E. 3 the platelet count fell from a preinjection level of 485,000 to 315,000. The platelets returned to the preinjection level within twenty-four hours.

Following the injection of 20 c.c. of E. 4, a depression in the platelet count was noted from the preliminary count of 525,000 to 455,000 within twelve hours. At the end of twenty-four hours a count of 495,000 was obtained. The experiment was repeated, using 40 c.c. of E. 4. This dosage produced a drop in the platelet count from the preliminary level of 495,000 to 350,000 within twenty-four hours.

Injection of 20 c.c. of E. 5 caused a depression in the platelet count from a preliminary level of 500,000 to 405,000 within four hours. At the end of twenty-four hours the platelets numbered 485,000.

Fig. 1.—Platelet level following injection of 20 c.c. of thrombocytopenic extracts.

Fig. 2.—Platelet level following injection of 10 c.c. of thrombocytopenic extracts.

Fig. 3.—Determination of minimal effective dose.

Fig. 4.—Platelet level following injection of control extracts.

The experiments were repeated using 10 c.c. of the splenic extracts, E. 2, E. 3, and E. 5. After the injection of E. 2 a depression of the platelet level resulted that was essentially the same as that produced by 20 c.c. of the extract.

Ten cubic centimeters of E. 3 produced a less marked depression of the platelets. The platelet count prior to injection was estimated at 520,000; sixteen hours later it was 400,000; and within twenty-four hours it had attained the preinjection level.

The injection of 10 c.c. of E. 5 was followed by a maximal platelet depression of 75,000 within eight hours.

In an attempt to determine the minimal effective dose of the extract, 4 c.c. of E. 2 were injected intravenously. A depression of 55,000 in the platelet count was obtained within eight hours. At this time 8 c.c. of the extract was injected. Twelve hours later the count dropped an additional 10,000 platelets. Then 10 c.c. of the extract was injected, and it was noted that a total maximal platelet depression of 185,000 was reached twelve hours after the injection of 10 c.c. of the extract.

Experiments using the control specimens were carried out with the same procedure employed in the cases of essential thrombocytopenic purpura. Twenty cubic centimeters of the extract (E. 6) prepared from the normal spleen were injected. A depression in the platelet count from 475,000 to 460,000 in four hours was noted. There was a return to the preinjection level within twelve hours. Other control specimens produced the following results:

After the injection of 20 c.c. of E. 7 (splenic vein thrombosis) no depression was noted. Twenty-four hours later the platelet count exceeded the initial count by 28,000. Twenty cubic centimeters of E. 8 (congenital hemolytic anemia) caused a drop of 22,000 platelets within four hours with a return to the preinjection level within eight hours. Following the injection of E. 9 (chronic lymphatic leucemia) a depression of 45,000 platelets within four hours was observed, with a return to the preliminary count within twelve hours. Ten cubic centimeters of E. 10 (aplastic anemia) produced a depression of 40,000 platelets within four hours. After the injection of 20 c.c. of E. 11 (Banti's syndrome) a drop of 22,500 platelets within four hours was noted.

Examination of the bone marrow imprints and sections revealed little, if any, change in the number of megakaryocytes of the rabbits injected with the extracts of thrombocytopenic purpura as compared with the normal and control rabbits.

The only deviation from the constant findings was seen in the case of E. 1. In this case a reduced number of megakaryocytes was found. The megakaryocytes showed no outstanding changes in the cells, such as degeneration, pyknotic nuclei, or vacuolation of the cytoplasm. Sections of the spleen, liver, and lung were studied and failed to show any significant pathologic changes. Particular attention was directed to the examination of the lung sections to determine the presence of megakaryocytes, as reported by Howell and Donahue.⁴

DISCUSSION

It is well established that some relationship exists between the spleen and blood platelets. This is evidenced by the marked and rapid rise in the platelet

count following splenectomy on patients with essential thrombocytopenic purpura, a finding substantiated in all of our cases. The number of circulating blood platelets in the peripheral blood is dependent upon a normal maturation process in the bone marrow. Wright's¹⁷ original finding that the megakaryocytes are the only source of true platelets has been repeatedly confirmed by many investigators. Frank,² Limarzi and Schleicher,⁶ and Seeliger,¹¹ have noted in essential thrombocytopenic purpura an increase in the megakaryocytes of the bone marrow associated at times with immature forms. This suggests a maturation arrest of the megakaryocytic tissue and thus speaks for a lack of platelet formation rather than an increased destruction of these elements.

TABLE II
MEGAKARYOCYTE COUNTS

SPLENIC EXTRACTS	BONE MARROW IMPRINTS	BONE MARROW SECTIONS
E. 1	8.1	8
E. 2	14.3	9
E. 3	14.7	12
E. 4	13.8	10
E. 5	11.2	9
Control	11.7	11
(Splenic vein thrombosis)		
Bone marrow of a normal sacrificed rabbit	12.5	10

Results described elsewhere in this report are not fully in accord with those of Troland and Lee.^{15, 16} These workers report a depression of the platelet count to the level commonly seen in persons with essential thrombocytopenic purpura. For the most part, the preparation of the splenic extracts, weight of the splenic tissue, and the method of counting platelets in this study was similar to that employed by Troland and Lee.

It has been demonstrated that the five extracts prepared from the patients with essential thrombocytopenic purpura, when injected intravenously, produce a moderate depression of the circulating blood platelets. This reduction ranges from 70,000 to 177,000 blood platelets, and is very transient in duration. In practically every instance platelet counts returned to the preinjection level within twenty-four hours. Torrioli and Pusie¹⁴ showed that large doses of an aqueous extract of a normal spleen caused a considerable reduction in the circulating blood platelets of rabbits when injected intravenously. An acetone extract of a normal spleen in this series produced no significant depression in the blood platelet count.

Because of the megakaryocytic hyperplasia found in essential thrombocytopenic purpura, bone marrow sections and imprints were obtained at the point of maximal depression of the blood platelets to determine the relationship of the thrombopenia to the megakaryocytes. No disturbances in the number or cell structure of the megakaryocytes were detected.

Due to the short-lived depression of the circulating blood platelets one may speculate that the extract contains a substance which interferes with the rate of formation of the platelets from the megakaryocytes. It is, of course, possible that if these injections were continued for some time an effect on the megakaryocytes would result.

CONCLUSIONS

1. The intravenous injection of acetone splenic extracts of cases of essential thrombocytopenic purpura produces a transient significant depression of the platelet count in rabbits.

2. The splenic extracts exerted no effect upon the number or cell structure of the megakaryocytes of the bone marrow.

3. Specimens of the spleen, liver, and lungs of rabbits obtained after the injection of thrombocytopenic splenic extracts showed no distinctive pathologic changes.

4. The intravenous injection of acetone splenic extracts from six control cases produced no significant change in the level of the platelet count in rabbits.

I wish to express my gratitude to Dr. Robert W. Keeton and Dr. Louis R. Limarzi for their invaluable advice and criticism.

THE RELIEF OF MUSCULAR WEAKNESS BY PYRIDOXINE HYDROCHLORIDE*

EDWARD E. ROSENBAUM, M.D., SIDNEY PORTIS, M.D., AND
SAMUEL SOSKIN, M.D., PH.D., CHICAGO, ILL.

THE fraction of the vitamin B complex known as B₆ has recently been synthesized. It is chemically described as 2-methyl-3-hydroxy-4, 5-di-(hydroxymethyl)-pyridine.^{1, 2} The Council on Pharmacy and Chemistry of the American Medical Association has accepted pyridoxine as the official name of this vitamin. The hydrochloride is to be known as pyridoxine hydrochloride.³ A deficiency of this substance in rats results in impaired growth and a characteristic dermatitis.⁴ Little is known concerning its physiologic activity, but there is some evidence that it is concerned with storage of fat⁵ and with the utilization of unsaturated fatty acids.⁶

Our interest was aroused by the early report of Spies and others⁷ on the spectacular influence of pyridoxine in relieving the muscular weakness of pellagrins. He reported that pellagrins who had been relieved as regards most signs and symptoms of the disease by vigorous treatment with nicotinic acid, thiamin chloride, and riboflavin, nevertheless still manifested extreme muscular weakness and fatigue. At this time the intravenous administration of 50 mg. of pyridoxine enabled patients (who still complained of extreme nervousness, insomnia, irritability, abdominal pain, weakness, and difficulty in walking) to experience dramatic relief of all these symptoms within as short a time as four hours. One of these patients, who had been unable to walk more than a few steps, walked two miles within twenty-four hours after the injection of 50 mg. of pyridoxine.

In view of Spies' results it seemed worth while to test the action of pyridoxine in patients suffering from clinical conditions characterized by extreme muscular weakness and exhaustion, in which no other signs or symptoms of a vitamin B complex deficiency were evident.

METHODS

Because of the difficulty of quantitating the patient's subjective feelings of muscular weakness, our tests were based on the ability of the individual to perform work to the point of exhaustion under standard conditions. For this purpose we employed two procedures:

(1) *Leg Test*.—With the patient in the supine position in bed, he was required to lift the extended right leg to the vertical position, at the rate of 24 times per minute, for as long as he was able to continue.

*From the Department of Metabolism and Endocrinology, and the Department of Medicine, Michael Reese Hospital, Chicago.

Aided by a grant from the A. B. Kuppenheimer Fund.

Received for publication, March 13, 1941.

(2) *Arm Test*.—In this test the work was done with the right hand and arm. While sitting up in bed, the patient was required to raise a 10-pound weight a distance of 13 inches, at a rate of 30 times per minute. He grasped a comfortable handle attached to a rope which ran over a pulley fixed at the foot of the bed. The resting position for this exercise was with the upper arm approximated to the lateral thoracic wall, so that the essential movement was a flexion of the forearm on the upper arm from the initial 90-degree angle to about a 30-degree angle.

The arm and leg tests were performed twice a day, with an intervening rest period of fifteen minutes. They were always conducted by the same observer in the same environment and at the same time of day. The tests were not considered satisfactory unless the results of two tests on the same limb coincided fairly closely. The average of these two tests was considered to be the work performance of the limb for the day. Preliminary experiments in normal people showed that the identical muscle testing procedures, performed daily, gave no indication of any increase in muscular ability due to training.

In order to avoid the possible psychologic effects of the therapy, all patients were given intravenous injections of saline daily from the beginning. When a constant base line of muscular ability had been established for a particular patient, a solution of pyridoxine hydrochloride* was substituted for the saline without the patient's knowledge. In some cases, after the results of the vitamin had been observed, the saline was again resumed as a further check upon the enthusiasm aroused in the patient by the beneficial effect of the treatment.

In our earliest cases varying doses of pyridoxine hydrochloride from 10 mg. to 50 mg. intravenously per day were used. We subsequently adopted a standard dose of 50 mg. a day for all cases for the purposes of this work. No toxic or ill effects of any kind were ever observed to occur from the use of these amounts of the vitamin.

The following is a summary of our results. Brief case histories are appended at the conclusion of this article.

Neurasthenia.—Our first case (Miss B. K.) was a 27-year-old female, whose ailment had never been definitely diagnosed. Physical and laboratory examinations had been consistently negative in the hands of numerous physicians, and at no time were any clinical signs of vitamin deficiency noted. She complained primarily of weakness and fatigue to such an extent that she had been practically bedridden for eight years. She was barely able to make the daily trip to the hospital for examination and treatment. We started this patient on pyridoxine hydrochloride without any preliminary tests with saline. Within five days she began to show increased muscular ability, as measured by our objective tests (Graph 1). Her appetite improved markedly and her weight rose from 99 to 104 pounds. After two weeks of treatment the patient stated that she was able to be up and out of bed for four hours a day. At this point we began to inject saline intravenously in place of the pyridoxine hydrochloride. Our objective tests showed no decrease in the patient's muscular strength, but she insisted that her weakness was returning and that she was no longer able to be

*Supplied by Merck & Co., through the courtesy of Dr. D. F. Robertson.

out of bed long enough to report for daily intravenous injection. We gave her 50 mg. tablets of pyridoxine hydrochloride to be taken orally, once a day at home, and advised her to return after two weeks. When next seen the patient reported that her strength was again returning. We now resumed the daily intravenous injections of pyridoxine hydrochloride. After fourteen more injections the patient was able to be up and about eight hours a day. We discontinued treatment and advised her to take fresh yeast at home. She has continued to improve and when last seen, five months after beginning pyridoxine, she was able to be out of bed eight hours daily, was attending a few social functions, and her weight had increased by 25 pounds.

Graph 1.

Hyperthyroidism.—We attempted the use of pyridoxine hydrochloride in three patients with hyperthyroidism, each of whom complained of marked weakness and fatigability. In every case there was a definite increase in muscular ability (Graph 2 illustrates one such case). Lugol's solution was withheld until we were able to demonstrate the effect of the vitamin. During this period the basal metabolic rates which were determined showed little change, so that the increase in strength could not be attributed to changes in the basal metabolic rate. In one case the pyridoxine hydrochloride was discontinued as soon as the patient showed increased strength and lugolization was begun. There was no further gain in strength. The Lugol's solution was continued and whole yeast was added to the diet. He immediately began to show further improvement as concerns muscular ability, although during this entire period his basal metabolic rate showed little variation.

Ulcerative Colitis.—Decided improvement in muscular ability was obtained with pyridoxine hydrochloride in 4 patients with ulcerative colitis. Objective tests could be made in only 2 of these patients, the others being unable to under-

days of pyridoxine hydrochloride administration, she was able to sit up in bed without support and to feed herself. After fourteen days of treatment she was able to begin walking. In no case were we able to note any improvement in the ulcerative colitis per se as regards frequency and number of stools.

Myasthenia Gravis.—Pyridoxine hydrochloride was of no apparent benefit in one case of myasthenia gravis which had been previously well controlled with prostigmin. For the purposes of observation, prostigmin was discontinued the previous night, and the patient was given 50 mg. of pyridoxine hydrochloride intravenously in the morning. By 6:00 P.M. the patient began to show acute signs of muscular weakness, as evidenced by her inability to eat or even swallow water. She was now given 100 mg. of pyridoxine hydrochloride intravenously, but showed no response. One-half hour later prostigmin was given, to which she responded almost immediately.

Malnutrition.—In 2 patients with anorexia nervosa and in one patient with cardiospasm we obtained no evidence of increased strength following the use of pyridoxine hydrochloride. All 3 patients were markedly underweight, were exceedingly weak, subsisted on deficient diets, and showed clinical signs of vitamin deficiencies. None of these patients showed any real response after receiving eight to fourteen daily injections of pyridoxine hydrochloride.

SUMMARY AND DISCUSSION

Noteworthy relief of muscular weakness has been obtained following the intravenous administration of pyridoxine hydrochloride in one patient with so-called neurasthenia, 3 patients with hyperthyroidism, and 4 patients with ulcerative colitis. No results were obtained in one patient with myasthenia gravis and in 3 patients with severe malnutrition. It is evident that our good results were obtained in patients in whom one might expect to find either a deficiency of vitamin intake or a vitamin requirement in excess of the normal intake, even though no recognizable symptoms of vitamin deficiency other than weakness were present. However, we cannot explain why the 3 patients with severe malnutrition with obvious manifestations of multiple vitamin deficiencies did not respond to pyridoxine hydrochloride. It is suggested that these failures might have been due to the absence of other vitamin factors which are essential to the action of pyridoxine hydrochloride.

CASE REPORTS

CASE 1 (Miss B. K.).—The essential details of the history and the results of treatment (Graph 1) with pyridoxine hydrochloride have been summarized above. It is worthy of note that this patient had been on a subminimal diet for eight years, eating from 800 to 1,000 calories a day, with very little meat and whole grain foods.

Physical examination showed a tall, thin female, 5 feet 9 inches in height, and weighing only 101 pounds. There were no other positive physical signs. Bronchoscopy showed an atrophic and hyperemic mucosa.

Laboratory Studies: Hemoglobin 80 per cent; erythrocytes 4,400,000; leucocytes 7,750 with a normal differential; urine negative; sugar 64 mg. per cent; nonprotein nitrogen 27 mg. per cent; chlorides 494 mg. per cent; cholesterol 298 mg. per cent; icterus index 6; carbon dioxide combining power 57.3 per cent; van den Bergh, direct and indirect, both negative; sputum negative for tubercle bacilli.

CASE 2 (Mrs. L. K.).—A white, divorced, 24-year-old female, entered the hospital with nervousness, weight loss, weakness, and prominence of the eyes for the past year.

Physical examination showed a marked exophthalmos, a diffusely enlarged thyroid gland, moist warm skin, a fine tremor of the hands, rapid pulse (90 to 110), and a blood pressure of systolic 130 and diastolic 70.

Laboratory studies were essentially negative, except for a basal metabolic rate of +41.

The report of the pathologist on the appearance of the thyroid after removal was consistent with the diagnosis of diffuse toxic goiter.

This patient received no Lugol's solution during the period of administration of pyridoxine hydrochloride, and her basal metabolic rate showed no noteworthy change. Nevertheless her muscular ability increased markedly, as shown in Graph 2.

At this time the patient refused to stay in the hospital because of difficulties at home. She received no medication while at home, and returned to the hospital one week later with the same signs and symptoms. Her basal metabolic rate was still +41. Lugol's solution (ten drops t.i.d.) was begun, without any pyridoxine hydrochloride. The patient showed no further increase in muscular ability, although her basal metabolic rate dropped to +13.

CASE 3 (Mr. S. D.).—A white, married, 35-year-old male, entered the hospital with nervousness, feeling of warmth and perspiration, palpitation, polyuria, diarrhea, enlargement of the neck, and the loss of 30 pounds of weight within two months.

Physical examination showed a slight exophthalmos, a diffusely enlarged thyroid, warm, moist skin, a fine rapid tremor of the hands, a pulse rate of 100, and a blood pressure of systolic 144 and diastolic 72.

The only significant laboratory test was a basal metabolic rate of +80.

The postoperative examination of the gland showed a diffuse toxic goiter, consistent with the clinical diagnosis of diffuse toxic goiter with hyperthyroidism.

This patient showed an increase in muscular ability immediately after his first dose of pyridoxine hydrochloride. After he had received five daily doses it was necessary to stop the pyridoxine and to start Lugol's solution because of his continued toxic state. However, by this time his arm pull had increased from 35 to 44, and his leg lift from 45 to 85. The basal metabolic rate taken on admission was +81, and after pyridoxine hydrochloride it was +72.

Five days after the beginning of treatment with Lugol's solution (10 drops t.i.d.) the basal metabolic rate dropped to +53, but there was no change in muscular ability. Whole yeast was then added to the diet, and within seven days the arm pull increased to 38 and the leg lift to 260. The basal metabolic rate at this time was +50.

CASE 4 (Mrs. B. R.).—A white, married, 38-year-old female, entered the hospital with nervousness, palpitation, a swelling in the neck, and weight loss over a period of three months.

There was a marked exophthalmos, a diffusely enlarged thyroid, a fine rapid tremor of the hands, warm moist skin, rapid pulse rate (105), and a blood pressure of systolic 140 and diastolic 80.

Repeated basal metabolic rates ranged from +80 to +40. Other laboratory studies were negative.

The diagnosis of diffuse toxic goiter with hyperthyroidism was confirmed by examination of the thyroid postoperatively.

This patient was given thiamin chloride, 15 mg. intravenously, for five days, but showed no increase in strength. Pyridoxine hydrochloride was then substituted for the thiamin chloride, and within ten days her leg lift increased from 40 to 250, and her arm pull from 16 to 85. Her basal metabolic rate remained unchanged during this period.

CASE 5 (Mr. L. L.).—A white, 19-year-old schoolboy, with a history of chronic non-specific ulcerative colitis of three years' duration, entered the hospital complaining of an acute exacerbation of the colitis.

Physical examination disclosed an emaciated youth, with a right lower abdominal scar, the site of an appendectomy three years previously. Proctoscopic examination showed a hyperemic mucous membrane. Radiographic studies were consistent with a diagnosis of chronic ulcerative colitis.

No causative specific organisms could be found on repeated stool examinations. Hemoglobin was 50 per cent and erythrocytes were 2,890,000.

Medical treatment was attempted, consisting, over a period of several weeks, of a course of neoprontosil, repeated transfusions, iron, high vitamin high-caloric diet, and autogenous vaccine. The patient failed to show any improvement. An ileostomy was performed six weeks after admission.

We first saw the patient three months after admission. He was weak and emaciated; he had developed contractures of both legs and was having frequent, severe rectal hemorrhages.

Because of the state of his leg muscles it was possible to test only his arms. These showed the definite improvement in muscular ability summarized in Graph 3. This increase was paralleled by a general feeling of increased strength. At this time a hemicolectomy was performed and the patient died soon afterwards. Post-mortem examination showed a non-specific colitis complicated by a diffuse peritonitis.

CASE 6 (Mr. W. N.).—A white, 26-year-old male, German refugee, had an eleven-year history of chronic ulcerative colitis. Seven years prior to his admission he had had an ileostomy performed in Germany with but little relief; he continued to have acute exacerbations of his colitis. When we first saw him, he had entered the hospital for the second time within a month. He was having five to six bloody mucous stools a day. He had developed a crop of furuncles over his legs and arms, and he had swollen, tender, reddened wrists and knee joints. He was extremely emaciated and so weak that he could not sit up in bed. Laboratory studies were negative. It was impossible to perform any objective tests because of the arthritis and marked weakness. He had been receiving thiamin chloride intravenously (15 mg. daily), to which we added pyridoxine hydrochloride (50 mg. daily). The next day he was sitting up in bed, asking to be allowed up, and his appetite was excellent. We continued to give the pyridoxine hydrochloride for one week. The patient continued to evidence increased strength, but neither his colitis per se nor his arthritis changed. Pyridoxine hydrochloride was discontinued after a week and fresh yeast (three cakes a day) was added to his diet. He was discharged two weeks later, his arthritic symptoms were gone, and his colitis improved. He was advised to continue taking yeast at home.

He re-entered the hospital six weeks later with a re-exacerbation of his colitis and arthritis. He had not taken any yeast because of the "gaseous feeling" which he claimed followed its use. On this admission the patient failed to show any further response to pyridoxine hydrochloride.

CASE 7 (Mrs. J. L.).—A 54-year-old white, married female entered the hospital with cramping abdominal pains and a diarrhea of two weeks' duration.

Physical examination was negative except for a rapid irregular pulse rate. Radiographic, proctoscopic, and laboratory studies established the diagnosis of nonspecific ulcerative colitis complicated by a chronic cystitis and an auricular fibrillation of undetermined etiology. The patient was treated symptomatically with sedatives, transfusions, and high caloric low-residue diet. On an empirical basis she was given a treatment with carbarsone and emetine hydrochloride, and later sulfanilamide therapy. To supplement her diet she was given thiamin chloride, 25 mg. intravenously, nicotinic acid 25 mg., b.i.d., cevitamic acid 200 mg., b.i.d., and liver extract 1 c.c. intramuscularly. In spite of these measures her condition remained unchanged.

When first seen by us, the patient had been in the hospital for eight weeks. Because of her cardiac condition and marked weakness, objective tests were impossible. Her weakness had progressed so far that she even required help to eat. We gave her intravenous saline for five days with no effects. We then started pyridoxine hydrochloride. The next day the patient felt much stronger, responded readily to questions, and noted an improvement in her appetite. By the time 150 mg. had been given (three daily doses) she was able to sit up in bed for five minutes without assistance. After ten doses she was sitting up in a wheel chair, and after two weeks of treatment she began to take a few steps; she was then discharged from the hospital. At no time during this period was there any change in frequency and number of stools.

CASE 8 (Mr. E. S.).—A white, married, 40-year-old male, when first seen had weakness and fatigue. Three months ago he had had a colostomy performed because of chronic ulcerative colitis. His colitis had improved, but he still complained of fatigue on slight exertion.

Physical examination was negative, except for the colostomy opening. Laboratory studies offered no aid.

This patient was started on pyridoxine hydrochloride and showed a gradual improvement in strength. At the end of ten days his arm pull had increased from 35 to 70 and his leg lift from 30 to 90. During two weeks of treatment he gained 10 pounds; in the previous three weeks he had gained only 3 pounds.

COMPARATIVE EFFECTS OF PROPYLENE GLYCOL AND SOME OTHER AGENTS ON OXYGEN CONSUMPTION OF THE ORGANISM*

W. VAN WINKLE, JR., M.D., SAN FRANCISCO, CALIF.

THE voluntary running activity of white rats receiving propylene glycol was found previously to be increased somewhat.¹ These rats were not depressed, and they stored more glycogen than normal animals. The oxygen consumption of isolated liver perfused with propylene glycol was decreased, and the organ stored glycogen simultaneously.² These results are related to the possible food value of propylene glycol, which has a definite glycogenic action. But some increase in general activity should theoretically increase oxygen consumption or leave it unchanged. Therefore, it was thought desirable to investigate further the metabolic actions of this glycol, using oxygen consumption as the criterion. This report presents the results obtained.

METHOD

The apparatus used was of the closed-circuit type, a unit consisting of a Hempel desiccator acting as a rat chamber, which was connected by glass tubing and a three-way stopcock to a large glass cylinder of 4,500 c.c. capacity and

*From the Department of Pharmacology, Stanford University School of Medicine, San Francisco.

Received for publication, March 31, 1941.

graduated at 10 c.c. intervals. Soda lime and calcium chloride were put in the desiccator to absorb carbon dioxide and water. The large cylinder was filled with pure oxygen. As a rat used oxygen, water was allowed to siphon into the large cylinder from an 18-liter reservoir, thus equalizing the pressure inside the system with that of the atmosphere. The amount of water siphoned over was a measure of the oxygen consumed, after appropriate corrections for changes in temperature and barometric pressure. Six such units were operated at once.

The rats were observed for seven hours in this metabolic arrangement. No rat was used for more than four consecutive days. Usually 2 runs with the use of glycol or other agents were made, alternated with 2 control runs. The oxygen consumption was expressed as cubic centimeters of oxygen for 100 sq. cm. of body surface per minute. Since the metabolism varied with the environmental temperature, the control observations on each rat were plotted against the environmental temperature and the line through these points calculated by the method of least squares. The point at which this line crossed the 22°-axis was chosen to represent the average control result. Direct comparison of the results on controls and with different agents was made by moving the experimental points parallel to the control line until the 22°-axis was reached. The values so obtained were averaged, and the averages are summarized in Table I.

The nutritional state of the animals and the environmental temperature were as close to those of previous feeding and activity experiments as possible.¹ The animals were fed the usual stock diet of this department and were not fasted prior to the determination of oxygen consumption. The environmental temperature was not held constant but was carefully observed, and the mean values of oxygen consumption were corrected for the variations in temperature.

The doses of propylene glycol and other agents used and methods of administration were as follows: propylene glycol, 5 c.c. and 10 c.c. per kilogram, gastrically; benzedrine, 2 mg. per kilogram, subcutaneously; pentobarbital, 30 mg. per kilogram, subcutaneously; and chloral hydrate, 250 mg. per kilogram, intraperitoneally. The other agents, besides glycol, were used as a further check on the results with the glycol. Benzedrine, which is a general excitant, was expected to increase the oxygen consumption, and pentobarbital and chloral, depressants, were expected to decrease it. However, only the benzedrine acted according to expectations. A total of 505 determinations on 19 rats was made. The duration of each observation was seven hours. The other agents were compared in the same rats receiving the glycol.

CONTROL RESULTS

A total of 256 control observations on 19 rats showed an average oxygen consumption of 1.363 c.c. per 100 sq. cm. per minute at 22° C. (Table I). This value had a variability of less than 3 per cent.

GLYCOL AND OTHER AGENTS

Propylene glycol, in both doses used, depressed the oxygen consumption significantly, i.e., down to an average of 1.142 c.c. from the control average of 1.363 c.c. Benzedrine raised the oxygen consumption in 14 rats and increased

†Standard error of mean.

the activity, i.e., increased general excitability but did not cause tremors; the oxygen consumption was raised to 1.607 c.c. Interestingly enough, pentobarbital decreased the oxygen consumption only slightly in 12 rats. This was interesting, since the animals which received propylene glycol behaved in the same way as did the unmedicated controls and were not narcotized, whereas those receiving pentobarbital were markedly depressed and, in fact, comatose, although the reflexes could be elicited. Recovery occurred at the end of a seven-hour period. Therefore, the depression of oxygen consumption caused by propylene glycol was not due to a decrease in general activity. This confirmed the observations on the isolated perfused liver and explained why the rats, although showing no depression of running activity, were able to store energy (liver glycogen) better than control rats. The burning of propylene glycol requires less oxygen to release a given amount of energy than do most other foodstuffs (except fat).

The results in 2 rats with chloral, which markedly depressed these animals and caused coma with loss of reflexes, were also interesting in that the oxygen consumption was practically the same as that of the controls, contrary to expectations. However, the results with the agents, other than glycol, are of value in showing that the depressant effects of propylene glycol on oxygen consumption are peculiar to this agent, since all other agents tried, except benzedrine, compared favorably with the controls. The explanation of this effect of propylene glycol is not at hand, although the results in the whole animal are consistent with a similar depression of oxygen consumption of the isolated liver perfused with this glycol. This storage of glycogen in the isolated liver, as well as in whole animals, indicates storage of energy for which there is less need of oxygen, despite a fair general activity of the animals.

CONCLUSIONS

1. Propylene glycol was found to depress the oxygen consumption of white rats, this depression not being due to a decrease in activity, since the depressions of pentobarbital and chloral in the same rats did not significantly decrease the oxygen consumption.

2. These results on whole animals are in agreement with previous results on isolated liver perfused with propylene glycol, which also showed a decrease in oxygen consumption.

3. The doses of propylene glycol used were beyond those likely to be taken as solvent or vehicle in food or medicinal agents, but the depression of oxygen consumption could occur with very large or toxic doses. This result is essentially of scientific importance, because the use of propylene glycol has a wide margin of safety.

CLINICAL CHEMISTRY

INSULIN FERRIHEMOCHROMOGEN*

ROBERT D. BARNARD, M.D., CHICAGO, ILL.

DURING the course of an investigation on the conjugation of ferriheme (hematin) with various nitrogenous substances in liquid ammonia (a process by which it is possible to prepare ferrihemochromogens which are soluble in aqueous media at physiologic pH) it was desired to study the reactions of ferriheme with a protein in this solvent. Insulin was used in this particular instance because it is one of the few proteins which is soluble in anhydrous ammonia.^{1, 2} When it was discovered that certain insulin ferrihemochromogens formed by this reaction showed a modification of the characteristic physiologic activity of the hormone, this modification was studied. The results indicate for these soluble insulin conjugates some of the properties possessed by the protamine conjugate and other relatively insoluble depot forms of insulin.

Certain nitrogenous substances combine with ferriheme to give rise to a class of compounds called ferrihemochromogens. Among these nitrogenous substances termed "suitable" by Bertin-Sans and de Montessier, are ethylamine, ammonia, aniline, glycine and taurine,³ nitrite⁴ (in the nitro form), cetyl pyridinium chloride and nicotinamide⁵ and cyanide (in the isonitrile form). Some nitrogenous substances are "unsuitable" in this sense; acetanilid and sulfanilamide⁵ and triethanolamine⁶ come into the latter category. The presence of quaternary nitrogen seems to be essential to the formation of a coordination compound with the iron of ferriheme.[†]

Basic proteins, which contain a large proportion of quaternary nitrogen, can combine with large amounts of ferriheme. Globin can, in fact, take up fully thirty times the quantity of heme as there exists, preformed, in hemoglobin. This capacity of globin is exceeded by that of insulin which was found to be capable of combination with a maximum of about eight times its weight of ferriheme chloride—a ratio of one iron atom to each nitrogen of the insulin molecule.

EXPERIMENTAL DATA

Crystalline insulin assaying 24 units per milligram or amorphous insulin assaying 20 units per milligram was dissolved in anhydrous ammonia in a

*From the Department of Ophthalmology of the Chicago Medical School.

†Another type of coordination compound, that with hydro-acid radicals of small ionic volume, is possible. These are polar in nature and have been termed "hemochromogens." The term "ferrihemochromogen" is more appropriate. "Suitable" ferriheme formers may or may not contain nitrogen, and this need not be in the quaternary form, viz.; azide ion,³ cyanide ion (in the nitrile form⁴) and cyanamide ion.⁵ The combinations of insulin with ferriheme appear to be exclusively of the ferrihemochromogen type.

Received for publication, December 26, 1941.

pyrex Dewar flask and treated with various amounts of ferriheme chloride.¹⁰ The ammonia was allowed to boil off at room temperature through a mercury trap, the last traces being removed by a suction pump. The insulin ferriheme conjugate was less soluble in anhydrous ammonia than either of its components, for, before all the ammonia boiled off, it precipitated as a gelatinous strawberry-colored mass. This became a greenish-black residue on removal of all the ammonia. This residue was dissolved in water to a final concentration of 10 units per cubic centimeter calculated on the basis of original insulin content.

A few of the theoretically numberless pigment conjugates with varying insulin and ferriheme ratios were prepared. One with a high ratio (5:1 of insulin to ferriheme), one with a low ratio (1:6), and one which was completely saturated with ferriheme (1:8 insulin ferrihemochromogen) were tested for physiologic activity. The first showed no difference in activity from that exhibited by ordinary insulin when given in the same manner and dosage. Subcutaneous injection postprandially of 10 units in a 2.72 kg. rabbit caused convulsions in 208 minutes, while the control solution of ordinary insulin under the same conditions brought the blood sugar level to the convulsive level in a litter mate in 197 minutes. The effect of insulin-ferrihemochromogen ratios of 1:6 and 1:8 on the blood sugars of rabbits is given in Table I. There appears to be a definite prolongation of the insulin effect even when these conjugates are given intravenously or intraperitoneally, a condition which does not obtain when the depot forms of insulin are given in this manner.¹¹ The 1:8 ratio of insulin and ferrihemochromogen (which is fully saturated with the pigment

as evidenced by the settling from solution of small amounts of ferriheme) was also tested by the mouse method. Ten animals were convulsed in an average of seventy minutes while one-fourth the dosage of ordinary insulin caused convulsions in 10 mice in an average time of twenty minutes.

No toxic manifestations other than for the insulin effect have been noted in any of the animals used, some of which have been pushed to the convulsive level repeatedly by the administration of the insulin ferriheme conjugate over the past year.

The nitric oxide and carbon monoxide derivatives of 1:8 insulin ferrihemochromogen have been prepared. Their study is in progress and is of interest since they appear to be somewhat resistant to tryptic digestion. Attempts to form the cyanamide and the cyanide derivatives of 1:8 insulin ferrihemochromogen have not been successful.

SUMMARY

A series of water-soluble conjugates formed by the reaction of insulin and ferriheme chloride in anhydrous ammonia have been prepared. Insulin combines with ferriheme to a maximum ratio of 1:8 where a relationship of one insulin nitrogen to one ferriheme iron atom exists.

Chemical studies indicate that the combination is similar to that formed by nicotinates and ferriheme where the nitrogen of the former is coordinated in the 4_o electronic orbit of the iron (ferrihemochromogen linkage) and is different from that formed between cyanamide and ferriheme where the nitrogen is polar covalent with the 3₂ orbit (ferrihemide linkage).

The molecular weight of 1:8 insulin ferrihemochromogen is calculated to be in the neighborhood of 315,000. Consequently, it resembles in physiologic action the "depot" forms of insulin, and, even with intravenous or intraperitoneal injection, administration to rats and rabbits results in hypoglycemia which is delayed in its onset and prolonged in duration.

Repeated administrations in rabbits have indicated neither acute nor chronic toxic effects other than for the hypoglycemic convulsions induced, and this is considered as evidence against the reputed toxicity of ferriheme (hematin).

I wish to acknowledge my indebtedness to Dr. R. G. Roberts, of the Chicago Medical School, and to Dr. Walter S. Bridgins, of Armour and Company, for their material help in the investigation.

CLINICAL USE OF THE CEPHALIN-CHOLESTEROL FLOCCULATION TEST*

RICHARD W. LIPPMAN, M.D., AND H. BAKST, M.D.
NEW YORK, N. Y.

WE BECAME interested in the cephalin-cholesterol flocculation test, as developed by Hanger,¹ because of the simplicity of this method for evaluating "irritation of liver cells" and the significance of clinical jaundice. We have had the opportunity to study the test in 114 patients and present the results as indicating that the test can be of definite clinical value.

Recently Rosenberg² has reported a considerable series which confirms the statements of Hanger. In 155 selected cases, he found that the test was reliably correlated with the clinical findings and felt that negative or slight reactions are indicative of obstructive jaundice, while prompt and strong reactions are indicative of parenchymatous jaundice.

The test is performed by adding to 4 c.c. of normal saline solution 1 c.c. of cephalin-cholesterol suspension³ and 0.2 c.c. of the serum to be tested. After mixing, the tube is allowed to stand at room temperature for twenty-four hours, then read. A homogeneously cloudy solution is read as a negative test. Complete flocculation and precipitation, with a clear supernatant fluid, is read as four-plus. We have considered three-plus and four-plus tests as "positive" and one-plus and two-plus tests as "doubtful."

For confirmation, as many tests as possible were performed on each patient. In most cases, the icterus index, total protein and partition, and total cholesterol were determined, and in many cases bromsulfalein or galactose tolerance tests were done as well. It was impossible to obtain pathologic or operative proof in all cases, but cases were excluded from consideration unless the diagnosis was reasonably established.

In Group I, there were 83 cases with no clinical or laboratory evidence of intrinsic liver disease or of biliary obstruction. Of these, only 4 showed positive tests. Two were in cases of hyperthyroidism, one coincident with severe pernicious anemia. One was in a case of Cooley's anemia with a markedly enlarged liver. The fourth was a case of bronchial asthma and probable periarteritis nodosa. In each of these it is conceivable that liver damage or irritation was present in the absence of other positive tests. It is well known that

*From the medical service of Dr. J. J. Hertz and the Chemical Laboratory of the Beth Israel Hospital, New York City.

Received for publication, December 26, 1941.

The cephalin-cholesterol mixture used in our tests was kindly furnished by Dr. F. M. Hanger. Method of preparation can be found in the literature.^{1,2}

liver damage occurs in hyperthyroidism. There were 12 more cases with doubtful tests. Of these, 3 were cases of hyperthyroidism, and one was a case of primary disseminated arteritis. In some of these repeated tests were later negative.

In Group II there were 22 cases with evidence of intrinsic liver disease. The 4 cases of catarrhal jaundice were all positive and became negative with the subsidence of clinical jaundice. Of the 6 cases of portal cirrhosis, 5 were positive and one was doubtful. Of 10 cases of longstanding chronic passive congestion due to cardiac failure, 4 were positive and 2 doubtful.

In Group III there were 9 cases of obstructive jaundice. Two were strongly positive. In one of these the test was taken just before exitus, after many months of increasing jaundice. The other was in a case where the jaundice was of only three weeks' duration; at operation a carcinoma of the pancreatic head was found. These results are compatible with those of Pohle and Stewart,³ who found that the flocculation test was positive in 18 of 23 cases of obstructive jaundice. This may be explained on the basis of damage to the liver, which occurs with long-standing biliary obstruction or with ascending infection and hepatic damage accompanying obstruction.

TABLE I

	0 NEGATIVE	1-2 PLUS DOUBTFUL	3-4 PLUS POSITIVE
I. No liver disease or biliary obstruction	67	12	4
Cholecystitis	10	2	0
Hyperthyroidism	3	3	2
Others	54	7	2
II. Intrinsic liver disease	4	4	14
Catarrhal jaundice	0	0	4
C.P.C. of liver	1	2	4
Portal cirrhosis	0	1	5
Others	0	1	1
III. Obstructive jaundice	7	0	2
Carcinoma of head of pancreas	5	0	2
Common duct stone	2	0	0

CONCLUSIONS

We feel that the cephalin-cholesterol flocculation test is of definite use in the evaluation of clinical jaundice and hepatic disease. It is no more infallible than any other test of liver status. However, in doubtful cases and in "false" positives, there is usually a factor which makes the existence of subclinical hepatic damage or irritation (by other testing methods) a possibility.

That the test is exceedingly inexpensive and simple to perform makes its value greater, and we suggest that this test be used routinely in the study of cases with jaundice or with suspected hepatic disease.

RETENTION OF NONPROTEIN NITROGEN IN THE BLOOD OF THE RABBIT FOLLOWING INTRAVENOUS INJECTIONS OF A HYPERTONIC SOLUTION OF DEXTROSE*

R. H. RIGDON, B.S., M.D., AND FRANCES MOORE
MEMPHIS, TENN.

RENAL lesions have been observed in both man and experimental animals following the intravenous injection of hypertonic solutions of sucrose.¹⁻³ Recently Rigdon and Cardwell⁴ studied these lesions and found that the primary changes in the kidney occurred in the epithelial cells in the convoluted portion of the tubules. These cells were swollen, and their cytoplasm stained very lightly with eosin. The nucleus was shrunken, and the periphery was serrated. There was a retention of nonprotein nitrogen in the blood of the rabbits showing these histologic changes.

Investigators have usually found it difficult to produce renal lesions by the intravenous injection of hypertonic sucrose with any degree of regularity.^{1, 2} Rigdon and Cardwell⁴ observed that many of their clinical cases were dehydrated when they were first given the hypertonic solution of sucrose. In view of this clinical observation, these investigators dehydrated rabbits before and during the period in which the sucrose was given. With this technique they were able to produce renal lesions routinely. Accompanying this lesion there was a retention of nonprotein nitrogen in the blood.

It was suggested by Rigdon and Cardwell⁴ that this renal lesion resulted from a retention of sucrose and water in the cytoplasm of the epithelial cells in the convoluted portion of the renal tubules. The nuclei of these cells were shrunken as the result of dehydration. The swollen epithelial cells sometimes completely blocked the lumina of the tubules. This process by which retention of nonprotein nitrogen occurred following the intravenous injection of a hypertonic solution of sucrose was reversible as shown by a diminution in the quantity of nonprotein nitrogen that was present in the blood of these rabbits following the addition of water and cabbage to their diet.

In the present experiments a hypertonic solution of dextrose was given intravenously to rabbits to study its effect on the kidney and on the retention of nonprotein nitrogen in the blood. The technique was the same as that used in previous studies when a hypertonic solution of sucrose was given to rabbits.⁴

All rabbits given only oats for three days before experiment begun.

*Rabbits either died or were killed at this time.

†Rabbits given cabbage, water, and oats at this time to see if the N.P.N. would return to normal.

Rabbits 800, 801, 802, 803, 928, 929, 930, 931, 933, 934, 935, and 979 received 25 c.c. of dextrose each day for three successive days.

Rabbits 808, 809, 900, 901, and 978 received 25 c.c. of dextrose each day for five successive days.

Rabbits 806, 807, and 980 were controls; they received no dextrose.

METHODS AND MATERIALS

Normal adult rabbits were used. They were given only oats for three days. At this time one group was given water, cabbage, and oats. A second group was kept on a diet of only oats. All of the rabbits were given 25.0 c.c. of a 50.0 per cent buffered solution of dextrose* (*d*-glucose) intravenously each day for three to five days. The controls were given only oats and no dextrose during the time of the experiment.

The nonprotein nitrogen and urea nitrogen content of the blood were determined by standard methods at intervals during the experiment. The rabbits were killed at varying times, and the kidneys were placed immediately into a solution of 10.0 per cent formalin. Paraffin sections were made and were stained with hematoxylin and eosin.

The rabbits were weighed at frequent intervals. When some of the rabbits, given only oats and dextrose, showed a retention of nonprotein nitrogen, they were given cabbage and water. This procedure was used for those rabbits in which the function of the kidney was permitted to return to normal as indicated by the level of nonprotein nitrogen in the blood.

EXPERIMENTAL DATA

Fourteen rabbits were fed only oats and were given dextrose intravenously. Each of the animals that lived for either four days or longer showed a retention of nonprotein nitrogen in the blood. Rabbits 900, 928 and 931, as shown in Table I, were given cabbage and water after they developed a retention of nonprotein nitrogen. The nonprotein nitrogen in Rabbit 900 was 120 mg. per 100 c.c. on the seventh day and on the seventeenth day of the experiment it had returned to within the range of normal. The nonprotein nitrogen in Rabbit 928 was 148 mg. per 100 c.c. on the fourth day of the experiment, and the nonprotein nitrogen in Rabbit 931 was 87.5 mg. per 100 c.c. On the eleventh day of the experiment the former rabbit's nonprotein nitrogen was 34 mg. per 100 c.c., and the latter's was 33 mg. per 100 c.c.

Five rabbits as shown in Table I were given cabbage, oats and water during the period in which the hypertonic solution of dextrose was injected. There was only a slight rise in the level of the nonprotein nitrogen in any of these rabbits. Rabbits 902 and 903 showed the greater degree of retention. They did not receive adequate amounts of cabbage during the time of the experiment.

Three rabbits (Table I) were given only oats, and the nonprotein nitrogen was determined at frequent intervals. The highest level of the nonprotein nitrogen was 67 mg. per 100 c.c. on the third day in Rabbit 807 and 60 mg. per 100 c.c. in Rabbit 806 on the sixth day. The results of this experiment illustrate the effect of dehydration on the retention of nonprotein nitrogen in the blood of the rabbit.

Urea nitrogen determinations were made in Rabbits 978, 979, and 980. They were 25.0 mg. per 100 c.c. in Rabbit 978 on the second day of the experiment, 28.0 mg. per 100 c.c. in Rabbit 979, and 22.0 mg. per 100 c.c. in Rabbit

*The dextrose was supplied by Eli Lilly and Company.

980. The urea nitrogen was 50.0 mg. per 100 c.c. in Rabbit 978 on the third experimental day. It was 60.0 mg. per 100 c.c. in Rabbit 978 on the fourth and only 30.0 mg. per 100 c.c. in the control, Rabbit 980. Rabbit 980 had only 25.0 mg. per 100 c.c. urea nitrogen on the fiftieth day. These observations show that the urea nitrogen of the blood increases in the rabbit following the intravenous injection of a 50.0 per cent solution of dextrose when the animals are dehydrated.

Fig. 1.—The graph illustrates the loss in weight and the amount of nonprotein nitrogen in the blood of the rabbits at different intervals during the experiment.

All of the rabbits lost weight during the time of the experiment. The average decrease in weight of the group given cabbage, water, oats, and the hypertonic solution of dextrose was 60 Gm. Those given only oats lost an average of 389 Gm. Fig. 1 illustrates the loss in weight of the rabbits and the amount of nonprotein nitrogen in the blood at varying intervals during the experiment.

Pathologic studies were made on the kidneys from Rabbits 801, 807, 903, 929, 933, 935, 978, and 979. Each of these animals was killed. The kidneys from Rabbits 809 and 901 were also studied histologically. These rabbits were dead for two hours or less before the kidneys were removed. There were no macroscopic lesions observed in the kidneys. The epithelial cells in the con-

voluted portion of the tubules in Rabbit 929 were slightly swollen and the cytoplasm was filled with small pink granules. A small amount of albumin was present in the lumina of the tubules. The kidney from Rabbit 807 showed essentially the same characteristics as the kidney from Rabbit 929. The epithelial cells in the kidney of Rabbit 979 were swollen, and the cytoplasm stained lightly with eosin. The kidneys from the other rabbits showed only some swelling of the epithelial cells in the convoluted portions of the tubule. In fact, there was very little histologic difference in any of these sections. The kidneys from the rabbits showing a retention of nonprotein nitrogen were very similar to the controls and also to those in which the level of nonprotein nitrogen was elevated and then returned to normal.

Fig. 2.—Rabbit 979. The epithelial cells in the convoluted portions of the tubules are swollen. Usually the cytoplasm is finely granular and stains deeply with eosin. This rabbit was given 25.0 c.c. of a 50.0 per cent solution of dextrose daily for three days. The nonprotein nitrogen on the fourth day at the time of death was 113 mg. per 100 c.c.

DISCUSSION

The data obtained from this study show that rabbits given 3 to 5 intravenous injections of a hypertonic solution of dextrose (25.0 c.c. of a 50.0 per cent solution) develop a retention of nonprotein nitrogen when the intake of fluid is restricted. Following the retention of the nonprotein nitrogen, if the animals are given fluids in the form of water and cabbage, the level of the nonprotein nitrogen in the blood rapidly returns to normal. This observation indicates that the mechanism by which the nonprotein nitrogen is retained in the blood is a reversible process. We are unable to give the maximum level which nonprotein nitrogen may reach and still return to normal.

No characteristic pathologic changes were observed in the kidneys of those rabbits that developed a retention of nonprotein nitrogen following the intravenous injection of a hypertonic solution of dextrose. The epithelial cells of the convoluted portion of the tubules may become slightly swollen and the cytoplasm may become granular. Small amounts of albumin were present in

a few of the tubules. The kidneys from the rabbits given oats and those from the rabbits given dextrose, oats, water, and cabbage showed essentially the same histologic changes.

The rabbits given hypertonic solutions of sucrose had swollen and vacuolated epithelial cells in the convoluted portion of the renal tubules. The nuclei of the epithelial cells were shrunken.⁴ It was interesting to observe the difference in the histologic changes in the kidney in the rabbits given the hypertonic solution of sucrose and in those given the hypertonic solutions of dextrose. There was, however, a retention of the nonprotein nitrogen in the blood of the rabbit following the intravenous injection of both of these sugars.

Oats were selected for the basic diet of these rabbits since the amount of fluid obtained from them is only negligible. Cabbage was used primarily for its high-water content.

It would be interesting to know if there are any clinical complications following the use of hypertonic solutions of dextrose similar to those observed following the intravenous injection of hypertonic solutions of sucrose. Hypertonic solutions of dextrose are frequently used clinically for the reduction of intracranial pressure. Masserman⁵ observed the effect of various amounts and different concentrations of dextrose on 85 normal patients. He found that "the administration of 50 Gm. or less in 20 per cent solution produced no untoward clinical sequelae other than diuresis; however, the intravenous injection of 100 Gm. or more in 30 to 50 per cent solution caused headaches and other adverse symptoms in 72 per cent of cases, whereas 58 per cent of the patients receiving 185 Gm. or more suffered transient pyrexia." Blau⁶ has suggested that a hypertonic saline solution is preferable to hypertonic dextrose to reduce cerebrospinal pressure.

SUMMARY

Rabbits when dehydrated and given a daily injection of 25.0 c.c. of a hypertonic solution of dextrose for three to five days developed a retention of nonprotein nitrogen and urea nitrogen in the blood.

Following the retention of nonprotein nitrogen, when fluids were given, the nonprotein nitrogen content of the blood returned to normal.

There were no characteristic pathologic lesions observed in the kidney of the rabbits given solutions of hypertonic dextrose and developing a retention of nonprotein nitrogen.

CONCENTRATION OF SULFAGUANIDINE (SULFANILYLGUANIDINE) IN THE PERIPHERAL BLOOD OF HUMAN BEINGS AFTER ITS INTRODUCTION INTO THE LARGE BOWEL AND AFTER ORAL ADMINISTRATION*

JOHN L. KEELEY, M.D., AND WILLIAM M. MCCORD, PH.D., M.D.
NEW ORLEANS, LA.

SULFAGUANIDINE (sulfanilylguanidine), a sulfonamide derivative, has been described by Marshall and his associates¹ as a chemotherapeutic agent for intestinal infections. Relatively small amounts of the drug are absorbed from the gastrointestinal tract, thus providing a rather high concentration in the intestine where it may act on the coliform bacilli of the intestinal flora. It has been shown¹ that in dogs sulfaguanidine is absorbed to a much greater degree by the small bowel than by the large bowel and that the levels of the sulfaguanidine in the blood after absorption from the large bowel are much lower than the levels of sulfanilamide when the latter drug is given by the same route.

Five patients with well-functioning colostomies and with clinically and grossly normal gastrointestinal tracts above the site of obstruction afforded the opportunity of comparing the blood levels of sulfaguanidine which might result from its oral administration with those found after the drug was instilled into the large bowel in human beings. The procedure to be described was carried out after the colon had emptied spontaneously in the usual manner and at a time when no further activity of the large bowel was expected for at least six to eight hours. Doses of 3 to 5 Gm. (60 or 100 mg./kg. of body weight) of sulfaguanidine† were used in the form of suspensions and were introduced into the large bowel in a manner not liable to initiate peristalsis. The suspension was introduced into the distal loop of a transverse colostomy in 2 patients, into the proximal loop of a sigmoid colostomy in 2 patients, and into the distal loop of a sigmoid colostomy in one patient. Blood samples were collected at intervals during the following four to six hours. At the end of these periods of sampling, the dressing covering the colostomy was inspected to detect evidence that the suspension had been expelled. The loop of large bowel was then flushed with warm water to remove as much of the drug as possible. A dose of the drug similar to that placed in the large bowel was then given by mouth, and blood samples were collected at intervals during the subsequent seventeen hours. The levels of free sulfaguanidine in the blood samples were determined according to the method described by Marshall and his co-workers.²

*From the Departments of Surgery and Biochemistry, Louisiana State University School of Medicine, New Orleans.

Received for publication, January 14, 1942.

†Sulfaguanidine through the courtesy of Lederle Laboratories, New York.

The results are shown in Table I, and the trends of the concentration of the drug in the blood are represented in Fig. 1. There was no evidence that the drug had been expelled from the colon, yet a measurable concentration of sulfaguanidine was not found in the peripheral blood of any of the 5 patients during the four to six hours following its introduction into the large bowel. Concentrations

Fig. 1.—Sulfaguanidine levels in the peripheral blood after oral administration.

*Sulfaguanidine removed from colon by lavage.

of the free form of the drug, varying from 0.89 to 2.13 mg. per cent, were found in the peripheral blood in all 5 of the samples withdrawn two hours after oral administration. The peaks of concentration occurred within two to seven hours, and the maximal blood level was 2.62 mg. per cent. In general, the blood levels corresponded to the dosage, being higher when larger amounts of the drug were given.

Following the oral administration of the drug, one patient complained of vertigo which lasted for twenty-four hours and another was nauseated for six hours. In 3 of the patients erythrocyte and leucocyte counts and hemoglobin determinations were made at the beginning and at the end of the experimental period. No significant differences were found.

CONCLUSION

Sulfaguanidine, in the form of an aqueous suspension, when introduced directly into the large bowel through a colostomy stoma, is not absorbed from the left half of the colon in human beings.

THE IMMEDIATE EFFECT OF CIGARETTE SMOKING UPON BASAL METABOLIC RATES OF UNIVERSITY MEN AND WOMEN*

VERZ R. GODDARD, PH.D., AND JACK G. VOSS, M.A.
LOS ANGELES, CALIF.

THE object of this investigation was to determine the immediate effect of cigarette smoking upon the basal metabolic rate of the smoker, since a question as to the existence of such an effect had arisen. In spite of a careful search of the literature, little definite evidence was found. There seems to be, however, a general impression among clinical workers that smoking is followed by a rise in basal metabolism. We resolved to test this assumption under conditions approaching those under which clinical determinations are made. It was hoped that a definite answer to the question of the immediate effect of smoking could be obtained from the results.

Males¹ noted that the injection of rats with minimal doses of nicotine, the active principle of cigarette smoke, produced a transient rise in metabolic rate, followed by a more prolonged period of subnormal metabolic activity. This may be taken as an indication that smoking is capable of affecting the metabolism in some way. Furthermore, Schlumm² found a high basal metabolic rate (average +19.9 per cent by Harris-Benedict standards) in heavy smokers in Germany; the basal metabolic rates fell to a normal level soon after smoking was discontinued. More recently, Hiestand, Ramsey, and Hale³ reported further evidence for an increase in basal metabolism as an immediate result of cigarette smoking. There is, therefore, some indication in the literature that smoking may affect the metabolic rate.

Received for publication, February 17, 1941.

EXPERIMENTAL

The subjects taken for these tests were men and women of college age, selected at random from students apparently in good physical condition at the time of the experiment. All were accustomed to smoking either habitually or occasionally. The subject relaxed for one-half hour before the first test; the control basal rate was then determined, using the Benedict-Roth recording metabolism apparatus. Two six-minute tests were averaged for the control run. Following this, the subject was allowed to sit up and smoke approximately three-fourths of a cigarette. Physical exertion was kept at a minimum. The subject then lay down again for another rest period of twenty-five to thirty minutes, at the end of which time two more six-minute runs were taken. From the average of these, the apparent basal metabolic rate after smoking was determined. The deviation from the control test, previously obtained, was expressed as percentage difference. The calculations of the normal calories per hour were made by use of the standards of Dubois, as modified by Sandiford and Boothby.

TABLE I

SUBJECT	SEX*	SMOKING HABITS†	BASAL RATE PER CENT	NORMAL CAL./HR.	ACTUAL CAL./HR. (CONTROL)	AFTER SMOKING CAL./HR.	PER CENT DEVIATION

Standard precautions and procedures (i.e., testing for leaks, determining absorption of carbon dioxide, etc.) were used throughout the experiment. The subject was, of course, in basal condition and had not smoked on the morning of the tests. In order to control a factor which might possibly vary, the same brand of cigarettes was used in all cases. It was shown at one time by the Bureau of Investigation of the American Medical Association⁴ that this brand contained 1.44 per cent nicotine, which was slightly below the average for standard brands. The necessity for this precaution is indicated by the work of

Haag,⁵ who found that the blood pressure of anesthetized dogs, given intravenous injections of smoke solutions prepared from several brands of cigarettes, could be correlated with the nicotine content of the cigarettes.

The 20 subjects were selected from more than 40 upon whom control tests were run. Only those tests in which, by all criteria, the subjects appeared relaxed, and in which the oxygen consumption in the two six-minute periods agreed within 3 mm. on the chart were considered. Results of doubtful validity were not used.

The results of the tests are shown in Table I. The last column was obtained by dividing the difference between the two previous columns by the control (actual calories per hour) and multiplying by 100.

DISCUSSION

The results given here shown that the apparent basal metabolic rate determined approximately one-half hour after smoking may be either above or below the control test taken prior to smoking, but that the deviation is by no means constant. In many cases the difference obtained was certainly great enough to be considered significant.

The work of many investigators has indicated that smoking, or nicotine, stimulates the adrenal glands to an increased secretion of adrenaline. Houssay and Molinelli^{6, 7} showed that nicotine acts directly upon the adrenal medulla of dogs, causing release of the hormone by a specific reaction with that tissue. Haggard and Greenberg⁸ found a rise in blood sugar after smoking, which they attributed to the action of adrenaline. Johnson and Short⁹ observed a rise in the peripheral skin temperature after smoking, while Short and Johnson¹⁰ noted that pulse rate, blood sugar, peripheral skin temperature, and blood pressure were similarly influenced by smoking and by small amounts of adrenaline.

In the recent report of Hiestand, Ramsey, and Hale³ an adrenaline effect was pointed out as the probable cause of the physiologic responses to smoking. In 82 per cent of their subjects (not in basal condition) the metabolic rate was increased following smoking. Sixty per cent of our subjects showed an increased basal metabolic rate, whereas 35 per cent showed a lowering in the rate. The mean value of the percentage deviation was ± 2.3 in our study, while the above authors reported an average of ± 8.9 . They did not attempt to explain the lowering of the metabolic rate, immediately following smoking, in 13 per cent of their subjects.

As Haggard and Greenberg⁸ showed, when the blood sugar is raised, an increment in carbohydrate oxidation, and, therefore, a higher metabolic rate was to be expected. For this reason, a rise in basal metabolism following smoking was anticipated. However, a possible explanation for the unexpected variation in results has been tentatively advanced. It is well known that the sympathetic nervous system varies in responsiveness in different individuals, and that the adrenals are under its control. It is suggested that the response of these glands to the stimulation due to smoking occurs after different time intervals in different subjects, causing a preliminary rise in basal metabolic rate, followed by a drop

to subnormal values before the return to normal. This supposition is borne out by the work of Males¹ on rats. Johnson and Short² noted a time difference in their subjects in changes of the peripheral skin temperature after smoking, and Hiestand, Ramsey, and Hale³ noted changes in responses of their subjects over a period of forty-five minutes following smoking, with regard to heart rate, blood pressure, oxygen pulse, and metabolic rate.

Haggard and Greenberg⁴ observed that the respiratory quotient reached its peak in about fifteen minutes after smoking, and during the next thirty minutes returned to the normal level or slightly below. As the method of indirect calorimetry was used in our determinations, it is evident that in cases of apparent increase in the basal metabolic rate, the actual increases may have been even greater than those calculated, since the method of calculation assumes a respiratory quotient of exactly 0.82. The work of Dill, Edwards, and Forbes¹¹ on ten subjects, however, indicated that the smoking of one cigarette resulted in no appreciable change in respiratory quotient.

With regard to interpreting our own results, therefore, it is possible that (1) the "metabolic rate-time curve" may have been distinct and characteristic for each person; and (2) the basal metabolic rates of our subjects were determined at different points on their individual curves.

With regard to other phenomena observed, it was found that the pulse rate was generally higher, the body temperature usually higher or constant, and the rate of respiration often higher after smoking. This is in general agreement with the work of Short and Johnson and others, although Hiestand, Ramsey, and Hale found a decrease in the rate of respiration. It was further noted that sex seemed to have no influence upon the immediate reaction to smoking.

It was significant that all the control basal metabolic rates of our subjects showed a negative deviation from the predicted standards. This is in general accord with the results of Martin,¹² Mason,¹³ and Tilt and Walters,¹⁴ obtained upon subjects in tropical or subtropical climates.

SUMMARY

1. The apparent basal metabolic rate after smoking generally shows an appreciable deviation from a control rate determined prior to smoking.
2. The generally accepted rise in basal metabolism some time after smoking is by no means a universal phenomenon.
3. A rise in pulse rate, respiration rate, and body temperature following smoking is generally observed.
4. The sex of the subject apparently does not influence his energy output following smoking.
5. A possible explanation of the individual response to smoking is offered.

Grateful acknowledgment is made to our voluntary subjects for their faithful cooperation, and to Dr. William C. Boeck, of Los Angeles, for his helpful suggestion with regard to interpretation of our data.

LABORATORY METHODS

GENERAL

SLIDE AGGLUTINATION IN DETECTING PERTUSSIS ANTIBODIES*

COMPARISON OF SLIDE WITH TUBE AGGLUTINATION

LUCY MISHKOW, B.A., NEW YORK, N. Y.

DIAGNOSIS by means of slide agglutination has been used successfully for some time in Brucellosis,^{1,2} and in typhoid-paratyphoid infections.^{3, 4} More recently Evans and Maitland⁵ recommended slide agglutination for the diagnosis of pertussis. Using a concentrated antigen of live *H. pertussis* and examining the slides microscopically, they obtained more positive results on the slide than on macroscopic tube agglutination.

The main advantages of slide over tube agglutination are (1) the small amount of serum required for the test, (2) the rapidity of the reaction (agglutination usually occurs within a few minutes) and (3) the simple apparatus necessary to carry out the test. Therefore, if on further tests slide agglutination should prove sufficiently sensitive to detect weakly positive sera, it would be an improvement on the more cumbersome and time-consuming method of tube agglutination. With this object in view we have tested a fairly large number of sera by slide and tube agglutination.

The use of a live antigen in slide agglutination as recommended by Evans and Maitland⁵ seemed undesirable, since it would be necessary to prepare a suspension of the bacilli and standardize it for each day's tests. We found, after several trials, that we could use with equal success a suspension that was killed by means of 0.5 per cent formalin, or 1:50,000 dilution of merthiolate. This antigen did not lose its agglutinability after seven months' storage, which was the period of this investigation. Antigens that were killed by means of gentian violet in a 1:20,000 dilution or brilliant green in a 1:40,000 dilution became less agglutinable upon storage and were therefore not used. The antigen that we employed in our tests was prepared as follows:

A forty-eight-hour growth of *H. pertussis* on freshly prepared Bordet-Gengou medium was emulsified in sterile physiologic saline. The suspension was filtered through sterile cotton to remove particles of agar, and the bacteria were precipitated by centrifugation. They were washed twice in saline, and after the second washing they were suspended in physiologic saline which contained 1:50,000 merthiolate. The antigen was stored at 8 to 10° C.

The optimum concentration of the antigen for rapid slide agglutination was determined by titration with an antipertussis rabbit serum and was later

*From the Bureau of Laboratories, New York City Department of Health.
Received for publication, July 15, 1941.

checked with known positive human sera. Serial dilutions were made of the positive serum, and each dilution was tested with various concentrations of the antigen. As a control a live suspension of the bacilli was used in a concentration of 100 billion as recommended by Evans and Maitland. We found that a concentration of 25 billion bacilli per milliliter of the killed antigen gave more clear-cut agglutination than higher concentrations, and agglutination took place in the same dilutions as with the live antigen. We therefore used our antigen in a 25 billion concentration.

Before each day's test, the antigen was diluted with sterile physiologic saline to 25 billion bacilli per milliliter and was filtered through a 60-mesh monel metal wire gauze to remove clumps. It was then titrated with the positive serum to determine its sensitivity on the day of the test. The same positive serum was used throughout this study, and its titer remained remarkably constant.

The Test.—The sera were tested undiluted; 0.01, 0.02, 0.04, and 0.08 ml. amounts were used according to the method of Welch-Stuart⁷ for typhoid-paratyphoid diagnosis. The stated amounts of serum were measured into the center of 4 paraffin rings on a glass slide by means of a pipette that was graduated into 0.01 ml. A drop of the antigen was added to the serum from a standardized capillary pipette that delivered approximately 0.015 ml. in each drop. The serum and antigen were thoroughly mixed by means of a wooden applicator, beginning with the smallest amount of serum. The slide was tilted back and forth for one minute, and a preliminary reading was made. The final reading was made after an additional three minutes' incubation at room temperature. All readings were made macroscopically, using a constant light. We found it unnecessary to read the agglutination on the slide microscopically since the clumps were distinctly visible to the naked eye.

Strongly positive sera agglutinated usually within one minute; weakly positive sera required two to three minutes. Where agglutination was complete, the clumps were large and the fluid clear. A serum was considered negative when it showed incomplete or no agglutination after four minutes' incubation at room temperature; a longer period of incubation could not be used, as the mixtures began to dry after four minutes.

Agglutination usually took place first in the 0.01 and 0.02 ml. then in the 0.04 and 0.08 ml. amounts of the serum, thus showing that the optimum proportion of serum to antigen was in the 0.01 or 0.02 ml. amounts of the serum. The final results were recorded on the basis of agglutination in 0.01 ml. of the serum. When agglutination was complete in the undiluted serum, serial dilutions were made, and 0.01 ml. of each dilution was tested for agglutination. The result of the titration was recorded in terms of the highest dilution of the serum that showed distinctly visible clumps.

TUBE AGGLUTINATION

Antigen.—The preparation of the antigen was described in detail in a previous publication.¹⁰ A formalinized saline suspension of a forty-eight-hour growth of *H. pertussis* on Bordet-Gengou medium was standardized and was tested for agglutination with a known positive serum. It was stored in con-

centrated form at 8 to 10° C. On the day of the test the antigen was diluted to contain approximately 2,500 million bacilli per milliliter.

The Test.—The sera were tested in 1:10 to 1:1,000 dilution or higher if necessary. To 0.1 ml. of the serum dilutions, 0.9 ml. of the antigen was added, and the tests were incubated in a water bath overnight at 52° to 56° C. An antigen control in saline without serum, and an antigen titration with a positive serum were included in each test. Readings were made macroscopically, using a constant light. The titer of the serum was recorded in terms of the highest dilution that showed distinctly visible clumps. For the purpose of comparison with slide agglutination, a serum was recorded positive on tube agglutination when there was distinct agglutination in the 1:10 dilution of the serum. Doubtful or no agglutination in the 1:10 dilution when all the higher dilutions were negative was recorded as negative.

We tested 342 sera for slide and tube agglutination. Among these were sera from persons who were vaccinated against pertussis; from groups of mice that were immunized with various pertussis antigens; from persons with clinical pertussis; from persons with colds or coughs, who were exposed to pertussis; from persons without illness some of whom had been exposed to pertussis; and from groups of normal mice. The results are summarized in Tables I and II.

Table I shows that more positive results were obtained on slide than on tube agglutination with sera of persons who had clinical pertussis and those who were suspected of having pertussis, or were exposed to actual cases of this disease. Slide agglutination appears to be specific since no more positive results were obtained on the slide than on tube agglutination among persons who were not exposed to pertussis, although a large number of them had coughs or head colds at the time of the test.

Table II shows that the agglutination titers on the slide and in the tube did not run parallel. On the whole however, all of the sera that had a high titer on tube agglutination also had a fairly high titer on slide agglutination. Slide agglutination proved to be more sensitive than tube agglutination in detecting weakly positive sera as there were 28 sera positive on the slide and negative on tube agglutinations, as compared with 5 sera that gave a low titer of agglutination in the tube and were negative on the slide.

CONCLUSION

1. The results obtained in this study have confirmed the findings of Evans and Maitland that more positives are obtained on slide than on tube agglutination in detecting pertussis antibodies.

2. We found that an antigen that was preserved with merthiolate and stored at 8 to 10° C. had given equally good results as a live antigen that was recommended by Evans and Maitland, and it retained its agglutinability during the seven months' period of this study. In all probability it will remain unchanged for a much longer time. This antigen has the advantage over a live antigen in that it is always available and it eliminates the necessity of preparing and standardizing the antigen for each day's test.

3. The results obtained on slide agglutination were as specific as on tube agglutination since no more positives were obtained on the slide than on tube agglutination with sera from persons who had no clinical symptoms of pertussis and no history of exposure to pertussis.

4. Slide agglutination has the advantage over tube agglutination in that the result may be obtained within a few minutes, and with a carefully standardized antigen more positive results may be obtained with weakly positive sera.

5. In the testing of large numbers of sera, slide agglutination would be very helpful in eliminating negative or doubtful sera. The positive sera could then be titrated by tube agglutination if the exact titer of the serum is required.

6. From present indications a positive result on slide agglutination may be taken as diagnostic of pertussis infection, when there was no previous pertussis vaccination and no vaccine therapy. A negative result does not exclude pertussis infection since a fairly large number of clinically typical pertussis patients do not develop agglutinins until late in the disease or until convalescence.

Technical assistance in this study was given by Edna Lewis and Ruth Orange in carrying out the tube agglutination tests.

A SIMPLE DEVICE FOR THE PROTECTION OF THERMOSTATS IN WATER BATHS*

ROBERT FINKELSTEIN, M.S., CHICAGO, ILL.

IN MANY electrically operated water baths, the thermostatic control necessary to maintain a constant temperature is exposed to the destructive action of mercury if the thermometer is broken.

Fig. 1.—Simple protection for thermostats.

Mercury can ruin a water bath beyond repair by attacking the solder of joints in the bath and the metals in the thermostat. This can be avoided by placing a small test tube around the bulb of the thermometer in such a manner that the top of the tube is below the water level. The test tube can be adjusted to fit the type of water bath and thermometer as required. In the event of thermometer breakage, the mercury will fall into the test tube. A simple clamp device that will hold the tube upright can be constructed, depending upon the type of water bath. The mercury therefore will not come in contact with metal connections.

THE ANTIFOGGING EFFECT OF SOAP ON EYEGLASSES AND DIAGNOSTIC MIRRORS*

LOUIS PELNER, M.D., BROOKLYN, N. Y.

TO ANY physician who has had to operate wearing eyeglasses and a face mask, fogging or steaming of the glasses is a real hardship. The mask diverts the warm exhaled air along each side of the nose and causes it to condense on the cooler surfaces of the eyeglass lenses. Fogging results, and this makes it difficult for him to see through the lenses.

Johnson¹ discussed this problem in a short article and contributed a unique solution. He attached a piece of adhesive tape along the top of the mask and pasted this to the skin of the nose. This does not allow the warm air coming from the mouth and nose to be diverted toward the glasses. Other contrivances, such as metallic inserts along the top of the face mask and loosely fitting sacs covering the whole head, have also been tried, but these require special equipment.

The present contribution concerns means of treating the glasses themselves so that the warm air cannot condense on their surfaces. It consists of chalking a few lines across the lens with a piece of soap, and then polishing the glass with soft paper or a handkerchief. A thin coating of soap remains on the surface which repels the condensation of the warm air. The visibility is not decreased by this fine coating.

The method is also applicable to laryngeal mirrors and other diagnostic mirrors that come in contact with warm, moist air. Other methods, such as warming the mirror or coating it with saliva, are in use, but the simplicity of the present plan serves to recommend it. For diagnostic mirrors, I have found the antifogging effect of naphtha soap to be more effective than ordinary white soap.

Realizing that a solution so simple could hardly be original, I referred to a book² published by Henley and Company, which contains among its 10,000 formulas, one which prevents the "dimming" of eyeglasses and other glassware. The formula consists of adding a form of soap to glycerin and oil of turpentine.

SUMMARY

Soap exerts an antifogging action on eyeglasses and diagnostic mirrors.

A SIMPLIFIED "LYOPHILE" DESICCATOR FOR SMALL LABORATORIES*

L. ROYAL CHRISTENSEN,† NEW YORK, N. Y.

A NUMBER of devices have been described^{1,2} for the desiccation of biological materials from the frozen state by evaporation of the water under a high vacuum, with subsequent condensation of the vapor in a condenser held at a very low temperature. For this process, the term "lyophile" has been proposed.^{1,3} These devices have been intended primarily for the processing of relatively large volumes, and as a consequence have a much greater capacity than is necessary for the handling of occasional small batches of material. Further, these devices are in general of a somewhat complicated design, necessitating the services of a machine shop and skilled workmen in their construction. It is the purpose of this paper to describe a modification of the lyophile apparatus, developed for use in a small laboratory, which possesses certain advantages with regard to convenience, adaptability, simplicity of construction, and inexpensiveness.

Fig. 1 presents a diagram of the apparatus. *A* is the condensing unit, a 1 liter, short neck, pyrex flask, fitted with a 34/45 standard taper ground glass joint and a 3-way stopcock of large bore, *C*. *B*, the connection between the condenser and the vessel containing the material to be dried, *F*, is made of pyrex tubing with an internal diameter of approximately $\frac{3}{4}$ inch, bent at right angles at each end, and fitted with two 34/45 standard taper ground joints (inner part) as illustrated. The end fitting the condenser is extended beyond the ground joint to within $1\frac{1}{2}$ inches of the bottom of the flask. *D* is a large metal can holding the freezing mixture of dry ice and 95 per cent alcohol; it in turn is held in a wooden box *E* surrounded by 2 inches of fine sawdust or other suitable insulating material.

In use, a mixture of cracked dry ice and alcohol is placed in the metal container, and the condensing flask is immersed to thoroughly chill it. Five pounds of dry ice will operate the apparatus for six hours or more. The alcohol may be re-used (usually about six times) until it has absorbed enough water from the atmosphere so that ice crystals form in it when the dry ice is added. The material to be dried is frozen around the interior of a suitable container by rotating the container and contents for a few moments in the dry ice-alcohol bath. The rate of drying is dependent in a large measure on the total surface area of the material to be dried, so that the layer of frozen material is made as thin as practical. The apparatus is then assembled as illustrated, the joints being made vacuum tight by means of a suitable sealing compound such as "Lubri-Seal." Evacuation of the apparatus is carried out by means of a Cenco

Hyvac pump, or its equivalent, attached to the three-way stopcock during the entire period of desiccation. A McCleod gauge is not essential to determine the degree of vacuum. In our experience the pump is operating satisfactorily if the valves make a sharp metallic click as they seat. It has not been found necessary to interpose a trap between the condenser and the pump to prevent water vapor from entering the pump, as suggested by several workers.^{2, 3, 5} In this laboratory the oil in the pump is changed every four to six months, and while it contains some water, it does not seem to affect materially the operation of the pump. In this connection, removal of the water and debris from the oil by centrifugation in a Sharples centrifuge renders it again fit for use. When desiccation of the material is complete, the vacuum is broken by turning the three-way cock, and the material is removed from the desiccator.

Fig. 1.

By virtue of the standard taper joints it is possible to attach a wide variety of desiccation vessels to the apparatus. For desiccation of small volumes of material, a container made by sealing the open end of a 34/45 standard taper pyrex ground joint (outer part) has proved very satisfactory (Fig. 1, F). The most generally useful desiccation vessel in this laboratory has been a small vacuum desiccator (140 mm. inside diameter) with a ground joint in the lid fitting the pyrex 34/45 ground joint. It is not necessary to have this lid made to special order, since it was found after testing several sizes and makes of desiccators that several are made with a ground joint fitting perfectly with the pyrex standard taper joint. Corning Glass Works also manufacture a large pyrex vacuum desiccator, which is equipped with a 34/45 standard taper joint in the lid. In using either the small or large desiccator, the material to be dried is frozen around the sides of one or more beakers or other suitable containers, placed in the desiccator, and the desiccator is attached to the condensing unit.

Evaporation of the water vapor proceeds at a sufficiently rapid rate so that the material to be dried remains frozen during the entire period of desiccation. As shown by Greaves and Adair,⁴ sublimation of water vapor can be materially increased by raising the temperature, taking care, of course, to avoid melting the frozen material. In using a flask as a desiccating vessel, this warming may be accomplished by immersing the flask in a water bath at 30° to 40° C. At such temperatures the material will remain frozen if the pump is operating satisfactorily. The vacuum desiccators may be wrapped with rubber tubing held in place with adhesive tape. After a high vacuum has been attained, warm water may be circulated through this tubing. It is necessary to use a somewhat higher temperature here (40° to 50° C.), since the vacuum within the desiccator insulates the contents to a certain extent. It is impossible to give figures on the rate of drying, since this rate is dependent on so many factors: the material to be dried, surface area of the material, degree of vacuum, temperature of the desiccation vessel, and the like. However, when drying antisera, frozen around the sides of 600 ml. beakers, a rate of about 15 to 20 c.c. per hour was observed.

The chief advantage of this modification of the lyophile apparatus is its versatility. In addition to the desiccation vessels mentioned, there are in use in this laboratory several sizes and shapes of flasks and a pyrex manifold for the desiccation of small amounts of material in tubes with subsequent sealing of the tubes under vacuum. Other advantages of this apparatus are its simplicity and economy. A moderately skilled glass blower should be able to construct it from standard items of pyrex glassware in a few hours, or the Corning Glass Works will manufacture the apparatus to specifications for a reasonable sum. By no means least of the advantages is the ease and simplicity of cleaning and removal of frozen water vapor. It is necessary merely to disconnect the condenser from the connecting tube, thaw under the tap, and empty. This operation may be performed rapidly enough so that the material in the desiccation vessel does not thaw.

This apparatus has been used in this laboratory primarily for the desiccation of partially purified fibrinogen and prothrombin preparations to be used in the study of streptococcal fibrinolysin.⁶ The precipitated material, either fibrinogen or prothrombin, is dissolved in a small amount of water, frozen, and dried. It has been found that desiccation in the lyophile apparatus instead of over phosphorous pentoxide, as originally recommended,^{7,8} results in greater solubility, less denaturation, and greater stability of these materials. In addition to fibrinogen and prothrombin, materials dried in this apparatus have included partially purified fibrinolysin, bacterial polysaccharides, cultures of various organisms, virus suspensions, plasma and serum, and various antisera. Other possible uses include preservation of complement, typing sera, and soluble antigens.

SIMPLE MODIFICATION OF THE HANIKE-GIBBS DROP RECORDER*

W. H. OLSON AND H. NECHELES, M.D., PH.D.
CHICAGO, ILL.

THE Hanike-Gibbs instrument for recording drops of secretion applies the principle of displacement of an electrolyte solution with constant viscosity and conductivity. The instrument reported by Gibbs¹ in 1927 consists of 5 different parts with a number of connections and does not lend itself easily to experiments in which the rates of a number of different secretions must be measured at the same time. We have therefore modified the instrument, using the same principle.

Fig. 1 is a diagram of the modified drop recorder. The upper part of two glass cylinders *A* and *B* is solidly connected by a glass tube *C*. The first cylinder *A* is empty and connected to the cannulated duct of an organ, the secretion of which is to be measured. The second cylinder *B* is filled with a 10 per cent solution of sodium citrate.† The lower pole of this cylinder has a fine opening *F* through which a drop of the citrate solution is forced when a drop of secretion displaces air in the first cylinder. The falling citrate drop passes between platinum wire *K* and the brass funnel *L*, fixed in a glass tube *G* to which slight constant water suction is applied so that the drop of citrate passes rapidly between the contacts. The drop closes the electric circuit temporarily while touching the two contacts, and the signal magnet is activated. The contacts are connected from binding posts *H* and *J* in series with 115 volts A.C. or D.C. and to a small recording signal magnet. A fuse is introduced into the circuit. Due to the constant suction the amount of current transmitted is small enough to permit the use of an ordinary 6-volt laboratory signal magnet. The instrument can be made in the laboratory at low cost. We have used it for more than two years and found it so reliable, easy to use, and maintain that we feel it would be useful to many other laboratories. The instrument must be protected from radiating heat which will expand the air and citrate solution in the two chambers. The instrument will work for many hours unsupervised.

*From the Department of Gastro-Intestinal Research, Michael Reese Hospital, Chicago. A preliminary report was published in the *Proc. Am. Physiol. Soc.* p. 214, April, 1941.

Aided by the A. B. Kuppenheimer Fund.

Received for publication, August 18, 1941.

†Lately we have used instead a 3 per cent solution of commercial sulfuric acid, which is cheaper and which keeps the contacts *K* and *L* clean.

Samples of secretion can be removed from *E* at intervals for analysis. The samples are not diluted or mixed with other substances, and they are not exposed to electric sparks and electrolysis as in some other instruments. Refilling can be done swiftly and easily by turning the current off (a switch can be inserted at *J*), opening the clamps at *E* and *D*, and attaching a funnel to the

Fig. 1.—Diagram of drop recorder.

rubber tube at *D*. After *B* has been filled with the citrate solution to just below the level of *C*, clamp *D* is closed quickly. During the process of filling, some of the citrate solution escapes through *F* which may be closed during the filling, but we have not found that necessary. It may take then a few minutes before pressure equilibrium is reached in the system. We have found it of advantage to put the drop recorder below the level of the cannulated duct of the animal, because a slight suction on the duct may prevent clogging or, in the case of lymph, clotting.

We have used a set of 4 instruments, as shown in Fig. 2, to record simultaneously salivary, pancreatic, biliary, and lymph secretion.

Fig. 2.

DISCUSSION

We feel that, when a continuous quantitative record of the volume of a secretion is wanted, the displacement system should be employed in order to obtain more accurate results. For example, in the measuring of the secretion of bile or saliva, the concentrations of salts and of mucus usually change during the experiment. This results in a change in the viscosity of the secretion and in the size of the individual drop. Thus we have often found the size of a drop of bile to double its volume as the experiment progressed. Such uncontrollable changes can be avoided when a solution of constant composition is displaced by the secretion.

A SATISFACTORY TECHNIQUE FOR DELAYED TYPING OF THE PNEUMOCOCCUS*

G. McF. MOOD, M.D., AND E. H. FOWLER, M.A.
CHARLESTON, S. C.

WITH the widespread immediate use of the sulfa drugs instead of serum in the treatment of pneumonia, the typing of the pneumococcus seems of little value except for case records. Laboratory directions always state that a sputum is best typed as soon as possible after collection because of the early death of the pneumococcus and the overgrowth of contaminating bacteria. This work is presented to show that this is unnecessary except when "stat" typings are desired.

The suggested technique is based on the following work. Typings were run on more than 50 sputa of known type. Three generous smears were made on each of 6 glass slides and allowed to dry in the air. They were then wrapped in paper and stored, 3 at room temperature and 3 at icebox temperature. After intervals of twenty-four, forty-eight, and seventy-two hours, and one, two, three, and four weeks, each type was tested for the quellung reaction in the ordinary manner. It was found that all slides stored at either temperature for the varying lengths of time typed just as well as the original specimen. A few slides tested after storage for ten months gave good quellung reactions. There was no apparent reduction in the number of swellings or the size of the swollen capsule. Group sera swelled stored preparations as well as the type sera. To check against high temperatures of the tropics several types when dried were stored at incubator temperature (37.5° C.) for one month. These still gave good swellings. All types have been tested except types IX, XI, XXVII, XXVIII, XXXI, and XXXII which were not encountered during the period when the work was being done.

As a result of this work, it is suggested that exudates (with a few exceptions such as spinal fluids requiring centrifugation) immediately upon collection be smeared entirely across or at three locations on each of at least four clean slides and allowed to dry in the air. These may then be typed at one's convenience in the usual manner.

Since this seems to prove that delayed typings are possible, several advantages can be observed in the use of dried slides for typings:

1. Dry fields are easier to examine microscopically since there is less motion present than in a moist smear.
2. Drying on a slide keeps the organisms from deteriorating and contaminating bacteria from overgrowing and destroying the pneumococci.

*From the Department of Bacteriology, Medical College of the State of South Carolina.
Received for publication, August 19, 1941.

3. Dried slides can easily be mailed great distances for typing, and variance in time would not alter the results.

4. Smears from the pharynx, especially in children, can be made immediately and typed easily by this method without the risk of the swab's drying before it can be typed.

5. The most important advantage from the technician's standpoint is the lack of the necessity of "stat" work.

TRYPSIN AS A DIGESTANT OF SPUTUM AND OTHER BODY FLUIDS PRELIMINARY TO EXAMINATION FOR ACID-FAST BACILLI*

EDITH HAYNES, PH.D., INDIANAPOLIS, IND.

A NUMBER of methods have been used for the concentration of sputum preliminary to examination for acid-fast bacilli. Some of these fail to concentrate the organisms adequately; others are time consuming; and some require special apparatus and delicate technique. Since 1933 we have used an aqueous solution of trypsin to digest such specimens as sputum, stomach washings, pleural and abdominal fluids, urine that contained mucus, and pus from abscesses, with satisfactory results.

METHOD

A 0.5 per cent trypsin solution is made by adding powdered trypsin† 1:250 (Difco) to sterile water. Mix by shaking, and add 0.7 per cent N/1 sodium hydroxide solution, which gives approximately pH 8.5. Since trypsin acts over a wide range of hydrogen-ion concentration, it is not absolutely essential that the sodium hydroxide be added, but the trypsin is most active at pH 8.0 to 8.5. The trypsin solution should be kept in the refrigerator or, better, filtered through a Seitz filter if it is not used shortly after it is prepared.

1. An equal quantity of the trypsin solution, or more if the specimen is very thick, is added to the specimen in a bottle or large test tube, and mixed thoroughly, an applicator stick or glass rod being useful for this purpose.

2. The specimen is then incubated at 37° C. for thirty minutes, or until the mucus is thoroughly digested, which can be determined by drawing out the applicator stick or by the sedimentation of the cells. Stirring after ten to fifteen minutes' incubation may hasten the digestion.

3. After digestion is complete, the specimen is centrifuged at 3,000 r.p.m. for five minutes, or at 1,500 r.p.m. for ten minutes.

4. A loopful of the sediment is smeared on a glass slide, fixed as usual, and stained by the Ziehl-Neelsen method. If the smear is thin, methylene blue is used as a counterstain; if it is thick, 1 per cent aqueous picric acid is used. The sediment is also satisfactory for examination by the fluorescence method.

EXPERIMENTAL DATA

In order to compare the effectiveness of concentration of acid-fast bacilli in sputum by the trypsin method with the flocculation method of Hanks et al.,¹ a series of specimens was examined by both methods. Preliminary to digestion the specimens were heated in an Arnold sterilizer for thirty minutes and cooled (this is done routinely in our laboratory as a safety measure unless the specimen is to be used for culture or guinea pig inoculation). The specimens were then divided as evenly as possible (we used as much as 5 c.c. if the size of the specimen permitted) and put into 6 inch by $\frac{3}{4}$ inch test tubes. The procedure of Hanks et al.¹ for the concentration of tubercle bacilli and the trypsin method as outlined above were followed. Smears were made in a uniform manner, a 4 mm. loopful of the sediment being spread over an area 1.5 cm. by 3.5 cm., and fixed and stained by the Ziehl-Neelsen method. The acid-fast bacilli in 200 fields were counted, the number of fields being recorded as the bacilli were counted. Since the finding of a clump of bacilli does not increase the possibilities of finding the organism, each clump was counted as one.

Of 100 specimens of sputum which were positive by one or both methods, 14 per cent were positive by the trypsin method that were negative by the flocculation technique and 3 per cent were negative by the trypsin method which were positive by the flocculation technique. In 5 per cent of the specimens the same number of bacilli were found by both methods. In the remaining 95 specimens more acid-fast bacilli were found in 71.5 per cent of the trypsin-digested specimens, and in 30 per cent of these at least twice as many acid-fast bacilli were found in 200 fields by the trypsin technique as by the flocculation method. More acid-fast bacilli were found in 28.4 per cent of the specimens by the flocculation method, and 7 per cent of these had at least twice as many acid-fast bacilli as were found by the trypsin method.

DISCUSSION

As the results show, 11 per cent more specimens were positive by the trypsin method than by the flocculation method. Also more acid-fast bacilli were found in 71.5 per cent of the trypsin-digested specimens in contrast to 28.4 per cent of the specimens which showed more acid-fast bacilli in the portion of the specimens concentrated by the flocculation method. This indicates that a specimen might be found positive by both methods, but the bacilli would probably be found in less time in smears made from the trypsin-digested specimen. This is indicated further by the fact that 30 per cent of the smears made from the trypsin-digested specimen showed at least twice as many bacilli as the same specimen concentrated by the flocculation technique, while, of those smears which gave a higher count by the flocculation method, only 7 per cent had at least twice as many of the bacilli as were found by the trypsin method.

Not only is there a reduction in the time required for examination of smears over that required by some other methods, but the time necessary to carry out the procedure of digestion and concentration is reduced to a minimum. The steps of the procedure are few and simple. No delicate or involved technique is necessary, and no special apparatus is required. Although sputa vary considerably in hydrogen-ion concentration (from pH 5.0 to pH 7.5), it is not necessary to adjust each specimen to a certain hydrogen-ion concentration since trypsin is active over a wide range.

Sedimentation always seems to be very complete after thorough digestion of the mucus. The specific gravity is low (around 1.006 to 1.011), and the surface tension is such that it does not interfere with complete sedimentation. Recentrifugation of the supernatant fluid from a few positive specimens gave very little or no sediment and no positive smears.

Digestion of sputum which has been heated proceeds faster than that of unheated sputum if it contains considerable mucus. After heating, specimens may contain lumps of coagulated material, but these are soft and easily broken by means of an applicator stick or glass rod.

Considerable sediment is obtained from trypsin-digested specimens as the other organisms and body cells present are not digested. This we consider an advantage as they give a background which enables the technician to keep the field in focus more easily. Also any other organisms that may be of clinical importance, such as those of Vincent's infection and fungi, may be seen. If the smear is thick, however, picric acid is preferred as a counterstain, for methylene blue may stain so heavily that the acid-fast bacilli cannot be seen. If picric acid is used for the counter stain, a smear can be stained by another method for other organisms. The sediment is usually creamy in consistency and spreads easily, and the smears stick well to the slide.

The presence of phenol in specimens of sputum does not interfere with digestion by trypsin. Specimens in which unknown amounts of phenol were present have been digested with trypsin solution with no difficulty. To one specimen an equal amount of 5 per cent phenol was added and to that mixture an equal amount of trypsin, giving 1.25 per cent of phenol. No inhibition of the enzymatic action was observed; on the contrary, it seemed to be stimulated. It might be stated that trypsin has been used for the digestion of sputum specimens by the Indiana State Board of Health for the past three years, with satisfaction, all of the specimens being collected in bottles which are from one-third to one-half full of 5 per cent phenol when issued from the laboratory.

For the past eight years we have also used trypsin to digest specimens preliminary to culturing or guinea pig inoculation. Acid-fast bacilli treated as long as twenty-four hours with trypsin solutions are viable and will infect a guinea pig. After digestion of the specimen with trypsin the sediment is treated with oxalic acid to kill the other organisms present according to Corper's method² for culture, or prepared for guinea pig inoculation.

The trypsin powder is not sterile, and bacteria and higher fungi will grow in a solution of it, even at low temperatures. As these might prove a source of error, sterilization by filtering through a Seitz filter is recommended. However, we have found that unfiltered trypsin solution, if made with aseptic precautions and kept in the refrigerator, will remain in good condition for a few days, but one must be alert to the possibilities of error when using it. Also, if the solution is used immediately after preparation for the digestion of specimens for smears, it is not necessary to filter it. To digest specimens for culturing or guinea pig inoculation, sterile trypsin solution should be used.

Trypsin powder is relatively inexpensive. The amount needed for the digestion of a specimen costs less than one cent.

SUMMARY

A method of digesting sputum and other body fluids with trypsin preliminary to microscopic examination, culturing and guinea pig inoculation, has been presented.

This method is considered to be practical for it is simpler in procedure than other satisfactory methods and requires less of the technician's time.

In a comparative study of this method and the flocculation method of Hanks et al.,¹ of 100 positive specimens, 11 per cent more positives were found by the trypsin method. In 71.5 per cent of the smears made from the trypsin-digested portion of the specimens, more acid-fast bacilli were found than in smears made from the flocculation concentrate, and in 30 per cent of these at least twice as many bacilli were found. In contrast to these results, only 28.4 per cent of the smears made from the flocculation concentrate showed more bacilli than those made from the trypsin-digested portion of the specimen, and, of these, only 7 per cent showed twice as many or more acid-fast bacilli.

The author wishes to express gratitude to Dr. C. G. Culbertson and Dr. R. N. Harger for suggestions and encouragement, to Dr. Russell S. Henry, Mrs. R. C. Speas, and Mr. Frank E. Lane for supplying specimens from Sunnyside Sanatorium, and to Mrs. Martha Ann Deppe and Mr. George E. McCoy, who assisted with the experimental work.

AN IMPROVISED INVERTED MICROSCOPE^{*1}

C. WOLFSON, LAWRENCE, KAN.

THE inverted microscope has been employed in photomicrography,^{2,3} in tissue culture,⁴ and in micrurgy.⁵ Special advantages accrue from its employment in these various fields, and in the field of micrurgy these advantages have been sufficient to warrant the appearance of a commercial instrument.⁵

A description is herein given of an improvised inverted microscope which possesses the advantages of being readily available and inexpensive, for, except for two small prisms, the instrument is assembled from (1) microscope parts commonly available in the laboratory and (2) a few special parts which can easily be fabricated. The microscope parts used in the assembly suffer no mutilation. The instrument is designed especially for employment in conjunction with the Taylor micromanipulator,⁶ but no difficulty should attach to its alteration for employment in conjunction with the Chambers micromanipulator.⁵

Fig. 1 presents the essentials of the arrangement. The arm (A) and body tube (B-T) of a standard microscope are affixed to a cast-iron base (B). A prism-chamber (p-c) replaces the nosepiece, and supports the three standard

*From the Department of Anatomy, University of Kansas.
Received for publication, August 22, 1941.

objective lenses. A sturdy upright (*U*), mounted on the base (*B*), supports the condenser (*C*) and light source (*L*). A mechanical stage (*S*) is fixed to the base (*B*) and serves in turn as base for a thin upright (*u*) which supports, between the condenser (*C*) and the objective, a coverslip which serves as a "stage" (*s*).

Fig. 1.

The following details concerning the various parts of the instrument are pertinent (see Figs. 1 and 2) :

1. The arm (*A*) and body tube (*B-T*) are taken from a model 66 Spencer microscope.
2. The prism-chamber (*p-c*) is constructed of $\frac{1}{8}$ inch sheet aluminum. It is $3\frac{1}{4}$ inches long, and its internal cross section measures 1 square inch. It is screwed into the body tube (*B-T*) by means of a threaded collar (*tc*), and is locked in proper position by means of a lock-nut (*l-n*). Two $\frac{3}{8}$ inch holes are drilled in the roof of the prism-chamber (*p-c*), one concentric with the body tube (*B-T*) and the other concentric with the objective. Contained within the prism-chamber (*p-c*) are two right-angle prisms, as indicated in Fig. 2; these fit snugly into the chamber (*p-c*), and are held in position by means of screws (*x*) projecting through the floor of the chamber (*p-c*) and by plates which close its ends. The three objectives are mounted on a brass plate (*p*), each threaded into a collar (*c*), and this plate (*p*) is movable in a line perpendicular to the length of the prism-chamber (*p-c*). The plate (*p*) moves between two guides (*g, g'*).

3. A nicely-machined band (*e'*) fits snugly about the collar (*c*) into which the objective is threaded and can be fixed by means of a set-screw. Each band (*e'*) bears a small ma-

chined depression (not shown) which, when the desired objective is moved to center position, receives a spring-backed pin (not shown) projecting forward from the rear guide (g'). By means of these adjustable bands (c'), the objectives may be precisely centered.

4. The upright (U) which supports the condenser (C) and light source (L) is a $5\frac{1}{2}$ inch length of $\frac{3}{4}$ inch square brass rod. A brass plate (p') fixed to its lower end serves for attachment to the base (B); this plate (p') has slotted screw-holes which allow for adjustment of position. A brass plate (p''), fixed to its upper end, supports the condenser (C); this plate (p'') is attached to the upright (U) by means of a centered screw, so that the condenser (C) can be swung aside readily.

5. The condenser (C) is an achromatic piece, of N.A. 1.3, as supplied for Model 3 Spencer research microscope. The entire assembly, including rack and pinion, is employed.

6. The light source (L) is an 18-volt toy train lamp. It is energized with 110-volt A.C. current, a variable rheostat being inserted in the line. The lamp housing is an objective case, in one end of which a frosted glass is mounted. This housing is supported on the upright (U) by means of an adjustable framework (F).

Fig. 2.

7. A Spencer attachable mechanical stage (S) is fixed to the base (B), slightly to the front and left of the arm (A). Its attachment is at right angles to its usual attachment, so that the movement which is normally lateral is here the front-back movement. Rising vertically from the front-back movement is the $\frac{5}{16}$ inch circular upright (u), provided with a centered extension in the form of a $\frac{3}{16}$ inch rod. A horizontal bar projects centrally from this extension, and supports the coverslip "stage" (s).

CHEMICAL

DESICCATED PLASMA FOR NATIONAL DEFENSE*

MASS PRODUCTION METHODS BASED ON THE ADTEVAC PROCESS

JOSEPH M. HILL, M.D., AND ERNEST E. MUIRHEAD, M.D., DALLAS, TEXAS

THE need of plasma in national defense is too urgent for prolonged consideration of theories and speculations. Extensive clinical results and proved production methods of large capacity are required to answer the following questions:

1. In what form is plasma most suitable for defense needs and military use?
2. Should plasma be administered in hypertonic, normal, or diluted form?
3. By what methods can mass production be achieved?

It is the purpose of this paper to answer these questions in the light of the experience of the desiccated plasma service of the William Buchanan Blood, Plasma, and Serum Center of Baylor University. This service during the past twenty-one months† has separated the plasma from 1,191,000 c.c. of blood, and desiccated plasma has been made available in Dallas and vicinity to the same extent as ordinary intravenous fluids. As a result, the value of this type of plasma used in hypertonic solution has been proved in extensive clinical trial.

On the basis of this experience the following answers to the three questions on use and preparation of plasma are given as follows:

1. For military as well as civilian use plasma desiccated from the frozen state is the ideal type of plasma preparation.

2. It should be used in hypertonic form (four times concentrated) to realize maximum advantages.

3. Mass production can be achieved with complete safety by the following principles: (a) Simplified collection, (b) Pooling whole bloods, (c) Separation of plasma by the continuous separator of the De Laval type, (d) Seitz filtration, (e) Bulk desiccation by the adtevac process, (f) Granulation and packaging of maximum quantity in minimum space in ordinary vaccine vials by a sterile mechanical dispenser, (g) Use of sterile room for open or semi-open phases of above methods, and (h) Bacteriologic control of all steps.

ADVANTAGES OF DESICCATED PLASMA

Desiccation from the frozen state offers advantages in the storage, transportation, and use of plasma that can scarcely be challenged. First, quality

†Up to May, 1941.

must be considered. The remarkable ability of this method of desiccation to preserve proteins and all biologic properties without change has been pointed out by workers in this field.¹

Preservation of the proteins without deterioration is essential to assure solubility and to eliminate the possibility of protein denaturation as a cause of reactions. The excellent preservation of proteins by desiccation from the frozen state (sublimation desiccation) has been conclusively demonstrated by the electrophoretic studies of Seudder² and by our own clinical results.³⁻⁶ For military use solubility should be measured in seconds rather than minutes, so that resolution may be done just prior to administration whether it be on the field, in the collecting station, in the aerial ambulance, or under whatever conditions encountered in peace or war.

Such rapid solubility has been consistently maintained in the Baylor service and has proved to be one of the chief advantages of the desiccated form over our earlier method of storing concentrated plasma in the frozen state. Solubilities average from thirty to 120 seconds. In actual treatment of shock, 25 Gm. of plasma have been dissolved in 90 c.c. of water and administered intravenously, all within 180 seconds. These rapid solubilities are maintained during storage, apparently depending on the very low moisture contents of 1 per cent and less, attainable by this type of desiccation.

Another advantage of dry plasma which has not been properly appreciated and utilized is the fact that it will not support bacterial growth. In this respect the plasma may be considered as any inert chemical powder. This property is of tremendous advantage for safety in use, for storage, and for mass production.

Contrary to the statement of Blalock and Mason,⁷ a very definite advantage of reduced bulk is realized for desiccated plasma when packaged as described herein. For example, we placed amounts of plasma and water in two 60 c.c. vials, which is equivalent to 200 c.c. of normal plasma. This becomes a real advantage when the equipment for administration is included as discussed below.

The use of desiccated plasma has been considered expensive⁸ and freezing proposed as an alternative method of preservation. From earlier extensive experience we have found that the routine preservation of plasma by freezing had many disadvantages which were eliminated by preservation in dry form. Low temperature refrigeration is costly and may well exceed the small cost of desiccation. When the extra safety and elimination of waste through spoiling or outdating are considered, desiccated plasma becomes definitely more economical. Furthermore, the problem of fibrin precipitation during storage of liquid plasma or upon thawing of frozen plasma is largely eliminated by desiccation. In the dry form fibrin precipitation is impossible and after resolution there is no increased tendency toward fibrin formation.

HYPERTONIC PLASMA, THE IDEAL FORM FOR ADMINISTRATION

One of the greatest advantages of desiccated plasma is that it provides the most logical way to make concentrated plasma solution. The ideal form in which to give plasma, particularly for the treatment of shock, is the four times concentrated plasma immediately after redissolving in pyrogen-free water.

Numerous advantages, both technical and therapeutic, realized by giving this hypertonic plasma are (1) increased simplicity and speed of administration with a glass syringe replacing more complicated apparatus, (2) elimination of tubing and the work of preparing it, (3) reduction of bulk and weight through decrease in water carried, and (4) greater therapeutic effectiveness with speedier response.

The technical advantages of administration of plasma in the hypertonic form as listed are obvious. Simplicity, safety, and speed attained by this technique are always important in the treatment of shock but are doubly so in military use. If plasma can be given in a shell hole, this is the way to do it. With a 50 or 100 c.c. glass syringe the hypertonic (four times concentrated) solution can be given as easily as 50 per cent glucose.

Technical advantages are significant only if therapeutic effectiveness is assured. Bond and Wright⁹ first demonstrated that concentrated serum was effective in the treatment of shock in dogs. Best and Solandt¹⁰ in a larger series also showed concentrated serum to be effective in the treatment of traumatic and posthemorrhagic shock in dogs, but later Magladery, Solandt, and Best¹¹ denied any advantage of concentrated over whole serum. Clinical reports by Ravdin, Stengel, and Prushankin,¹² Levinson, Rubovits, and Neeheles,¹³ and Strumia, Wagner, and Monaghan¹⁴ have dealt with isolated cases of hypoproteinemia treated with concentrated serum or plasma, but its routine use as a superior therapeutic weapon in the treatment of shock was first reported in 1940.³

No large clinical series had been reported until the papers of Brown and Mollison,¹⁵ and Hill, Muirhead, Ashworth, and Tigertt,⁵ although preliminary summaries of comparatively large numbers of cases were given in our earlier papers. However, sublimation desiccation of plasma and its use in hypertonic form with emphasis on shock was practiced by the Baylor Plasma Service from its inception in August, 1939.

The advantages which we had at first assumed on theoretical grounds have since been brought out in extensive clinical trial. In Baylor Hospital alone concentrated plasma has been given to 276 patients. Of this number, 93 closely followed cases of shock are summarized and the evidence for hypertonic plasma presented in another paper.¹⁶ The results have confirmed our previously stated thesis^{3, 5} that the use of concentrated plasma is the ideal treatment of shock. The shock cycle of Moon¹⁷ is quickly broken by a rapid increase of blood volume due to withdrawal of interstitial water. This constitutes a physiologic correction of the pathologic change of shock. Due to the speed of administration, this correction is effected in the shortest possible time. In addition, the extremely rapid increase in blood pressure of the average case strongly suggests a direct stimulation of the vascular system with reduction of vascular capacity.

In posthemorrhagic shock where red cells have not reached critical levels of oxygen carrying capacity, hypertonic plasma is superior to blood in its rapidity of action and instant availability. Where critical red cell levels have been reached, concentrated plasma is of utmost value in combating shock during the period of preparation and giving of blood. For a discussion of this important question reference should be made to an earlier paper.⁶

In answering the theoretical objection that dehydration would contraindicate the use of intravenous hypertonic solution, it is significant that we have found this type of therapy completely effective in the presence of all ordinary grades of dehydration seen in hospital practice. This is in accord with the well-known fact that interstitial water is easily mobilized and large in amount. According to Gamble,¹⁸ this water makes up 15 per cent of the body weight and comprises a very effective reserve for the more important plasma volume. Of course severe dehydration approaching loss of 10 per cent of body weight would appear to be a definite contraindication for hypertonic plasma.

MASS PRODUCTION METHODS

The attainment of large volume production on our service has resulted not only from the adoption of new techniques but also from discarding two methods heretofore considered most essential¹⁹; namely, a closed type of centrifugation, and desiccation in original containers. These two requirements were abandoned because they constituted the chief obstacles to volume production. A partially open method such as described below has been proved perfectly safe in use with the observance of certain essential principles and checks.

First, it can be taken for granted that all precautions of careful technique and adequate bacterial culture control must be observed in any system. Second, conditions for bacterial growth must be completely eliminated following separation of plasma. If it must be stored before drying, it is kept frozen, but better yet is a balanced system where desiccation closely follows separation. In either event we have always employed Seitz bacterial filtration immediately prior to desiccation as an additional safeguard not only against bacteria but also possible pyrogenic substances. An important point in this connection is the use of filter-cel,* an infusorial earth preparation. This material is best introduced into some part of the system, such as the prefilter reservoir. It is sterilized with the equipment; when the plasma passes through the system, it is mixed with the filter-cel, and an even deposit forms over the surface of the Seitz disc. This coating greatly increases the capacity of the filter. After desiccation, bacterial growth is not supported and dryness is the greatest plasma safety factor. It can be handled in bulk with the same confidence as any other chemical or powder inert to bacterial growth, and it can be measured and placed in final containers with the same ease. It should, of course, be used immediately upon converting again into liquid form. Proper choice of unit sizes eliminates any need for brief storage as a liquid. Yet even here a safeguard is afforded by use in concentrated solution since this form is bacteriostatic to a large degree to all common contaminants.

It is obvious that the period of storage of liquid blood is the only break in the use of these principles. Where such preservation is essential to blood banking, safety can be attained by a completely closed collection system and a short period of storage. In our own service with 400 bleedings per month it has been feasible to keep blood only four to five days before separation of plasma. Of course, in large scale bleeding for national defense no storage would be necessary if the separator methods herein described were adopted for the immediate separation of plasma.

*A product of Johns-Manville Sales Corporation, New York, N. Y.

These principles have been worked out during the past two years in actual large scale use and have proved to be safe by the fact that no serious harm has resulted from a single dose, and a febrile reaction rate of 0.74 per cent has been attained in 694 administrations at Baylor Hospital. Furthermore, no reactions have been reported from extensive outside use.

The actual production methods, as shown in the American Medical Association Scientific Exhibit,²⁰ start with the bleeding technique. In our blood bank we have used a vacuum bottle collection technique. A rubber tube with two observation tubes and needles connected has been used. Vacuum is held during venipuncture by clamping a hemostat on the tube. Collapse of the tubing has in no way impeded withdrawal of blood. Our special mechanical shaker has been replaced by the simple expedient, now commonly employed, of inverting the vacuum bottle during collection. By this method the blood is drawn directly into the citrate solution, resulting in immediate mixing.

In bleeding for national defense we have suggested that defibrination might be preferable. Similar types could be bled into large chilled containers and defibrinated by a rotary paddle. The fibrin could be removed by a centrifugal strainer, and the bloods quickly pooled just before separation. Such methods have been standard in animal serum plants and should be considered seriously. Certainly the small hemoglobin content resulting from such methods must not be considered objectionable. We have given hemoglobin solution intravenously clinically up to 21 Gm. within fifteen minutes without reaction.

The second step of our methods is plasma separation. Two De Laval E-19 separators have been operated in cascade, the first unit separating and the second clarifying the plasma. With this smallest available motor-driven model, we have separated 25 liters of pooled blood in thirty minutes, a rate of 50 liters per hour. A true plasma yield of 50 per cent was obtained consistently. Of course, such capacities at high yields cannot be approached by conventional bottle centrifuges or, in fact, by any other methods. Furthermore, separators are available with capacities up to 1,000 liters per hour. Labor costs are reduced, and such large capacities with efficient yields make this method the obvious choice for mass separation. These conclusions are based on the separation of 778,280 c.c. of human blood by the continuous separator principle in four months. The pooling of whole blood prior to separation employed in our service since January, 1940, has many advantages. Typing is unnecessary, and large volumes are more easily handled. Moreover, agglutinins are completely removed, and the resultant agglutination of the corpuscles by forming larger particles aids in efficient separation and higher yields. Proportioning different types of blood or letting the pool stand as reported by Edwards, Kay, and Davie²¹ is unnecessary, particularly with the large pools of 25 to 100 bottles which constitute part of our separation routine. We believe this removal of agglutinins resulting from pooling of bloods, as contrasted with the suppression resulting from pooling plasma of different types, is of the utmost importance. For example, we have never found it necessary to restrict the giving of whole blood after administration of large doses of our concentrated agglutinin-free plasma although Mahoney et al.²² indicate that caution is necessary in the giving of blood following pooled plasma.

Disadvantages claimed for this method²³ have not been encountered during the eighteen months we have used it as a routine. First, contrary to these claims, high rates of hemolysis have not been found. By the method of Bing and Baker,²⁴ hemoglobin has varied between 20 and 75 mg. per 100 c.c. of unconcentrated plasma. The hemoglobin concentration has depended mainly on the age of the blood. We have discussed this question of hemoglobin elsewhere²⁵ and believe that it is of no significance whatever in the causation of reaction or other deleterious effects.²⁵ Indeed, the successful intravenous use of hemoglobin solution as a form of therapy reduces to an absurdity objections based on hemoglobin content.

Second, the method is partially open although we have redesigned covers and spouts to minimize this. Nevertheless, positive cultures were obtained on only three occasions, when the air was dusty during a two-day period from tearing down a nearby plaster wall. Since then, no contamination has been encountered, but, as an additional precaution, the air in our centrifuge room is electrostatically filtered.

Since the separation of plasma is immediately followed by Seitz filtration and desiccation, or freezing, filtration, and desiccation, bacterial contamination is no problem. We regard filtration of this type to be a safety factor of utmost importance as a final check against bacteria and pyrogenic substances. Since we have filtered the plasma from over 1,000,000 c.c. of blood, we cannot agree with Strumia and McGraw⁸ that plasma filtration by this method is sufficiently inconvenient to be a valid objection to its use. Of course, precipitation of fibrin occurs, but it need not clog the filter if a filter of proper size is used and filter-aid added to the plasma to adsorb particulate matter, such as fat and fibrin. The decrease of fibrinogen content by filtration seems to be of no clinical importance.

After filtration, the plasma is delivered from the collector into the large processing ampoules by a bell-protected tip. Desiccation from the frozen state in bulk by the adtevac process³ is then performed. This method utilizes the well-known fact that adsorbents, such as silica gel, have enormous capacities to take up water vapor. For efficient use in sublimation desiccation in vacuo, however, control of adsorbent vapor pressure and maintenance of capacity were required. These requirements, which had previously prevented the successful use of adsorption, were solved by the adtevac process. With maximum loads plasma moisture contents below the 1 per cent level set by Flosdorf and Mudd¹ were reached. With smaller loads moisture contents as low as 0.03 per cent as determined by the method of Flosdorf and Webster²⁶ were reached.

The chief characteristics of the process which make it ideal for large volume plasma desiccation are as follows:

1. It is not easily overloaded by initial rush of vapor in early phase.
2. Rapid spontaneous freezing eliminates expensive and troublesome pre-freezing.
3. Temporary interruptions of electric current do not interfere with drying. Thawing and spoiling of plasma are avoided.
4. Extreme rapidity of freezing and positive maintenance of plasma in frozen state give high quality product with unusual solubility.

5. Reliability is assured by use of standard equipment such as vacuum pump and ordinary small refrigeration unit for machine parts.

6. There is economy of operation.

7. The process is well adapted to any size capacity required.

That desiccation from the frozen state need not be expensive has been amply demonstrated in the use of the adtevac process. Inefficient methods of separating and handling plasma on a large scale can easily increase labor cost more than the small power costs required for drying.

Transference of plasma from bulk-processing containers to final units is easily accomplished by a stainless metal dispenser that can be sterilized as a unit in the autoclave. With ampoules such as we have used, a closed system during transference can be had by using a compression joint and a flexible bellows or tube. A rotary-driven worm used in our first model granulated and forced the plasma through a small metal tip into the sterile vial standing on the pan of a torsion balance. The delivery tip was protected with a metal bell or hood. A later model uses a plunger type transfer mechanism. The plasma is considerably reduced in bulk during transference, and solubility is increased by the granulation. After sterile rubber caps have been applied, a high vacuum is drawn through a needle and the whole top sealed. Deterioration of vacuum is prevented by sealing the rubber cap with celloidin or suitable plastic solution. While we are constructing a dehumidified, air-conditioned, sterile room for our procedures, no difficulty has been encountered with these methods in an ordinary closed small room.

These bottles of plasma, together with enough pyrogen-free water to make the four times concentrate have been kept in our emergency room, in the obstetrical bags, and in the central laboratory. They have also been mailed to distant points in and out of Texas, and they have been used without trouble. This dry form invariably has been preferred to the frozen solution of concentrate which we had formerly used, due to greater availability and speed in preparing for use.

SUMMARY AND CONCLUSIONS

1. Mass production methods suitable for national defense needs and proved by extensive routine use are presented.

2. The complete safety of these methods is reflected in a febrile reaction rate of 0.74 per cent.

3. The use of serum separators and other partially open methods essential for volume output is safe under the conditions described.

4. The advantages of desiccated plasma prepared by the adtevac process are discussed.

THE ASSAY OF HEPARIN*

R. H. K. FOSTER, PH.D., M.D., NUTLEY, N. J.

A NUMBER of different methods for assaying heparin have been described, some employing whole blood and some plasma. Some of these may be mentioned briefly. Jacques and Charles⁷ recently reviewed three methods, namely; (1) a modification of the Howell method by Charles and Scott,⁴ in which observations are made on the degree of clotting in samples of cat's blood containing varying amounts of the standard and unknown heparins; (2) a new thrombin assay, also a modification of the Howell method, in which a standardized thrombin is used to clot samples of oxalated beef blood containing varying amounts of the standard and unknown heparins, and (3) the Fischer and Schmitz method⁶ in which the clotting time of chicken plasma on addition of thrombokinase is determined for varying concentrations of unknown and standard heparin. Chargaff³ devised a method using chicken plasma, similar to that of Fischer and Schmitz but having the time constant and observing clot formation with varying amounts of heparin, following the addition of thrombokinase (the "muscle coagulin" of Fischer⁵).

In a recent communication, Schütz⁹ describes a method in which rabbit's whole blood is added to varying concentrations of standard and unknown heparin solutions. The concentration of heparin in successive tubes is increased by 25 per cent. The comparison is made the following day, and the two racks containing the standard and unknown are moved along until there is a matching of the tubes. In the present method in which beef plasma is used, the concentration of each successive tube is increased by antilog 0.15 (about 40 per cent). With this interval, the clotting range may be covered with only 5 tubes. The standard and unknown tubes are graded according to a procedure to be described later, instead of matching directly as in Schütz and other methods.

The purpose of this paper is not to present a completely new method of assay but rather to discuss a technique of comparing the clots in the standard and unknown tubes employing a method already described by Reinert and Winterstein.⁸ Only certain minor modifications have been made in their method in order that a statistical procedure may be applied to the results. Briefly, the method consists in observing the degree of clot formation at 37° C. in tubes containing heparinized citrated beef plasma to which calcium chloride has been added. The anticoagulating unit (a.c.u.) of Reinert and Winterstein is accordingly defined as that amount of heparin which inhibits for four hours the clotting of these units equal one Best¹ or Charles and Scott unit, or simply, "Toronto Unit." (Reinert and Winterstein; also the author's evaluation.)

*From the Pharmacology Laboratory, Hoffmann-La Roche, Inc.
Received for publication, November 7, 1941.

The principles of evaluation described below can of course be applied to methods other than that of Reinert and Winterstein, but their method seems well suited to these principles, and with beef blood more readily available in larger quantities than blood obtained from the cat, rabbit, or chicken, more samples can be run simultaneously.

TABLE I
AMOUNT OF HEPARIN IN MICROGRAMS TO BE USED IN EACH TUBE
(Each increment = antilog 0.15)

TUBE NO.	SERIES 1	SERIES 2	SERIES 3	SERIES 4
1	0.71*	0.78	0.85	0.92
2	1.00	1.10	1.20	1.30
3	1.41	1.55	1.70	1.84
4	2.00	2.19	2.39	2.59
5	2.82	3.10	3.38	3.66

*In practice, the nearest twentieth of a microgram is used. This brings the volume measurements to the nearest hundredth of a milliliter.

TABLE II
VOLUMES OF REAGENTS USED IN SERIES 1
(Series 2, 3, and 4 are to be arranged similarly. The concentration of heparin is 57/ml.)

TUBE NO.	PLASMA (ml.)	AMOUNT OF HEPARIN		0.9% SALINE (ml.)	CaCl ₂ * (ml.)
		γ	ML.		
1	1	0.7	0.14	0.66	0.2
2	1	1.0	0.20	0.60	0.2
3	1	1.4	0.28	0.52	0.2
4	1	2.0	0.40	0.40	0.2
5	1	2.8	0.56	0.24	0.2

*See text for concentration of calcium.

PROCEDURE

Fresh beef blood is collected at a slaughterhouse (or preferably from the living animal by venipuncture) in two 1-liter bottles, each containing 50 ml. of 4 per cent sodium citrate solution. The blood is drawn into each bottle until the 500 ml. mark is reached. The mixed blood thus contains 0.4 per cent sodium citrate. On arriving at the laboratory, the blood is centrifuged for thirty minutes at 2,000 r.p.m. The supernatant plasma is placed in the reservoir of a 10 ml. Koch pipette. One milliliter portions are measured into sulfuric acid-dichromate-cleaned 12 by 100 mm. test tubes. To each tube are added appropriate amounts of heparin solution, 0.9 per cent saline, and calcium chloride solution so that the total volume is always exactly 2 ml. Five milliliter Koch pipettes graduated to 0.02 ml. are used for the latter solutions. The tubes are stoppered with snug-fitting corks paraffined only on the end (otherwise they tend to slip out) and inverted 2 or 3 times. They are then placed in a water bath at 37° C. and examined three hours later.

The standard and unknown heparin solutions are each made up in 0.9 per cent saline to contain 5 gammas of heparin per milliliter. In an assay there are 4 sets of 5 tubes each for each sample. The weights of heparin used in these 20 tubes are shown in Table I. Table II shows the arrangement of the 5 tubes of

the first series. For convenience, charts are used giving the actual burette readings for heparin and saline solutions for each series.

As indicated in Table II, the volume of calcium solution is 0.2 ml. Since different plasmas vary, the amount of calcium required varies and this amount must be determined on each new plasma before the assay is run. To do this, 6 tubes are set up, each containing 1 ml. of plasma, 2 gammas of standard heparin (0.4 ml.) and calcium chloride in the following amounts: 0.8, 1.0, 1.25, 1.5, 2.0, and 2.5 mg. respectively. The total volume in each case is 2.0 ml. The concentration of calcium chloride giving nearest to a 2+ clot (see below) after thirty minutes is selected and used for the assay. Occasionally, a longer time than thirty minutes is necessary. If the time is more than sixty minutes, the test must be repeated, possibly with higher calcium concentrations. From a stock solution of calcium chloride the assay solution is made so that the right amount of calcium is contained in 0.2 ml.

In conducting an assay, the 5 tubes for Series 1 are prepared for the standard heparin and for each unknown sample in succession. Series 2 is then similarly prepared and finally Series 3 and 4. In this way, any changes in the plasma due to standing have a minimum of influence on the results. As many as 6 unknowns can be conveniently run simultaneously with the standard.

READING THE TUBES

The reading of the tubes involves the use of a clotting scale based on the proportion of the total possible clot formed in each tube. Complete clotting (usually with marked retraction) is called 4+, and no clot formation is called 0. Intermediate values then are +, 2+, and 3+. On a percentage basis, + = 25 per cent, 2+ = 50 per cent, 3+ = 75 per cent, and 4+ = 100 per cent. The 2+ or 50 per cent clot formation has been adopted as the end point for comparing the standard and unknown heparins. This corresponds to the ED50 (50 per cent effective dose) of the usual dose-effect curve. All values are computed to this basis. It is apparent that not all partial clots will correspond exactly to +, 2+, or 3+, and that many clots will lie at intermediate values. Such intermediate values are designated by changes in the above symbols. For example, a clot which appears to be slightly heavier than 2+ is called 2+(+) or if slightly lighter, 2+(-). A 3+(-) clot would be slightly heavier than a 2+(+). Also, a clot that is not quite complete is called 4+(-), and a very small clot is 0(+). Thus there are 13 classifications, varying (theoretically) by $8\frac{1}{3}$ per cent. It is not considered practical to attempt a finer classification under present conditions. Jacques and Charles' report: "At least four intermediate stages can be distinguished, and with practice, eight can be detected." This refers to whole blood, whereas, with plasma as in the present method, at least 11 intermediate stages can be ascertained with little difficulty.

One may ask, "Why resort to a clotting scale based on + values rather than one based directly on percentage, since the + values are ultimately converted into percentages?" The 3 principal + values are +, 2+, and 3+, corresponding to $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{3}{4}$ clots. It is easier for the eye to read, for example, "a

half clot plus a little more" [2+(+)] than "58 $\frac{1}{3}$ per cent." In other words, the clot, after first rough appraisal by the eye, is graded more precisely by shifting the + value to one side or the other of the main classification. If a graded series of "standard clots" could be prepared and photographed, the task of reading would be simplified and a percentage scale could be employed. The difficulty arises from the variation of clot characteristics from plasma to plasma. Rate of shrinkage, volume of clot, opacity, flocculation, and even color are the variable factors that meet the eye. For example, a 4+ clot may be shrunk to a small volume or may show no retraction whatsoever at the time of reading.

Fig. 1.—Curves showing the relation between the concentration and the degree of clotting on logarithmic probability paper. Solid lines: Best fitting straight lines for data on each set of tubes excepting Series 1 of the unknown. In this case, with only two points, the dashed line is the best fitting line, while the solid line is the more likely since it is more nearly parallel to the general slope.

It is obvious that the unaided inspection of a single tube may not accurately classify it. What might be identified as 2+ at one time may be considered 2+(-) at another. Therefore, the standard series is read first as carefully as possible, and the unknown tubes are then compared to these for grading. The tubes are in no sense paired as in the Schütz method, although frequently a tube from the unknown series may be observed to be identical with one of the standard tubes. Exact pairing facilitates the grading but is not necessarily the true end point.

The clotting process, as here observed, is not an "all or none" response and therefore is subject in a greater degree to the error of personal interpretation. In spite of this, it is believed that the end point here (defined as the formation of 50 per cent of the possible clot) can lead to a more accurate evaluation of anticoagulant activity than heretofore.

INTERPRETATION OF RESULTS AND CALCULATION OF POTENCY

After values have been assigned to each clot, an estimation of the concentration of heparin corresponding to a 2+ clot may be made by plotting the logarithms of the concentration of heparin against the probits of the graded clots or by plotting directly on logarithmic probability paper. The probits are determined by first converting the + values to percentages and the latter into probits by means of Bliss' table of probits.² The use of logarithmic probability paper has been the method of choice as it is more convenient and saves time. The data from a typical experiment are illustrated in Fig. 1. The heavily ruled ordinates correspond to the eleven + values (other than zero and 4+). They were drawn with India ink so as to remain as permanent reference lines while lightly penciled data could be quickly erased. There are usually 3 values that can be plotted (sometimes only 2 and sometimes 4), and the best fitting straight line is then drawn. (If the concentration intervals were less than antilog 0.15, more points would be available for plotting.) The "50 per cent dose" of heparin is indicated by the point at which this line crosses the 2+ ordinate. If only two points are obtained, it may happen that a line drawn through them does not have the usual slope. In such a case (see dashed line, Fig. 1) it should be drawn nearly parallel to the average slopes and between the points rather than through them, giving greater weight to the point nearest the 50 per cent or 2+ line. Slope as well as position must always be considered.

The calculation of potency may be made in a.e.u. (Reinert and Winterstein units) or in "Toronto Units." The following example is worked out in a.e.u. The standard contains 500 a.e.u./mg. (100 Toronto Units). If an estimation on one series shows the standard to have an equivalency of 2.35 gammas for a 2+ clot and the unknown 1.82 gammas, then the potency of the unknown is $500 \times 2.35 \div 1.82 = 645$ a.e.u./mg. This example, together with the other 3 series, is illustrated in Table III. For a complete assay the entire procedure is repeated on another day with a different sample of plasma. For the heparin assayed in Table III, the other four values were 600, 561, 622, and 614 a.e.u./mg. for the 4 series, respectively. The average for all 8 results was 595 ± 12 a.e.u./mg.

DISCUSSION

It may be asked if the relationship between the logarithms of the concentration of heparin and the probits corresponding to the percentage clot formation is actually linear or if it is a curved function. This cannot be answered with certainty at the moment, but in any event most of the data are randomly scattered about a straight line. When the majority of the data are not so scattered, the middle points are usually below the best fitting straight line and a curve drawn through them would have its convexity downward. This curving is slight in most cases and is not believed to be significant, but in any event the concurrent use of a standard neutralizes any such errors. Nevertheless, tests are under way to determine more accurately the exact nature of the dose-effect relationship.

A few points concerning the causes of error and variation in heparin assays may be briefly mentioned. There should be a minimum of time elapsing between

securing the blood and centrifuging it. Citrated beef plasma undergoes gradual changes on standing; therefore, a complete assay should be performed in the shortest space of time possible. In Table III it may be noted that the amount of heparin corresponding to a 2+ clot tends to diminish from the first to the fourth series. This apparent trend occurs as frequently in the opposite direction so is probably not significant unless it can be attributed to some changing characteristic of the plasma.

TABLE III.

EXAMPLE OF THE ASSAY OF AN UNKNOWN HEPARIN AGAINST THE STANDARD

STANDARD HEPARIN			UNKNOWN HEPARIN

1.8	2+		+		
2.6	+		0 (+)		
3.7	0 (+)		0		

When the tubes are being filled, especially with the plasma, the rate of delivery must be absolutely uniform and not too rapid. Since plasma is a moderately viscous liquid, a considerable amount adheres to the wall of the burette and drains slowly.

After the tubes are placed into the water bath, they should not be agitated. Any preliminary examination should be avoided or at least made with great care.

The volumes used are relatively small and a slight error in reading, even though no greater than the thickness of a graduation mark, can result in observable variation in the nature of the clot.

Cleanliness of the tubes is essential, the final cleaning being done with strong cleaning solution made of potassium dichromate and concentrated sulfuric acid. After thorough washing with tap and distilled water, the tubes are dried in an oven. If a brush is used in the preliminary cleaning before the acid, scratching of the glass should be avoided. The tubes should have as uniform a bore as possible.

Assays conducted in this laboratory have been on crude extracts as well as on the purified products. The crude extracts have shown potencies averaging about

400 a.c.u. per milligram, whereas the final product has averaged about 525 a.c.u. per milligram. This difference may not be the true difference in potencies since it has been pointed out by Jacques and Charles⁷ that salts and other impurities cause variations in the clotting process to such a degree that the true anticoagulant value, due to heparin, may be considerably different than the observed value. Nevertheless, the results on many samples have been uniform within the bounds of reasonable consistency. Assays on 10 consecutive crudes and on finished products are given in Table IV.

TABLE IV

ASSAYS ON TEN SUCCESSIVE CRUDE AND PURIFIED HEPARIN SAMPLES

(Four tests made on each crude and 8 tests on each purified sample. Each group of 5 tubes comprises a "test.")

SD = 23.5 units		SD = 25.1 units	

a.c.u., anticoagulating unit; Sm, standard error of the mean; SD, standard deviation.

There is probably no other biologic assay in which greater care must be exercised to obtain consistent results. The utmost in uniformity of manipulative procedure must be maintained at all times. This applies to the cleaning of the tubes and burettes as well as to exactness in measuring volumes, accuracy in preparing solutions, and the maintaining of constant time intervals for each step from start to finish. Surprisingly, however, the time of reading the tubes is of less importance than might be expected. It has frequently been observed that the majority of tubes show no observable change between two hours and four hours, the clotting curve apparently tending to level off after one or two hours. Further growth of clots after two hours, when they did occur, were rarely greater than one degree on the clotting scale. For this reason, the observation time of three hours was adopted as an average, and fifteen minutes one way or the other makes little difference. After twenty-four hours very few additional changes in clotting can be observed unless the tubes have been shaken.

SUMMARY

A technique has been described for determining the anticoagulant potency of heparin. The method consists in observing the degree of clot formation in recalcified citrated beef plasma to which varying amounts of heparin have been added. The degree of clotting is measured on a suitable clotting scale, after which the data in the form of the logarithms of the concentrations and the probits of the percentage clot formations are plotted to determine the "50 per

cent clotting concentration." The potency of an unknown preparation is estimated by comparing its 50 per cent clotting concentration with that of a standard. An assay is performed in several small series of tests so that a statistical evaluation may be obtained.

A SIMPLE CLINICAL METHOD FOR DETERMINING SULFONAMIDES IN BLOOD*

A. GOTH, M.D., NASHVILLE, TENN.

IN THE Bratton-Marshall method for determining sulfonamides in blood one has a very accurate and satisfactory method which is simple enough for all familiar with laboratory technique. This is not very time consuming if one has a well-equipped laboratory at hand, but it requires the making up of several quantitative solutions and cannot be carried out at the bedside. In order to make the determination of sulfonamides in the blood possible for clinicians in private practice and for those in small hospitals, a simple kit has been devised in which the reagents are put up in tablet form, with the exception of a small bottle of acetone.

The reagents are essentially the same as those in the Bratton-Marshall method with one major exception. Acetone is used for the precipitation of the blood proteins. After the blood has been shaken with acetone, the coagulated proteins settle out very rapidly, leaving a clear supernatant fluid, an aliquot of which can be used for the test. This avoids filtration and the necessity of carrying funnels and filters and saves considerable time. As the trichloroacetic acid used by Bratton and Marshall is hygroscopic, it has been replaced by oxalic acid in the reagent tablet.

*From the Department of Pharmacology, Vanderbilt University School of Medicine, Nashville.

Received for publication, November 22, 1941.

As the determination of the combined sulfonamides is rarely necessary in practice, the test here described, which determines the free forms only, answers most of our clinical needs.*

APPARATUS

1. Pipette (1) 0.2 c.c. for measuring the blood.
2. Test tubes (2) 100 by 12 mm. marked at 1 c.c. and 3 c.c.
3. Comparator block with 6 color standards.

REAGENTS

1. Acetone.
2. Tablet No. 1 containing 30 mg. of oxalic acid.
3. Tablet No. 2 containing 1 mg. of sodium nitrite.
4. Tablet No. 3 containing 5 mg. of ammonium sulfamate.
5. Tablet No. 4 containing 1 mg. of N (1-naphthyl) ethylenediamine dihydrochloride.

In the preparation of the tablets, sucrose can be used to increase the bulk. The size of the tablets should not exceed 30 mg. to avoid unnecessary turbidity of the solutions.

TABLE I

AMOUNT OF PHENOLSULFONPHTHALEIN (C.C.)	AMOUNT OF SULFANILAMIDE INDICATED (MG. PER 100 C.C.)
0.09	2
0.18	4
0.27	6
0.42	8
0.60	10
0.77	12

PROCEDURE

1. Deliver 0.2 c.c. of blood into a test tube.
2. Add acetone to the 3 c.c. mark. Shake and let stand until clear (one to two minutes).
3. Transfer clear liquid into another test tube to the 1 c.c. mark.
4. Add water to the 3 c.c. mark and shake.
5. Add tablets No. 1 and No. 2, shake and let stand for three minutes.
6. Add tablet No. 3, shake and let stand for one minute.
7. Add tablet No. 4, shake, and after one minute compare with color standards.

In the kit mentioned above a color chart is used but where this is unavailable color standards may be made up as follows.

Dissolve 10 mg. of phenolsulfonphthalein in 250 c.c. of N/10 solution of sodium hydroxide. To each of six 100 by 12 mm. test tubes add 5 c.c. of N/10 sodium hydroxide solution and varying amounts of the phenolsulfonphthalein

*The preparation of reagent tablets by the physician is impractical. At our request, the A. S. Aloe Company, St. Louis, Mo., is supplying these, together with a complete kit for carrying out this test.

solution as indicated in Table I. The test tubes containing the color standards should be sealed and protected from direct sunlight. They should be renewed every six months.

The same procedure and color standards can be used for the determination of sulfanilamide derivatives. The amount of drug indicated by the standards should be multiplied by certain factors, when sulfanilamide derivatives are determined. These factors are 1.37 for sulfapyridine, 1.42 for sulfathiazole, and 1.45 for sulfadiazine.

Fig. 1.—Recoveries of sulfanilamide in 30 blood samples. Comparison between the Bratton-Marshall method and the present clinical method.

In order to determine the accuracy of our method, 30 blood samples were analyzed with the Bratton-Marshall method and with our technique. As indicated in Fig. 1, our recoveries follow closely the ones obtained by the Bratton-Marshall method.

SUMMARY

A simple clinical method for determining free sulfanilamide and derivatives in the blood has been presented. All of the equipment required for the procedure can be placed in a small kit, and the test can be performed without laboratory facilities.

PROTHROMBIN STUDIES USING RUSSELL VIPER VENOM*

III. EFFECT OF LECITHINIZED VENOM ON PROTHROMBIN CLOTTING TIME

ROBERT C. PAGE, M.D., EDWIN J. DE BEER, PH.D., AND MARTHA L. ORR, M.S.
NEW YORK, N. Y.

THE use of Russell viper venom (*Daboia* venom) as a thromboplastin-like substance has been reported by many investigators.^{1, 2} More recently this venom has been employed, instead of brain extract, as the thrombokinase in the determination of the prothrombin clotting time.^{3, 4}

The coagulant action of Russell viper venom is potentiated by the addition of lecithin. Trevan and Macfarlane⁵ found that the hemostatic action of Russell viper venom was accelerated by the addition of small quantities of tissue extract or lecithin.

Leathes and Mellanby⁶ reported that lecithin from brain or egg yolk had the property of increasing the activity of the thrombokinase in *Daboia* venom.

Witts and Hobson⁷ compared the prothrombin clotting times of 43 human beings using Russell viper venom (dilution 1:50,000) and lecithinized venom (adding 0.05 c.c. of a 10 per cent alcoholic solution of ovolecithin to each cubic centimeter of venom solution). The clotting times with lecithinized venom were shorter and less scattered than with venom alone. The usual time was eleven seconds with a suggested range of nine to thirteen seconds. With venom alone the clotting times were from two to nineteen seconds longer. In prothrombin deficiency, coagulation remains impaired despite the addition of lecithin to venom. They concluded that, if venom is used in the prothrombin clotting time test, it must be fortified by the addition of lecithin.

In a later paper Hobson and Witts⁸ stated that Russell viper venom acts as a thrombokinase and accelerates the coagulation of blood or plasma in the presence of calcium and that the optimal concentration of the venom for use in the prothrombin clotting time test is 1:20,000. They conclude that, if Russell viper venom is used alone, the coagulation time may be affected by hemolysis, lipemia, the number of platelets *in vivo*, and, in certain circumstances, the speed and duration of centrifugalization, and that these inconsistencies are eliminated by the addition of lecithin to the venom.

Crosbie and Scarborough⁹ reported on coagulation studies with Russell viper venom alone and with venom plus a 10 per cent alcoholic solution of ovolecithin (B.P.C.†). Venom, in the absence of hemolysis and without lecithin,

*From the Chemical Laboratory of the Department of Surgery, College of Physicians and Surgeons, Columbia University and Presbyterian Hospital, New York, and The Burroughs Wellcome & Co. (U. S. A.) Experimental Research Laboratories, Tuckahoe, N. Y.

Received for publication, January 2, 1942.

†The British Pharmaceutical Codex, 1924, p. 557.

is a more potent source of thromboplastin than is brain extract. When lecithinized venom was used, the coagulation times were shorter and the scatter was reduced.

Edsall¹⁰ has reported that the coagulant action of Daboia venom appears to be exerted through an interaction with tissue extracts or with the cephalin contained in such extracts. Only a slight acceleration of coagulation was observed on employing 4 mg. of lecithin, comparable to that obtained with 0.002 mg. of cephalin. This may properly be ascribed to the unavoidable residual contamination of the lecithin with cephalin.

METHOD OF STUDY

Blood of patients in the hospital and of patients attending an outpatient clinic was obtained. Blood from patients, both with and without liver disease, was used. Four and one-half cubic centimeters of venous blood were drawn into a dry syringe and mixed with 10 mg. of potassium oxalate in a centrifuge tube. The blood was centrifuged at 1,500 r.p.m. for five minutes, and the oxalated plasma was drawn off. The test was performed within two hours after withdrawal of the blood, and, if hemolysis was present, the sample was discarded. The test was performed as follows: Two-tenths cubic centimeter of oxalated plasma was pipetted into a small test tube (75 by 10 mm.) and 0.2 c.c. of Russell viper venom,* 1:10,000 solution, was added. Calcium chloride solution (1.11 Gm. calcium chloride per 100 c.c.), 0.2 c.c., was then added, and the stop watch was started. The tube was agitated for ten to fifteen seconds in a water bath (37° C.), then removed and tilted until separate discrete fibrin particles could be seen. The first appearance of the fibrin particles was taken as the end point.

Prothrombin clotting time was determined on the undiluted plasma (100 per cent) and on 40 per cent plasma, diluted with physiologic saline solution.

The test was repeated, using the same plasma but with lecithinized venom. A 10 per cent alcoholic solution of lecithin† (egg) was used in the amount of 0.05 c.c. per cubic centimeter of venom. Venom of the same batch was used in both of the series of tests using venom and lecithinized venom. Each test was performed in triplicate, and the average time was taken for the result. The prothrombin clotting time in normal persons, by this method, for the 100 per cent plasma, is 20.76 seconds while that for the 40 per cent plasma is 33.10 seconds.¹¹

RESULTS OF STUDY

The routine use of venom and lecithinized venom was carried out on 30 patients, and the resulting data on the 100 per cent plasma are outlined in Fig. 1 with the diagnosis of each patient. The complete data of the 100 per cent and 40 per cent plasma using venom and lecithinized venom are plotted in Fig. 2.

In the undiluted plasma studies the spread obtained with venom alone was from fifteen to thirty-four seconds, while with lecithinized venom it was from

*Supplied as 'Stypven' Russell viper venom by Burroughs Wellcome & Co., Inc., New York, N. Y.

†Lecithin (Merck).

thirteen to thirty seconds. In the 40 per cent plasma studies the spread obtained with venom alone was from twenty-seven to forty-seven seconds, while with lecithinized venom it was from 17.5 to 34 seconds.

Fig. 1.—Bar graph showing comparison between prothrombin clotting times obtained with Russell viper venom alone and with Russell viper venom plus 0.5 per cent lecithin.

DISCUSSION

The addition of lecithin to Russell viper venom decreased the prothrombin clotting time in every instance (Figs. 1 and 2). An estimation of the extent by which lecithin shortened the clotting time was obtained as follows. The clotting times in which venom alone served as the thromboplastic substance were plotted against the corresponding times obtained with lecithinized venom and the equation for a straight line was calculated by the method of least squares. For undiluted plasma this was found to be $y = 5.74 + 0.554x$ where y represents the

expected clotting time for lecithinized venom and x represents the clotting time for venom alone.

Using this equation, one may obtain an idea of how effectively lecithin may be expected to reduce the clotting time. Substituting a value of twenty seconds for x one finds that the corresponding y value is 16.8 seconds, or, in other words, the presence of lecithin has reduced the expected clotting time by 16 per cent. If a greater clotting time, thirty-five seconds, is selected for x , the corresponding y value is 25.1 seconds and the reduction is 29 per cent. The percentage of reduction, therefore, is not constant but appears to be greater with prolonged clotting times. In the above discussion it must be borne in mind that the calculated values are the expected average values and the assumption was made that the data could be fitted by a straight line.

Fig. 2.—Comparison between prothrombin clotting time tests done with Russell viper venom alone and with venom plus 0.5 per cent lecithin on undiluted oxalated plasma and on 40 per cent oxalated plasma diluted with physiologic saline.

Certain prothrombin clotting times (Fig. 1) which would be classed as abnormal with venom alone and presumably by Quick's test⁴ would fall into the normal range when lecithinized venom is used. For example, one patient with dwarfism, large liver, and bleeding gums (Fig. 1) had a prothrombin clotting time of 33.7 seconds with venom alone and 20.7 seconds with lecithinized venom. Another patient with hemorrhagic sclera (Fig. 1) had a prothrombin clotting time of 30.4 seconds with venom alone and 17.5 seconds with lecithinized venom. A third patient with menorrhagia (Fig. 1) had a prothrombin clotting time of 30.1 seconds with venom alone and 18.3 seconds with lecithinized venom. In each of these three patients the prothrombin clotting time with venom alone was

prolonged, indicating prothrombin deficiency, while with lecithinized venom the prothrombin clotting time was in the range of presumably normal prothrombin times (with venom alone), i.e., 20.76 seconds \pm 2.3 seconds.¹¹

Lecithinized venom may fail to reveal moderate grades of prothrombin deficiency and, therefore, it is desirable to perform the prothrombin clotting time determination with venom alone. However, the use of lecithinized venom may prove to be a valuable adjunct, especially when more information has been secured as to the reasons for the difference between the prothrombin clotting times obtained with venom alone and with lecithinized venom.

SUMMARY

Prothrombin clotting time studies using a modified Quick's method employing Russell viper venom (Daboia venom) instead of brain extract have been carried out on 30 human beings.

Undiluted plasma (100 per cent) and 40 per cent plasma were used with venom alone and with venom which had been lecithinized by adding 0.05 c.c. of a 10 per cent alcoholic solution of lecithin (egg) to each cubic centimeter of venom.

The addition of lecithin to the venom accelerated the prothrombin clotting time in each plasma studied.

The percentage of reduction in the prothrombin clotting time is greater in plasma with prolonged clotting times than in plasma with rapid clotting times.

The prothrombin clotting time determination using Russell viper venom should be performed with the venom alone, and it is suggested that lecithinized venom be used as a supplementary procedure. The use of venom alone may reveal certain prothrombin deficiencies which are not evident when the venom is lecithinized. The use of lecithinized venom in some cases may prove to be a valuable adjunct, especially when more information has been secured as to the reasons for the difference between the prothrombin clotting times obtained with venom alone and with lecithinized venom.

We wish to express our appreciation for the cooperation of Dr. Louis Bauman in whose laboratory this work was done.

D. SC. (MED.), PHILADELPHIA, PA.

WITH THE TECHNICAL ASSISTANCE OF HERMAN SIPLET, A.B.

DIFFERENT methods for the determination of trypsin in duodenal contents have been proposed. Some of them are based on the estimation of the nonprotein nitrogen in the protein-free filtrate after the digestion of casein with the duodenal contents (McClure¹). Others determine the amount of amino acids in the filtrate by the Soerensen titration method (Leubner²). Hollander³ and Lueders⁴ measure the time in which a certain quantity of amino acids is formed in a gelatin solution. According to the law of Hedin, this time is inversely proportional to the concentration of the enzyme.

Anson and Mirsky⁵ have developed a method for proteolytic enzyme determination in which they use a hemoglobin solution as a protein substrate and after digestion determine the amount of those substances which give a blue color with the phenol reagent of Folin and Ciocalteu.⁶ The quantity of these substances formed during the incubation is a function of the enzyme concentration. Beazell, Schmidt, Ivy, and Monaghan⁷ have adapted the pepsin method of Anson and Mirsky for the determination of pepsin in gastric juice. The trypsin method of Anson and Mirsky is likewise applicable for clinical purposes, and we shall describe the method as we have modified it for use with the Evelyn colorimeter.

The duodenal contents are centrifuged and diluted with physiologic saline solution 1:50. The assay of the enzyme should be performed as soon as possible after collection of the test material. In any case it should not be kept overnight. It has been our experience that during twenty-four hours about 30 per cent of the tryptic activity is lost even if the drainage material is kept in the refrigerator.

PREPARATION OF THE HEMOGLOBIN SUBSTRATE

The hemoglobin solution contains 2 per cent denatured hemoglobin and is buffered at a pH of 7.5. The solution is prepared according to the method of Anson.⁸ Commercial products, such as Bactohemoglobin, give blank values which are too high, and therefore they should not be used.

INCUBATION

Five cubic centimeters of the hemoglobin solution are pipetted into test tubes. The tubes are stoppered with rubber stoppers and placed in a water bath, heated to 37.5° C., for about fifteen minutes to bring the hemoglobin solution to the right temperature. Then 1 c.c. of the diluted duodenal drainage is

*From the Medical Research Laboratory Samuel S. Fels Fund, Philadelphia.
Received for publication, January 12, 1942.

added in duplicate tubes. The contents of the tubes are mixed thoroughly by inverting several times. Then the tubes are replaced in the water bath. After fifteen minutes they are removed, and 10 c.c. of a 5 per cent solution of trichloroacetic acid are added from another test tube into which it had been measured previously. The solutions are well mixed by pouring the contents back and forth from one tube to the other several times. The stoppers are replaced and the tubes turned upside down repeatedly.* To get a clear filtrate, the tubes must stand for about fifteen minutes. The solutions are then filtered through a Whatman filter No. 3. Three cubic centimeters of the filtrate are transferred into a colorimeter tube, and 20 c.c. of distilled water are added.

PREPARATION OF THE BLANKS

Blanks are prepared to determine the amount of preformed color-giving substances in the duodenal contents and the hemoglobin solution. To 5 c.c. of the hemoglobin solution 10 c.c. of 5 per cent trichloroacetic acid are added. The tubes are stoppered and well shaken. Then 1 c.c. of the diluted duodenal juice is added, and the tube contents are thoroughly mixed. After fifteen minutes the solution is filtered. The filtrate of the blanks is treated the same way as the filtrate of the incubated samples.

PREPARATION OF THE STANDARDS

A stock solution of tyrosine is made by dissolving 15 mg. of tyrosine Pfanstiehl (which has been dried in vacuo over sulfuric acid) in 100 c.c. of water containing 0.5 per cent formalin. Before use the stock solution is diluted with distilled water 1:10. To a colorimeter tube are added 15 c.c. of distilled water, 5 c.c. of the diluted tyrosine solution, and 3 c.c. of 0.2 normal hydrochloric acid. The tyrosine stock solution can be kept for about two weeks in the refrigerator without change in strength.

DEVELOPMENT OF THE COLOR

To every colorimeter tube, including incubated samples, blanks, and standards, are added 1 c.c. of 3.85 normal sodium hydroxide and 1 c.c. of the phenol reagent (according to Folin and Ciocalteu).† The color reaches its maximum intensity in ten minutes and remains unchanged for a ten-minute period, during which the colorimeter readings should be made.

For adjusting the galvanometer scale to 100 the following "reading blank" is used. Into a colorimeter tube are pipetted 20 c.c. of water, 3 c.c. of 0.2 normal hydrochloric acid, 1 c.c. of 3.85 normal sodium hydroxide, and 1 c.c. of the phenol reagent.‡

After the galvanometer scale has been adjusted to 100, the reading blank is replaced by the standard tube, and its color value is determined. It is advisable to read standards with every group of unknown samples as the phenol reagent is not absolutely stable and slight changes in it may occur. The Rubicon filter No. 660 is used. The calibration curve shows that this filter gives results in accordance with the logarithmic law of Lambert and Beer. After the color value of the standard has been determined, all incubated samples and blanks are read.

*In order to precipitate any of the material adhering to the stoppers.

†The tubes are stoppered and the contents are mixed by inversion.

Fig. 1.—Four activity curves made from different duodenal contents.

Fig. 2.—Standard activity curve represents the average of the four curves of Fig. 1.

CALCULATIONS OF THE RESULTS*

$K = \frac{L}{0.075}$. K is the calibration constant; L is the photometric density of the standard; 0.075 is the tyrosine content of the standard in milligrams.

The quantity of tyrosine developed by 1 c.c. of the diluted sample is formed from the equation $C = \frac{L_1 - L_2}{K} \times \frac{16}{3}$. L_1 is the average photometric density of the duplicate incubated samples. L_2 is the photometric density of the blank. $\frac{16}{3}$ refers to the dilution. C = milligrams of tyrosine per cubic centimeter of the diluted duodenal material.

TRYPSIN UNITS

For our definition of a trypsin unit we have applied the definition which Beazell, Schmidt, Ivy, and Monaghan have given for a pepsin unit. Accordingly, one trypsin unit represents such tryptic activity which develops an equivalent of 1.0 mg. of tyrosine per minute under the conditions described. The results are expressed in trypsin units per 100 c.c. of duodenal material. For the conversion of the milligrams of tyrosine into trypsin units an activity curve was constructed in the following manner. Various dilutions of highly active duodenal contents were incubated with the hemoglobin solution; the developed quantities of tyrosine were plotted as ordinates, and the corresponding concentrations of the duodenal contents, as abscissae. Four such "activity curves" were then constructed from four different duodenal contents; in every curve the point in the abscissa corresponding to 0.15 mg. of tyrosine on the ordinate was marked to find the dilution of the duodenal content which corresponds to $\frac{1}{100}$ of a trypsin unit. From this the abscissa values were recalculated and expressed in trypsin units. The curves were thus reconstructed and brought into one coordinate system (Fig. 1). Fig. 2 represents the average curve of the four curves and can be used as a standard curve for converting the tyrosine values into trypsin units. Multiplication by 5,000 gives the trypsin units per 100 c.c. of the undiluted duodenal material.

The estimations performed in duplicates on 57 specimens show an average difference of 2.2 per cent between the duplicates.

CONCLUSION

A method has been described for the determination of tryptic activity in duodenal material by means of the Evelyn photocolormeter.

AN ADAPTER FOR MICROCENTRIFUGE SHIELDS*

JOSEPH C. BOCK, CH.E., PH.D., MILWAUKEE, WIS.

IN MICROANALYTICAL procedures the use of very small centrifuge tubes is not infrequently required. These tubes from 0.5 ml. to 3 ml. capacity must be suspended in correspondingly small holders called shields. We believe that the most commonly used type is the Cornell style, $\frac{1}{2}$ inch outside diameter and about $2\frac{1}{4}$ inches long.† Even the smaller type centrifuges equipped with standard heads will not support these small shields but require a special head, costing several dollars. The larger floor type centrifuges which are most commonly used in the laboratory require an additional adapter to attach the microhead to the shaft.

Fig. 1.

A very simple adapter is described which permits the use of the microshields with the ordinary head and shields for the 15 ml. centrifuge tubes.

*From the Department of Biochemistry, Marquette University School of Medicine, Milwaukee.

Received for publication, January 22, 1942.

†E. H. Sargent & Company, catalogue No. S17195.

Fig. 1 illustrates the arrangement. An ordinary iron washer of $\frac{7}{8}$ inch outside diameter is drilled out until the microshield can just be pushed through, a so-called sliding fit. After the washer has been pushed up until it touches the ring of the shield, it is held in place by a piece of heavy walled rubber tubing of $\frac{5}{16}$ inch inside diameter and $\frac{3}{32}$ inch wall. The pieces of tubing should be of exactly the same length for all of the shields used in order to equalize their weight. The rubber tube is slipped over a round piece of material, such as a dowel, is marked in $\frac{1}{2}$ inch lengths, and is cut with a rolling motion with a very sharp knife. The washers must, of course, be of the same thickness and should be balanced before they are attached to the shields. Our shields with the adapter have the same weight within a range of 0.2 Gm.

SUMMARY

An easily made adapter for microcentrifuge shields is described. The changing of centrifuge heads is obviated.

THE DIRECT BIURET METHOD FOR THE DETERMINATION OF SERUM PROTEINS AS APPLIED TO PHOTOELECTRIC AND VISUAL COLORIMETRY*

GEORGE R. KINGSLEY, M.S., PHILADELPHIA, PA.

FURTHER investigation of the direct biuret method for the determination of serum proteins has led to several important refinements of the original procedure.¹ As modified, the method is more accurate, requires less time and fewer precautions than formerly, and is adaptable to visual as well as photoelectric colorimetry. An increase in concentration of the components of the biuret reagent permits accurate determination of serum protein up to 11 per cent. The use of a ready-mixed biuret reagent prevents precipitation of protein or cupric hydroxide. Such precipitation may occur if strong sodium hydroxide and copper sulfate solutions are improperly mixed in the presence of protein. The formation of turbidity, at times a complicating factor in the original method, is delayed by the addition of ether to the reaction mixture. Development of the biuret color under these controlled conditions is rapid, and readings may be made immediately after ether extraction and centrifugation. The improved direct method requires only ten minutes for the determination of serum total protein and twenty to twenty-five minutes for a protein fractionation.

REAGENTS

Biuret Reagent (TP) for Total Protein.—To 500 c.c. of 14 per cent sodium hydroxide ("carbonate free") in a pyrex bottle or flask, add 100 c.c. of 1 per cent copper sulfate ($\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$) solution and mix. Protect from dust and other contaminants. A rubber stopper may be used.

*From the Division of Biochemistry, Laboratories, Philadelphia General Hospital, Philadelphia).

Received for publication, January 26, 1942.

Biuret Reagent (ALB) for Albumin.—To 300 c.c. of 23 per cent sodium hydroxide ("carbonate free") in a pyrex bottle or flask, add 100 c.c. of 1 per cent copper sulfate solution and mix.

Ether.—U.S.P. grade is satisfactory.

Sodium Chloride.—0.9 per cent.

Sodium Sulfate.—23 per cent.

Standard Serum (for Calibration).—Obtain 5 to 10 c.c. of a single or mixed specimen of normal serum free from cells and hemolysis. Determine the protein concentration in duplicate samples by the macro- or micro-Kjeldahl method. Let C represent grams per cent total protein.

METHOD FOR PHOTOELECTRIC COLORIMETRY

Standardization.—Prepare stock standards in duplicate by measuring 1 c.c. portions of the analyzed serum into 10 c.c. volumetric flasks and diluting to the mark with 0.9 per cent sodium chloride. Mix. Prepare in duplicate a series of dilute protein standards by adding varying amounts of the stock standard and 0.9 per cent sodium chloride, as indicated in Table I, to 4 c.c. of the biuret

TABLE I

STOCK STANDARD (c.c.)	0.9 NaCl (c.c.)	PROTEIN EQUIVALENT (C) (GM./100 c.c.)
0.1	2.0	0.1C
0.2	1.9	0.2C
0.5	1.6	0.5C
0.7	1.4	0.7C
1.0	1.1	1.0C
1.2	0.9	1.2C
1.5	0.6	1.5C
Blank	2.1	0.0

reagent (ALB) as prepared for albumin determinations. Add 2 c.c. of ether to each tube, stopper, shake vigorously for approximately ten seconds, centrifuge for five minutes at about 2,500 r.p.m., and read in a photoelectric colorimeter. The readings of standard solutions are plotted against concentration of protein represented by each standard. From the graph so obtained colorimetric readings can be converted into concentration of protein. As an alternative, the concentration of protein in an unknown serum can be calculated by substituting the readings of the unknown and standard sera as obtained in the biuret total protein determination and the protein concentration of the standard in the equation $X = (U - B) \frac{C}{R - B}$. X equals the grams of protein in 100 c.c. of the unknown serum; U, the reading of the unknown; B, the reading of the blank; C, the grams of protein in 100 c.c. of the standard serum; and R, the reading of the standard serum. $\frac{C}{R - B}$ need be determined only once (in duplicate) for each standard serum and will remain constant unless mechanical or other changes occur in the photoelectric colorimeter. The calibration should be verified periodically with fresh standard serum.

Total Protein.—To exactly 6 c.c. of biuret reagent (TP) in a photoelectric colorimeter tube add 0.1 c.c. of fresh serum (free from cells and hemolysis)

with a micropipette after wiping the outside of the pipette. Rinse the pipette three or more times with the biuret reagent. Add 2 c.c. of ether, stopper, shake vigorously for approximately ten seconds, remove the stopper, and immediately centrifuge at about 2,500 r.p.m. for five minutes. Read in a photoelectric colorimeter within ten minutes after centrifuging. A green filter transmitting light between 500 and 570 $m\mu$ with maximum transmission at 540 $m\mu$ is satisfactory. The reading of the blank (Table I) is constant at 65-69 on the Klett-Summerson photoelectric colorimeter and needs to be determined only once for each new set of reagents.

If the serum is clear and contains only traces of hemoglobin and no more than normal concentrations of other pigments, fairly accurate results are obtained without ether extraction and centrifugation if readings are made five minutes after the development of the biuret color. When ether is not used, carefully mix the solutions by inverting; avoid shaking.

*Albumin.*³—Add 0.5 c.c. of serum to 7.5 c.c. of 23 per cent sodium sulfate in a test tube (18 by 120 mm.) and mix thoroughly by inverting. Add about 3 c.c. of ether and shake vigorously for twenty to thirty seconds. Cap or stopper the tube and centrifuge five to ten minutes at about 2,200 r.p.m. After centrifugation, slant the tube so that the tightly packed globulin precipitate separates from the walls of the tube. Insert a pipette through the ether layer preferably along the lower wall, withdraw 2 c.c. of the albumin solution, add to 4 c.c. of the biuret reagent (ALB) in a photoelectric colorimeter tube, and mix immediately. Then add 2 c.c. of ether and proceed as in the biuret method for total protein. Under certain conditions the use of ether may be omitted as stated above. To calculate the amount of albumin present, determine the protein equivalent of the reading by means of the graph or equation obtained by the standardization and multiply by 0.784.

Globulin.—Total protein minus albumin equals globulin.

METHOD FOR VISUAL COLORIMETRY

Standard I.—Add 1 c.c. of standard serum of known protein content and 1 c.c. of 0.9 per cent sodium chloride solution to 140 c.c. of biuret reagent (TP) and mix.

Standard II.—Add 2 c.c. of standard serum to 140 c.c. of biuret reagent (TP) and proceed as for Standard I.

Standard III.—Add 3 c.c. of standard serum to 139 c.c. of biuret reagent (TP). These standards will keep at least one month if stored in a pyrex bottle in a refrigerator.

For the determination of protein proceed as in the photoelectric method. Shake 6 c.c. of the standard biuret solutions with 2 c.c. of ether and centrifuge simultaneously with the unknowns. Remove sufficient colored solution from beneath the ether layer by means of a pipette and compare in a colorimeter against both a higher and a lower standard at room temperature. Use a green filter (maximum transmission at 540 $m\mu$) in the colorimeter eyepiece. If the reading is within 10 to 15 per cent of the reading of one standard, the comparison with the other standard may be omitted.

Calculation.— $X = \frac{A \frac{r_a}{10} + B \frac{r_b}{10}}{2}$ where X is the protein concentration of

the unknown in grams per 100 c.c.; A and B, the protein concentrations of lower and higher standards in grams per 100 c.c. of the standard serum; and r_a and r_b , the readings of lower and higher standards when the unknown is set on the left at 10 mm. A similar use of two standards has been described by Goudsmit⁴ for the determination of creatinine by means of a photoelectric colorimeter.

Fig. 1.—Biuret color intensity at increasing protein levels and the effect of different concentrations of copper sulfate and sodium hydroxide.

DISCUSSION

The biuret reaction mixture employed contains approximately 11.5 per cent sodium hydroxide and 0.16 per cent copper sulfate, concentrations that are considerably higher than those originally used.¹ When copper sulfate is increased to this strength, the ratio of protein concentration to biuret color produced is linear up to 11 per cent protein as shown in curve 1 (Fig. 1). Curve 2 represents the biuret color produced with the approximate concentration of reagents originally used. Increase in sodium hydroxide concentration also is necessary to avoid the precipitation of cupric hydroxide, especially on standing. Concentrations of sodium hydroxide as high as 13 per cent can be used, but 11.5 per cent was found to be sufficient for a stable reaction mixture. The presence of carbonate in the biuret reagent may cause precipitation with a

decrease in color. For this reason sodium hydroxide solutions were prepared from clear 70 to 75 per cent solutions which had stood until sodium carbonate had separated.

Robinson and Hogden² stated that in the direct biuret method¹ the solutions were not perfectly clear, a straight line relationship did not continue above 8 per cent protein, and results comparable to their indirect method were obtained only by the most rigorous control of the time of reading; these objections do not apply to the modified procedure. Several of the time-consuming operations of the indirect method of Robinson and Hogden are avoided in the direct method since their procedure requires precipitation of protein with trichloroacetic acid, the redissolving of protein precipitate with sodium hydroxide, and the removal of excess cupric hydroxide by centrifugation.

When ether is used, careful control of time of reading is unnecessary as solutions remain clear for about twenty minutes after centrifugation. On longer standing turbidity does develop, especially in some cholemic sera. However, if the solutions are again shaken with ether and centrifuged, clear solutions are obtained with unchanged protein values even though the solutions have stood for several hours.

The increased amount of copper employed results in a higher blank, and, at lower concentrations of protein, proportionately greater amounts of reagent uncombined with protein are present. The greater part of the light absorption of the excess biuret reagent is removed by the 540 $m\mu$ filter. Probably for this reason the 540 $m\mu$ filter has proved to be superior (in my experience) to the 560 $m\mu$ filter recommended by Robinson and Hogden.² However, if a visual colorimeter is used, it is necessary to employ a series of standards representing approximately 3, 6, and 9 per cent protein. The greater ease of operation and accuracy of the photoelectric colorimetric method makes its use preferable.

The 540 $m\mu$ Klett-Summerson filter absorbs all significant color due to the presence of bilirubin up to 25 mg. per cent. When 50 mg. per cent of bilirubin, a concentration rarely encountered in serum, was added to a serum containing 5.4 per cent protein, an apparent protein value of 5.5 per cent was obtained. Correction by means of a blank containing the added bilirubin and biuret reagent gave a value of 5.3 per cent; this indicates that the preparation of a blank to correct for the presence of bilirubin is unnecessary.

Slight hemolysis can be tolerated, but excessive hemolysis may give rise to errors. Attempts to correct for excessive hemolysis by means of a blank containing serum diluted with saline have been unsuccessful.

RESULTS

Excellent agreement is shown by the biuret and Kjeldahl methods when protein determinations are made on normal serum. The results of protein fractionation by the biuret and Kjeldahl methods of blood serums of 6 normal women and 9 normal men are presented in Table II. Kjeldahl determinations were made on 1 c.c. samples of serum. Boric acid was used in the distillation of the ammonia.⁵ It is apparent that the accuracy of the biuret method does not differ significantly from that of the Kjeldahl method. In chronic liver disease dif-

ferences averaging 0.5 Gm. have been observed between the results of serum total protein determinations by biuret and Kjeldahl methods.⁶ Further studies (to be published) also have shown small differences in some other diseases. It is debatable, of course, whether such differences are due to variation in total nitrogen, in biuret linkages, or both and consequently as to which method is giving results most nearly indicative of the actual concentration of serum protein.

SUMMARY

The direct biuret method for the determination of serum total protein and albumin has been modified and improved. Rapid and accurate determinations of serum proteins up to 11 Gm. per 100 c.c. in 0.1 c.c. samples of serum can be made by the new method. Application of the method to visual and photoelectric colorimetry is outlined.

I am indebted to Dr. John G. Reinhold, of the Division of Biochemistry, for suggestions and criticism.

MEDICAL ILLUSTRATION

A SIMPLE METHOD FOR DETERMINATION OF EXPOSURE TIME IN PHOTOMICROGRAPHY*

HARRY A. TEITELBAUM, M.D., PH.D., AND JAMES C. PLAGGE, PH.D.
BALTIMORE, Md.

TO THE nonprofessional photographer who does not use photographic equipment often enough to become expert in its manipulation, the simple application of mechanical devices that increase his efficiency is of great help. Photomicrography gives rise to problems which are particularly concerned with the amount of light that reaches the photographic plate. If the specimen being photographed varies in the intensity of the stain in different areas and also in thickness, as in supravitality stained tissue mounted *en masse*, it is difficult to determine by visual inspection the exposure time for different fields even in the same specimen. With sufficient experience one can estimate roughly the exposure time, but several photographs are often required to determine the correct time before satisfactory results are obtained. This frequently causes an unnecessary waste of time and materials.

The technique to be described uses standard equipment in a rather simple manner. A photoelectric cell (Fig. 1 A) was built into the wide end of a small camera having a fixed bellows (Fig. 1 B), the narrow end of which consisted of tubing (Fig. 1 C) about one-half inch long that fitted snugly into the microscope barrel in place of the ocular. The photoelectric cell was connected to an exposure meter (Fig. 2),† to record the intensity of light being transmitted through the microscope. Fig. 3 shows the complete equipment.

In using this equipment the field to be photographed is chosen and carefully focused. The microscope ocular is then removed, and the photoelectric cell is put in its place. A light reading is taken on the exposure meter. The photoelectric cell is replaced by the camera, and the focus is checked. The time of the first exposure is guessed. With the same setup additional shorter and longer exposures of the same specimen are made, the variations in time being figured in geometric progression. To economize on both photographic material and time, the trial exposure method,¹ in which several exposures are made on

*From the Department of Gross Anatomy, School of Medicine, University of Maryland, Baltimore.

†This photoelectric exposure meter P. W. can be obtained from Pfaltz & Bauer, Inc., Empire State Building, New York.

one plate, may be used. In this way one eventually arrives at the correct exposure for a given reading on the exposure meter. This procedure is repeated for different meter readings.

Fig. 1.—Photoelectric cell mounted on camera bellows. A, Photoelectric cell; B, camera; C, adapter for microscope tube.

Fig. 2.—Exposure meter.

We used the foregoing method to establish a workable curve (Fig. 4) which would suit our particular purpose. After several successful photographs were made with different amounts of light, we plotted our points, using exposure meter units as the abscissa and the time of exposure as the ordinate. Then we drew a rough curve and joined these points. In order to add intermediate points to our curve and at the same time prove its validity, several additional points along its course were tested. Good negatives were obtained by using the meter

readings and exposure times which fell on the curve. Negatives which were not made with the amount of light, and exposure time indicated by the curve were either overexposed or underexposed.

The curve obtained in Fig. 4 resulted when Wratten M plates and D-76c developer were used. Different types of plates would naturally give different curves.

Fig. 3.—Complete equipment assembled with microscope.

Although the curve was constructed chiefly from low-power photomicrographs ($\times 100$ to $\times 200$), it was tested for higher systems of lenses, including oil immersion, and found to be equally useful. Satisfactory pictures were obtained, regardless of specimen, thickness of section, stain, or magnification. The only requirement to be observed rigidly is that the exposure time be varied according to the exposure meter reading. The meter reading itself can be adjusted by changing the aperture of the diaphragm on the substage condenser, or in the light source if one is available there. This technique permits one to keep the intensity of light within the range of the curve that is most convenient for the exposure time units permitted by the mechanism of the camera shutter.

In Fig. 5 the application of the curve in Fig. 4 is illustrated. Extreme differences in light intensity and in magnification are shown in the four photographs. In A the amount of light employed was small, only 2 meter units, and the exposure time, as determined by the curve, was relatively long, one second.

In *B* the conditions were reversed, for the light meter reading was 55 and the exposure time was $\frac{1}{25}$ second. In *C* the magnification was low, $\times 100$, the light intensity was 15 units, and exposure time was $\frac{3}{10}$ second; in *D* the magnification

Fig. 4.—Graph showing relation of exposure meter units to exposure time.

was $\times 900$, with the light intensity and exposure time the same as in *C*. The development and printing techniques were comparable in all instances. Slight variations in the depth of the final print, as in *A* and *B*, may be adjusted to suit one's particular purpose during the printing process.

When filters that exclude much of the available light are used, the equipment may not be sensitive enough to register the amount of light reaching the photoelectric cell. In such instances it was found advantageous to take exposure meter readings without the filters and to make trial exposures for determining the time with the filters in place. The correct exposure time was naturally much greater for any light meter reading than that recorded in Fig. 4, because the photographs were actually taken with much less light than that used for determining the exposure meter reading. A workable curve, similar to that in Fig. 4, was made for such low light intensities and long exposures.

Fig. 5.—Sample photographs obtained by means of the graph illustrated in Fig. 4. The developing and printing processes were the same in each instance. *A*, Mammary gland anlage of treated pouch-young opossum, $\times 100$. Exposure meter reading, 2 units; exposure time, 1 second. *B*, Same as in *A*, $\times 100$. Exposure meter reading, 55 units; exposure time, $1/25$ second. *C*, Anterior lobe of hypophysis of guinea pig, $\times 100$. Exposure meter reading, 15 units; exposure time, $3/10$ second. *D*, Same as *C*, $\times 900$. Exposure meter reading, 15 units; exposure time, $3/10$ second.

SUMMARY

A simple method for determining the exposure time in photomicrography by the use of a photoelectric cell and exposure meter is described.

We wish to express our appreciation to Professor Eduard Uhlenhuth for his interest and advice in working out this problem. We wish to give full credit to Doctors Raymond K. Thompson and Glenn H. Algire, who adapted the photoelectric cell as described in this paper.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

PERTUSSIS, a Note on the Cultivation of *Hemophilus*, Anderson P. M. M. J. Australia 2: 224, 1941

Flexible copper wire, gauge 19, was used in lengths of 15 cm., and on one end a tiny loop was made and dressed with a thin layer of cotton wool. These swabs were sterilized in tubes and were then ready for use. For the taking of the swab the child was seated on its mother's lap and the head was extended firmly against her shoulder. The manipulator bent over the child and passed the wire along the wider anterior nares into the post-nasal space. A side-to-side movement was then imparted to the swab, and the finger could feel the tip passing over the posterior pharyngeal wall. It was then quickly withdrawn, the end of the swab being depressed slightly and describing an arc. The wire was usually found to have taken on a curved shape.

Swabs were taken from children as young as 3 months old, and no difficulty was encountered; toddlers and older children occasionally coughed, but no failures occurred. The swabs were rubbed onto Bordet-Gengou medium containing 15 per cent of horse blood and incubated for four days, and a satisfactory proportion of positive cultures was obtained.

McCLURE-ALDRICH TEST. A Clinical Study and Evaluation, Lichtenburg, N. H. A. J. Dis. Child. 62: 743, 1941.

Thirty-three newborn infants given the McClure-Aldrich test on the first day of life and 50 infants tested after the "physiologic weight loss" was corrected had an average saline absorption time of 10.4 minutes.

Seventy normal newborn infants who were given no supplementary fluids and were tested at the time of greatest "physiologic weight loss" had an average saline absorption time of 26.3 minutes, two and a half times as long as that of the control groups.

Twelve normal newborn infants who had an average saline absorption time of 9.9 minutes on the first day of life showed an increase of absorption time to an average of 20.8 minutes on the third and fourth days, when the weight loss was maximum. The absorption time returned to an average level of 12.7 minutes on the day of discharge, when the weight loss and the state of hydration were, in part at least, corrected.

There was no difference between the absorption times of physiologic solution of sodium chloride and a solution of twice that concentration. Normal potassium chloride solution, however, was absorbed more than twice as quickly as physiologic solution of sodium chloride.

The McClure-Aldrich test is valuable in determining and following up the state of hydration of the body tissues. The absorption time depends, however, on the state of hydration at the site at which the test is performed and the mechanical ease of diffusibility of the injected saline solution into the intercellular spaces of the skin. It may be true that edema is a result of local or generalized toxicity and anoxemia and represents an attempt by the body to dilute the toxins. The result of the McClure-Aldrich test, however, may be regarded as indicative only of the extent and intensity of the edema, regardless of its cause. It may be a measure of tissue toxicity but only so far as, and when, the toxicity directly parallels the local edema.

NEPHROTIC SYNDROME, Acacia in the Treatment of, Goudsmit, A., Jr., Binger, M. W., and Power, M. H. Arch. Int. Med. 68: 701, 1941.

In 28 patients with the nephrotic syndrome who were treated with acacia the following observations were made:

1. The concentration of acacia in the serum resulting from the injection of 60 to 150 Gm. ranged between 1,000 and 2,500 mg. per 100 c.c.

2. The concentration of serum proteins usually diminished. As an average this amounted to 22 per cent of the original concentration. This related decrease could not be correlated with the amount of acacia administered, with the resultant concentration of acacia in the serum, or with the initial concentration of serum proteins. Increases in circulating plasma volume and concomitant dilution of its constituents appear to account adequately for the decrease of serum proteins.

3. The gross changes in colloid osmotic pressure subsequent to injections of solution of acacia are directly related to the absolute changes of the concentration of the serum proteins and of the concentration of acacia. If certain values are assigned for the "specific" osmotic pressures of serum proteins and of acacia, the changes of colloid osmotic pressure can be predicted fairly accurately. In approximately half of the patients the calculated changes were within 6 mm. of the observed values.

4. The colloid osmotic pressure of the serum may be increased, unchanged, or decreased after a course of injections of solution of acacia. An increase is most likely to occur when the initial colloid osmotic pressure is most subnormal.

5. These changes of colloid osmotic pressure, under the general regimen to which these patients were exposed, appear to be essentially unrelated to the degree of effectiveness of the treatment.

SULFANILAMIDE, A Simple Micro Test for, and Its Derivatives in Blood, Churg, J., and Lehr D. *Am. J. M. Sc.* 202: 589, 1941.

REAGENTS

A. 15 per cent aqueous solution of trichloroacetic acid.

B. 2 per cent para-dimethylaminobenzaldehyde (p-BA) in 95 per cent ethyl alcohol. (If stored in a glass-stoppered brown bottle, the reagent keeps for at least a month. It is almost colorless if prepared from fresh p-BA. Crystalline substance which has turned strongly yellow due to prolonged standing is unsuitable for use.)

C. N/6 HCl (for determination of total sulfanilamide concentration).

EQUIPMENT

A. Test tubes, 10 mm. in diameter, calibrated at 1.5 c.c., 2 c.c., 3 c.c., and 4 c.c., with rubber stoppers.

B. Blood pipette, 0.1 c.c.

C. Small (1 inch) funnel and filter paper (Whatman No. 2, 4.25 cm.).

D. Graduated centrifuge tubes (for determination of total sulfanilamide concentration).

E. Comparator (block or slide) with blue glass filter, a set of permanent standards (Table I) and comparison tubes (10 mm. inside diameter) calibrated at 1 and 1.5 c.c.

TABLE I
COMPOSITION OF PERMANENT NONFADING STANDARDS

K ₂ Cr ₂ O ₇ (C.C.)	K ₂ Cr ₂ O ₄ (C.C.)	H ₂ O (C.C.)	CORRESPONDING CONCENTRATIONS OF SULFANILAMIDE IN BLOOD (MG. IN 100 C.C.)
0.5	0.1	9.4	0
1.0	0.25	8.75	1
1.5	0.4	8.1	2
1.9	0.5	7.6	3
2.2	0.7	7.1	4
2.5	0.9	6.6	5
2.7	1.3	6.0	6
3.0	2.1	4.9	8
3.0	3.7	3.3	10
	0.5%		
3.0	5.0	2.0	15

PROCEDURE

A. Determination of Free Sulfanilamide

1. Place 1.5 c.c. of water in the calibrated test tube.
2. Add 0.1 c.c. of blood (drawn from finger or ear lobe) and rinse the blood pipette several times with the water in the tube. Shake the tube gently for a minute or two until the blood is completely hemolyzed.
3. To precipitate the proteins, add 15 per cent trichloroacetic acid up to the 2 c.c. mark (approximately 8 drops). Close the tube with a rubber stopper and invert several times. This step may be performed immediately following 2, or within several hours.
4. After two minutes filter the mixture directly into the comparison tube up to the 1 c.c. mark. Instead of filtering, the mixture in the precipitation tube may be centrifuged for five minutes at high speed, and 1 c.c. of clear supernatant fluid transferred to the comparison tube by means of a capillary pipette. This is especially convenient if several tests are run simultaneously.
5. Add the p-BA up to the 1.5 c.c. mark, mix by inversion and compare with the standards in the comparator, either immediately or within two hours. In the latter case the comparison tube must be tightly stoppered.

The p-BA reagent should be shaken before use.

If the drug level in the blood is found to exceed 10 mg. per 100 c.c., accurate determinations are obtained by repeating the test with double dilution of the blood. For that purpose 0.1 c.c. of blood is hemolyzed in 3 c.c. of water and trichloroacetic acid added up to the 4 c.c. mark (about 18 drops). Otherwise the procedure remains unchanged. The readings are multiplied by 2.

B. Determination of Total Sulfanilamide

The procedure as described above remains unchanged up to Step 4. Steps 4 and 5 are modified as follows:

4. Place 1 c.c. of the filtrate or centrifugate in a graduated centrifuge tube, add 1 c.c. of N/6 HCl, mix, and heat in a boiling water bath for one hour in order to hydrolyze the acetylated sulfanilamide. The mixture evaporates almost completely. Cool to room temperature and bring the volume up to 1 c.c. with water.
5. Add the p-BA reagent up to the 1.5 c.c. mark, mix by inversion, transfer into a comparison tube and compare with the standards. The readings are then multiplied by 1.15 to compensate for the decrease in color intensity due to the addition of hydrochloric acid.

C. Determination of Sulfanilamide Derivatives

With appropriate standards the test can be applied equally well to the determination of sulfapyridine, sulfathiazole, and other sulfanilamide derivatives. For clinical purposes, sufficiently accurate results can be obtained with these compounds by using the sulfanilamide standards for comparison, provided the readings are multiplied by the following factors:

	Free	Total
Sulfapyridine	1.5	1.7
Sulfathiazole	1.7	2.0

These factors take into account the higher molecular weight of sulfapyridine and sulfathiazole, the loss in precipitation due to the poor solubility of these compounds, and, in determination of total drug concentration, also the decrease in color intensity caused by the addition of hydrochloric acid.

T. N. T. Derivative in Urine, Improved Webster Test for, Ingham, J. *Lancet* 2: 554, 1941.

Place 50 c.c. of urine in a convenient sized beaker (400 c.c.) and add 50 c.c. of 20 per cent (by volume) sulfuric acid (1 part concentrated H_2SO_4 plus 4 parts H_2O). Mix.

Place beaker on tripod, supported by wire gauze, and heat over Bunsen flame till the liquid boils.

Boil for one minute; allow to cool. Cooling may be hastened by running cold water over outside of beaker.

After cooling, pour the mixture of urine and acid into a separatory funnel of 200 c.c. capacity and add 50 c.c. of ordinary (methylated) ether. Shake up well and then allow to settle for about fifteen minutes. The lower layer of urine and sulfuric acid is next run off by removing the top stopper and opening the lower tap.

The ethereal solution of acidified urine remaining in the separatory funnel is then washed twice with 1 per cent aqueous solution of sodium carbonate. This is done as follows. Add 20 to 25 c.c. 1 per cent sodium carbonate (aqueous), shake, and, after allowing to settle for five to ten minutes, run off the lower layer. Repeat. (If the person has been taking purgatives, such as rhubarb, senna, cascara, phenolphthalein, which yield anthraquinone derivatives, the sodium carbonate solution will show a reddish-violet color).

After this treatment with sodium carbonate the ethereal solution in the funnel is washed with water, as follows. Add 50 c.c. tap water, shake, allow to settle for fifteen minutes, and then run off the lower layer as before. (Occasionally a troublesome emulsion forms in the ethereal extract while washing with water but it is easily dispersed by adding a few drops of absolute alcohol and shaking gently.)

Now place 5 c.c. of the ethereal extract, so washed and prepared, in a test tube and quickly add, without shaking, 5 c.c. of a 5 per cent alcoholic solution of potassium hydroxide (5 gr. caustic potash dissolved in 100 c.c. of methylated spirit of absolute alcohol). A violet cloud indicates a positive result. The liquid in the test tube should be watched carefully, for the color develops quickly and just as quickly fades. The intensity of the color varies from the faintest tint to a deep violet according to the amount of TNT in the urine.

The unused ethereal extract remaining in the separatory funnel need not be thrown away but may be collected and later separated off from any TNT by distillation. It may then be used again in other tests.

For the routine everyday urine examination of workers in TNT factories the technique may be simplified as follows:

Apparatus Required.—Two ordinary test tubes (7 inches by $\frac{3}{4}$ inches); Bunsen burner or spirit lamp.

Reagents Required.—20 per cent (by volume) sulfuric acid; ordinary (methylated) ether; 5 per cent alcoholic solution of potassium hydroxide (freshly prepared).

Place about 10 c.c. of urine in one test tube; add about an equal quantity of the 20 per cent sulfuric acid; shake and bring to a boil; cool thoroughly under water tap.

When cold, add about 10 c.c. of the ether and shake well; allow to stand a few minutes until ether floats to the top. Pour some of the supernatant ether into the other test tube and to it add about 2 c.c. of the 5 per cent alcoholic potassium hydroxide solution. A dirty reddish purple color develops at once if TNT is present. The tint varies from faint to very deep according to the amount of TNT present and appears quickly and just as quickly fades. If no TNT is present, a light brown color only results and persists.

With this simplified technique the test is sensitive to 1 part in 10,000. It does not exclude anthraquinone derivatives (from the purgatives mentioned) which give a similar but pinker color which persists.

Erratum

On page 334 of the December issue of the JOURNAL in an article entitled "Age Incidence of Positive Tuberculin Reactions (Mantoux)" by Frances Pascher, M.D., and Marion B. Sulzberger, M.D. (with the statistical analysis by Alexander S. Wiener, M.D.), the formula appearing on the last line of the page should read:

$$P.E._{DIFF.} = \sqrt{(P.E._{P_1})^2 + (P.E._{P_2})^2}$$

Also on page 335 of the same article the fourth line under Table III should read:

"Therefore, $p_2 - p_1 = 29.5$ per cent and $P.E. (p_2 - p_1) = \sqrt{(0.06)^2 + (0.051)^2} = 0.081$, or 8.1 per cent."

GEORGES HAYEM (1841-1935)

"The future belongs to hematology."—Georges Hayem

CAMILLE DREYFUS, M.D., BOSTON, MASS.*

IT IS A great honor for me to speak before your esteemed Society in commemoration of the hundredth anniversary of a countryman who is called the father of hematology. His anniversary will not be celebrated in his fatherland, where an atmosphere of constraint and persecution compels the best of our profession to a humiliating silence. There it will be impossible to praise Georges Hayem despite all his contributions to the glory of his country. I am thus doubly fortunate to be able to express to you my deep feeling of gratitude and appreciation of your hospitality. I should also like to offer my very good friend, Dr. Nathan Rosenthal, my sincere thanks for this opportunity to commemorate Georges Hayem.

When, as a young doctor, I went to Paris for the first time, I attended a meeting of the Société médicale des hôpitaux de Paris on the Rue de Seine. Seated beside me was a little old man, his tanned face crowned with a snow white crop of abundant hair, with locks falling to his neck. He had a stiff little beard, a snub nose surmounted by gold spectacles; a vivid and piercing eye completed this remarkable head of a true scientist. I was deeply impressed by his appearance, and it was not until later that I learned that this old man, who was treated with great respect and deference, was Georges Hayem.

The story of his life hardly lends itself to the dramatics of a romanticized life. It is earnest and straight as the life of so many seekers after truth, and it seems that he experienced his allotment of great emotions, sudden turns of fortune, joys, and disappointments in the laboratory, when a hypothesis became a truth, or when a new observation came to overthrow a truth of yesterday. But we are not qualified to judge. Under a calm and impenetrable mask sometimes unfolds a tormented existence; and a life of action is often but an escape from

*Research Fellow at Tufts College Medical School.

Aided by a grant from the Dazian Foundation for Medical Research.

Read at the meeting of the Hematology Journal Club, the Mount Sinai Hospital, New York, N. Y., November 26, 1941.

personal suffering. I do not wish to have you believe for a moment that such was the case of Georges Hayem. However, I wish to indicate how frequent it is for people to take the secrets of their inner lives to their graves. Nevertheless in his life, it is obvious that there is nothing to remove it from the framework of a normal life.

He was born in Paris, Nov. 24, 1841, the son of Simon Hayem, a successful businessman of the Sentier section, who had hoped that his son would succeed him. By some strange fate, Georges Hayem preferred to be a student, and, perhaps by atavism, to choose a medical career.

His family had preserved the portrait and the memory of an ancestor, Isaie Servus Ulman, who practiced medicine in Metz. Louis XV, at that time still called Louis the Well-Beloved, having accompanied the army in the War of the Polish Succession, was seized in Metz with a bad case of dysentery. As the condition of the prince was growing progressively worse, the royal physicians, overcoming their prejudice, in desperation called in the Jewish doctor. Against every expectation, the remedies of Isaie Servus Ulman brought about a cure. In the midst of the delirious joy ushered in by this news to the entire kingdom, Hayem's ancestor deemed himself happy to obtain as his reward an improvement in the conditions of the Jews of Lorraine. There is no doubt that such a family heirloom was largely responsible for directing young Hayem toward medicine.

Georges began his medical studies in 1861. He completed a two-year course in one year; this was a remarkable achievement. In 1862 he received the highest honor in the examination for externship. He was admitted as an interne in 1863. He received the gold medal in 1867 from the Académie de médecine for his brilliant work. In 1872 he was accepted as a physician in the hospitals and was licensed to practice. Seven years later he was named titular professor, and finally in 1886 he was elected to the Academy of Medicine. He was just 45 years old.

The exceptionally rapid ascent cost Hayem many jealousies and grudges. But he was not the man to bother with public opinion. He was sure of himself, conscious of his worth, and seldom, if ever, stepped aside from this line of conduct. Henceforth, his life unfolds between his service at the hospitals and at home. He used to arrive early in the morning at the Saint Antoine in a fiacre. On entering his office he donned a simple white apron and a black velvet skull cap for ward rounds. He did not waste time in the exchange of civilities with his co-workers. He was rough and brisk and demanded much from others, as well as from himself. The students did not love him; they feared him. Much courage was needed to become his interne.

Paul Bensaude told me to what extent Hayem was feared. His brusqueness at first repulsed people, but at bottom this rudeness concealed timidity, and his closest associates knew that under this façade of brusqueness beat a heart on which one could depend. The fidelity they gave him is a touching testimony of their comprehension of this great man.

The public liked him. The people of the Saint-Antoine district greeted him with respect. His fame dates from the epidemic of cholera which ravaged Paris in 1870, during the siege. Hayem did not spare himself in caring devotedly and courageously for the stricken. He noticed that a great number of

the cholera victims died of dehydration. By intravenous injection of artificial serum, isotonic saline, or Hayem's serum, he managed to save 30 per cent of his patients, a considerable number for the time. This success brought him his nickname, Doctor Cholera.

Georges Hayem.

Until his death Hayem remained the master who looks upon his associates as his disciples. Bensaude, of whose world-wide renown by virtue of his work in proctology I need not remind you, has, like many others, surrounded Hayem with filial devotion. A few days before his death, Hayem asked for a camphor injection, and requested Bensaude to perform it. Hayem thanked him, with this remark: "Bensaude, you still don't know how to give an injection." Bensaude was then 67 years old.

In 1911, caught by the age limit, Hayem had to quit service at the Saint-Antoine Hospital. In the course of his farewell address, at the moment when he must leave his laboratory and his associates, you perceive the soft murmur of this sad life of the scientist whom others, more lucky than himself, have surpassed:

"I cannot complain," he said, "I have studied and taught medicine during a half century which shone with incomparable luster: the work of Pasteur, the

ascent of surgery, the discovery of serotherapy and radiology. This incessant, tumultuous growth of knowledge, ringing discoveries, is comparable to a rising tide that keeps on rising. How small one feels during the submersion! How fitting it is to be humble!"

In his private life cruel experiences were in store for him. First he lost a daughter whom he adored. A terrible malady overtook his wife. His older son was killed at Verdun. Later he lost his second son. To withstand implacable destiny, only one daughter was left him, and the affection of his son-in-law, his grandchildren, and his pupils.

On the sixth floor of his house at Auteuil, Hayem furnished a workroom where, in his last years, he practiced a hobby, modeled medallions, and showed his skill at painting.

It is impossible in the short time allotted me, to pass in review all the scientific work of Georges Hayem. His publications are so numerous and diverse that we are forced to limit ourselves to hematology. But we must not forget that other fields, particularly that of gastroenterology, were strongly influenced by his research.

Before launching on our selected subject let us mention, however, that his thesis for the doctorate was entitled "*Studies on Diverse Forms of Encephalism*" (1868), and that of his two master's theses, one treats of "*Bronchitis*" and the other of "*Arachnoid Hemorrhages*" (1872).

What was hematology in France before Georges Hayem? This question has not until the present had the development it merits. To discuss this question one must first descend to the obscure sources of modern medicine. Let us refer to two works, rarely cited, but which constitute in my mind the milestones on the narrow path leading out on the wide road of Georges Hayem's hematology. The first work is entitled "*The Medical Analysis of Blood*," and was published by Theophile de Borden in 1775. Only a pamphlet written in the style of the eighteenth century, it constitutes a brief opposing the pretensions of physics and chemistry to invade the field of medicine and to attempt to dominate it. He does not admit that these accessory sciences submit the phenomena of life to their close scrutiny. He speaks of a certain group of physicians "who claim that blood is composed of globules which can be counted, but no one must object to the arbitrary count. They go so far as to imagine bursting globules, broken globules, globules sticking together, as occurs with glass globules."

And, for our edification and consolation, he adds: "Sensible men will not pay attention to this childish prattle." Thus speaks the eighteenth century, opposing with its ironic verve the destiny of medicine. This is routine, mocked by Molière and Montesquieu, which would hold back the advent of a new era.

The second work which will help us form an idea of medicine before Hayem is entitled "*An Essay in Pathological Hematology*." It was written by Gabriel Andral, Professor of General Pathology and Therapy at the Paris Medical School, Member of the Royal Academy of Medicine, and Staff Member of the Hôpital de la Charité. It was published in 1843 by Fortin, Masson et Cie.

This little treatise seems to me to be of considerable interest in the history of hematology. Here we find in a nutshell the opinion of the period of transition from the eighteenth century medicine to the medicine of Georges Hayem.

The ideas exposed in this booklet surprise us as much as they charm us. And, if Hayem is the Father of Hematology, permit me to name Andral the Grandfather.

I quote for you a few passages of this pioneer's work:

"Until the present, direct observation of the blood has been invoked more rarely than reasoning. To cope with this problem, blood must be analyzed. Hematology will be in a position to gain valuable facts only when the blood of a great number of sick people will be submitted to a chemical investigation and examined under the microscope.

". . . but in order that microscopic analysis of blood might yield truly useful results, one condition is indispensable: namely, that we first acquire an exact knowledge of the varieties of the physiology of blood.

". . . Because of our failure to make a preliminary examination of the physiology of blood, many erroneous assertions have been made in connection with the changes produced in the blood corpuscles by illness. I am not afraid to state that until the present no alteration in form or texture, which might be considered the result of the influence of a disease, was definitely found in these small bodies, and also that all modifications of aspect described and other modifications which were briefly mentioned result from the progressive destruction which they undergo in proportion to the length of time they are cut off from the influence of life."

But aside from these considerations on methods, Andral had ideas on diseases of the blood. His notion, for example:

". . . and it is, in effect, the great increase in number of the red corpuscles which establishes in the blood the characteristics of plethora."

Or this one: "The blood cannot be deprived of a certain quantity of its corpuscles without causing serious disturbances of the nervous system, which are translated by various disorders of intelligence, emotion and movement."

And he adds what we understood only a century later:

"If the facts on this order were submitted to proper verification, they would doubtless prove of extreme importance, since they would demonstrate that the nervous system exerts a great influence upon the constitution of the blood, and consequently, in the same way, the blood, when it is altered, can modify nervous action. Thus, a disturbance of the nervous system is capable of altering the blood."

These sentences, which might have been written in our time, are the more remarkable when we consider that Gabriel Andral had to struggle against his elders, who, he says, "rejected the microscope as useless, or feared it as a source of error."

Only a century ago there was a slogan of the "microscopic illusion," a slogan which risked to push back for years the coming of the scientific era of medicine.

In his textbook *Cours de microscopie*, Alfred Donné explains in a limpid style the struggle he had to sustain to give the indispensable basis to medical sciences in general, to hematology in particular. Here is what we read—not without emotion—in his book published in 1844:

"For seven years I gave myself up wholly to public teaching of microscopy applied to medical studies. I founded this teaching at my cost, at my risks and perils.

"I can draw out satisfaction from my effort since it took place in the midst of the decadence of teaching, despite the indifference of the physicians and the obstacles thrown to the way by microscopic observation itself. The success obtained went beyond what my zeal and my convictions permitted to hope."

And with a just pride he added:

"My lectures, attended by a great number of French and foreign pupils, contributed to make the importance of the microscope understood and to win the interest and the confidence which it merits. I know what there is still to accomplish in diffusing the knowledge of the use of this instrument in medical practice, to popularize it, as it has to be. But by looking back to a half score of years, by seeing the progress of this science, it is impossible to lack confidence in its future."

"I applied," he said, "the instrument to medical studies, the instrument, which was used habitually by botanists and entomologists."

The work of this great and modest man, which an ungrateful forgetting leaves covered with a thick layer of dust in many libraries, merits to be remembered by those who care for the becoming of the sciences. He was the first, I am sure, who performed the idea of projecting the microscopic pictures by means of an apparatus which he constructed himself to allow his pupils to convince themselves of the reality of a world which the majority of the physicians of his time considered as an illusion.

I found in the *Collection of Reports on the Progress of Literature and Science*, published under the auspices of the Ministry of Public Education and edited in 1867 by the Imperial Printing Office, the echo of the memory of Gabriel Andral:

"We must point out again as one of the titles of which French medicine of our day may boast, the research in the field of liquid composition of the diseased organism. The appearance of the small volume entitled 'An Essay in Pathological Hematology' was a real event. This book has definitely banished a secular error and enthroned a great truth. It was not a question of admitting wherever possible alterations in the blood, but of demonstrating such changes, whenever they occurred."

I realize that I have given much space to Theophile de Bordeu, Gabriel Andral, and Alfred Donné, but I think that their ideas shed more light than could a commentator upon the birth of hematology, upon the "how" environment created by the French clinic, which will permit a mind like Hayem's to perfect that which his predecessors could only hope.

Is it not marvelous to see how these men of random means, in a conservative, even hostile environment, were able, by virtue of their courage and perseverance, to conquer a field, fertilize it, and sow the seed. The harvest, in the work of Georges Hayem, proved beautiful and rich.

The first findings of Hayem came to light at the time Louis Pasteur revealed to the world his discoveries, demonstrating the reality of infections

and identifying microbes. It was the greatest event, the sensation of the century. As a corollary to this discovery, his collaborators studied the organism's defenses in the struggle against the microbe invasion. The function of the white corpuscles was discovered, and it was not at all surprising that they usurped the public interest.

It was at this time that Hayem, somewhat apart from the fashion of the day, set out to build, stone by stone, the magnificent edifice of the red corpuscle. And his great work, "Of Blood and Its Anatomical Alterations," which appeared in 1889, and which he proudly called "long original memoir," will constitute for future generations a monument to contemplate with admiration. In 1878 he had already collected his hematologic publications in a monograph which may be considered as the first textbook on diseases of the blood.

In numerous publications Hayem describes the morphology of the red corpuscle, normal and pathologic. He distinguishes between the artefacts of preparation and pathologic modifications. He created the idea of the color index. He discovered the third figurative element of blood, namely, the platelets; he demonstrated their role in coagulation, a function which was fallaciously attributed to the leucocytes. With marvelous clarity and precision, he explained the phenomenon of coagulation. He showed what profit could be derived from a study of coagulation for the differentiation of hemorrhagic diseases. He taught the notion of the prolonged bleeding time, and observed the retractability of the coagulated blood corpuscle and its nonretractability in certain conditions. He prepared a solution, which to this day bears his name; this solution permits the preservation of the red blood cells without altering them for counting. After Potain and Malassez, he improved the hematologic technique. The list could be indefinitely extended, if I were not afraid of overstepping the limit of time granted me. At every instant, in the practice of treating diseases of the blood, we draw on his experience; at every step we utilize what we inherited from Hayem.

But this heritage became classical and, therefore, anonymous. Many valuable procedures in hematology were introduced by Hayem, but we have forgotten their origin as we have forgotten who taught us to walk.

Aside from these questions of technique, physiology, morphology, we owe to Hayem clinical descriptions of hematologic disorders, which have retained their full value throughout years of progress. It is revealing to read with what care he took, and made others take, his clinical observations in order to find an explanation for them. We who walk over an explored earth can hardly conceive of the difficulties and obstacles on the path of endeavor that this pioneer Hayem assigned himself.

With an admirable clinical sense he treads his way through the hemorrhagic diseases. The hematology of purpura is almost entirely his work. He presents this nosologic group with exemplary clarity:

"1. Scurvy, characterized by etiological conditions in which it is observed. It is found among individuals who were subjected to an inadequate diet . . . by the absence of certain essentials, and particularly those contained in vegetables.

"2. Hemophilia, a hereditary disease, characterized by a considerable diminution of the coagulability of the blood, that is, the property of the blood to join in a mass outside the organism; and by producing abundant hemorrhages on the occasion of the slightest wound.

"3. Purpura, 'a symptom and not a clinical entity.' The characteristics of purpura hemorrhagica from the hematological point of view are:

"a. The absence of appreciable anatomical modifications in the red corpuscles.

"b. A considerable diminution of the number of hemoblasts or platelets.

"c. The lack of constant modifications of the white corpuscles.

"d. Normal coagulation time of the blood.

"e. Absence of the transudation of the serum, resulting from the loss of the property of contraction, which the normal clot possesses." (*Lessons on the Diseases of the Blood*, 1900, page 532.) Later (page 588) Hayem complete this table with another sign: the prolongation of the bleeding time. Who would have guessed, I ask you, that his notations were written a half century ago?

In order to explain the pathogenesis of the purpura hemorrhagica, he recalls his experimental observations, collected at the time of injecting the serum of a bull into a dog. "The symptoms," he writes, "that occur in dogs thus treated correspond exactly to those of the acute hemorrhagic purpura."

And he wonders whether it is possible that "under the influence of certain infections, toxic infections, or even simple auto-intoxications or disturbances of the general diet, alterations in the serum appear, similar to those that are brought about by the heterogeneous serum."

You will perhaps reproach me for having quoted too much. But, in submitting to you all these texts, I wished to have you share in my pleasure and admiration for the luminous and proverbially French clarity of the master. Besides, there is a pitfall to be avoided:

The ideas of today, as of all times, are impregnated and supported by aspirations, by notions barely formulated, common to our contemporaries, which create the atmosphere of a generation. Thus, all too often, in reading or commentating the work of a forerunner, we have the tendency to introduce into the thought of that author our own background, the subconscious plan of our own ideas; we let ourselves go, illuminating with today's light the landscape of Yesterday's Master.

"An ardent reader," wrote Michel de Montaigne, "often discovers in the writings of others perfections which the author had not accomplished or even noticed."

In order to avoid the risk of an interpretation of this type I have let Georges Hayem speak for himself. You are the judges.

The importance of an author, said our André Gide, is contained not only in the value of his work, but also in the opportunity of his message. Georges Hayem's message was certainly timely. Andral was still maintaining that blood was nothing but "liquid flesh." But Hayem knew that to describe the diseases of the blood, he had to describe the diseases of the hematopoietic system. Here is the grand idea formulated: "Very often," he says, "there are present in anemia cases, sensitive modifications of the hematopoietic system, and not merely functional disturbances."

The framework of anemia which he traces has lost nothing of its actuality.

"1. Diseases caused by hematopoietic disturbances, characterized essentially by anemia.

"2. Anemias caused by loss of blood.

"3. Diseases resulting from a hyperplastic or neoplastic lesion of the hematopoietic organs. Leukemia and pseudoleukemia.

"Toxemia. Saturnine Anemia."

One finds in the body of his memoir, as he calls it, ideas which not only answer the needs of his own time, but which also constitute as Montaigne remarks, "food likely to nourish divers hungers of successive generations."

This one for example:

"Blood and serum possess specific properties as to species, the idea of the species being all-important; it will be painful to see it substituted by the idea of toxicity."

Or this idea, expressed in a discussion of the nature of pernicious anemia:

"Pernicious anemia . . . is anemia in those who, while taking the necessary food, have become incapable of assimilating it and extracting from it the necessary materials for the reparation of the blood."

Or this one: "The presence of red corpuseles with nuclei will facilitate the diagnosis of leukemia; with reference to this, we recall the case of a ten-month-old baby suffering from leukemia, whose blood contained a great number of these corpuseles, although the number of white corpuseles was hardly greater than 30,000."

Others before Hayem have successfully delved into hematologic problems, but I do not find it necessary to discuss to whom it is proper to attribute priority in conceiving one method of investigation or another for the description of a given technique. Every conception, every description will carry the personal imprint of the author. And what counts is the echo, the determining influence upon posterity. There will always be historians who discover the forerunners of men of genius.

While rendering respectful homage to other French pioneers of clinical hematology, Potain, Malassez, See, Vidal, Gubler, to cite only a few, we must realize that in this admirable phalanx, from the point of view of hematology, the work of Georges Hayem dominates from a great height, and his is the work that has prevailed. No clinician or investigator before him had, on the whole, as complete and comprehensive a view of the disorders of the blood.

Jolly said of Louis Malassez (and it could well be said of others) that he evoked in us the memory of men of a race almost extinct, of those artisans of the Middle Ages and the Renaissance, who, in the shadow of their workrooms, spent their lives perfecting and polishing some masterpiece with their own hands.

Georges Hayem, on the contrary, is of another mettle. Surrounded by pupils soon to become masters in their own right, he taught at the bedside of the sick or in the lecture room. He had this divine gift of the true professor to communicate, to transmit a brilliant synthesis of the past, together with his own discoveries and those of his contemporaries.

Is this not a sufficient reason for considering his hematology a unit filled with his "spiritual energy," kneaded with his own hands, as his original and personal masterpiece?

If many problems in hematology have changed in aspect, if we now hold different opinions from Hayem's on many questions, having at our disposal better means of investigation, it does not detract from the immensity of his work. He created the hematologic clinic, while hematology might have become and remained a pure morphologic science. As his own anatomopathologist he became the first hematologist.

He showed that, if the clinic without the laboratory is often an uncertainty, the laboratory without the clinic is always a danger.

Providence has put him in the right place by assigning to him a place in a clinic. Providence did better than could have done the secret wish of Hayem himself. Did he not wish to become the successor to Claude Bernard?

Who knows whether the brilliant synthesis of clinic and laboratory would have been evolved? For the strength of Hayem does not lie in abstract speculation (toward which he was driven by some secret longing in his soul), but in constantly confronting and correcting the soul's vision by clinical reality.

Rarely did a man have such clear, such precise vision of the highway that medicine would bestride. Hayem is a descendant of the prophets of Israel when he evokes in a stirring allegory his medicine at the crossroads. I could not forgive myself if I did not read it to you in part.

"Visualize the heads of our School, the eminent clinicians who are the honor of French medicine, as travellers who have walked for a long time and who, at the moment they believe they had come to the end of their tiring journey, about to take a well-deserved rest, suddenly see looming in their path a steep mountain. In their wake they have brought an army of pupils whom they have guided on this road. They are stopped as if by a barrier. These travellers, completely tired out, halt, but not all of them feel the same way about it. Up on the mountain, whose summit is invisible, a few men, taking a wholly different road, carry a flag and make signs of encouragement. Our travellers install themselves in the valley, and some say, 'We shall not go any further; the horizon we shall be able to see from here is sufficient for us. You who are young, climb on, follow these sturdy pioneers, and come back to tell us of the marvels you will encounter in their wake. We are sorry we have no more strength to complete this long and arduous journey.' Still others, luckily fewer in number, are prone to be skeptical and mocking. 'This road is not ours,' they say. 'This mountain is shrouded in clouds. You will be making a useless ascent. You will be like those excursionists who, upon reaching the summits of the Alps, are dazzled by the resplendent sun, and see nothing under their feet, the ground being hidden in opaque clouds.'

"At that time," he continues, "I was still among the young. My principal master was Vulpian, a standard-bearer, as remarkable a scientist as he was a clinician, an indefatigable worker who fell like a soldier on the battlefield. His hand pointed in the right direction. I could not hesitate.

"I thus continued on my way, but sought a path to my taste. Leaving my old masters in the valley, I did not wish to take new guides, and soon I was no longer disdained for being somewhat apart from the great road where the young were crowding, the newcomers, elbowing one another, stumbling over one another's heels.

“These joyous companions, gleefully climbing the mountain which had now become easily accessible, do not realize, having left the base, that the men of my generation needed a certain courage to undertake its ascent.”

And he concludes: “The excursion is far from completed. To teach medicine in our day is to continue one’s education. Isn’t that what constitutes the incomparable charm of our profession?”

Hayem died at the age of 94. He was spared the sorrow of seeing his country in misery, his compatriots in distress. He was spared the humiliation of having the “*ius civitatis sine suffragio et honore*” applied to himself, seeing himself excluded from the French community because he was a Jew. He was spared the humiliation of being dismissed from the school, and from the Academy to whose renown he had devoted all his laborious life. He did not have to suffer the humiliating insults of the laws of discrimination. But what matters the decrees of an ephemeral government in the face of Hayem’s genius?

I think Hayem would have found it sweet and satisfying to know that in the United States, where admiration for his work is so whole and sincere, there are united this evening men without prejudice, ardent defenders of liberty and human dignity, who are thinking of him with love and respect. He would have found it sweet and satisfying to know that he would have had among these men, on this hospitable soil, a second Fatherland.

CLINICAL AND EXPERIMENTAL

THE POLYCYTE*

ERIC PONDER, M.D., D.Sc., MINEOLA, L. I.

IT IS generally recognized that the figures for Cooke's polynuclear count (Cooke, 1914) are related to the life history of the polymorphonuclear in the blood stream. In making the count 100 polymorphonuclear leucocytes are grouped according to the number of lobes in the nucleus of each; "if there is any band of nuclear tissue except a chromatin filament connecting different parts of a nucleus, the nucleus cannot, for the purposes of the polynuclear count, be said to be divided." This is called Cooke's criterion, and distinguishes the polynuclear count from the Arneeth count, from which it is derived. The count is then expressed (taking an average normal count as an example):

I	II	III	IV	V
12	25	44	15	4

Multiplying the number in class I by 1, the number in class II by 2, the number in class III by 3, and so on, and dividing by 100, one gets the mean for the count, in this case 2.74. The significance of the figures in the various classes lies in the fact that it has been shown that the cells of class I are young cells recently derived from the marrow, that increasing lobulation occurs during the lifetime of the polymorphonuclear leucocyte in the blood stream, cells of class I becoming cells of class II, cells of class II becoming cells of class III, and so on, and that the cells of the higher classes, IV and V, are preferentially removed by death (Cooke and Ponder, 1927; Ponder, 1926a, 1926b, 1927; Yeager and Haterius, 1929; Climenko, 1931; Climenko and Ponder, 1934). The normal state is represented diagrammatically in Fig. 1, the arrows indicating the delivery of young cells from the marrow, the removal of old cells by death, and development from class to class. The "shift to the left," characteristic of marrow stimulation, results from an increased production of young polymorphonuclear leucocytes from the marrow, as in acute infections, or from an increased death rate in the higher classes, as in chronic tuberculosis (Ponder, 1927). The successive classes are shown as unequal in length because a cell stays in class I a shorter time than in class II, in class II a shorter time than in class III, and so on.

In 1927 Cooke described a type of polymorphonuclear leucocyte for which it is difficult to find a place in the scheme. It is unusually large, and its nucleus is hypersegmented, sometimes having as many as from 6 to 12 lobes. Cooke gave it the name of macropolycyte, and subsequently classified macropolycytes into

*From the Nassau Hospital, Mineola.

This investigation was carried out under a grant from the Simon Baruch Foundation.
Received for publication, April 21, 1941.

three types. Type I occurs very rarely in health,* occasionally in infection, and in states where there is a marrow reaction, in experimental anemia in the rabbit, and in pernicious anemia. Types II and III resemble megakaryocytes and are found in pernicious anemia.

Plate I.—1, Polycyte from Case 1, corrosive fixation; 2, polycyte, Giemsa; 3, macropolycyte from Case 3, Giemsa; 4, polycyte from blood of guinea pig; 5, propolycyte (note the two very small lobes attached to the third large lobe), Giemsa; 6, propolycyte, Giemsa. (Magnification $\times 344$.)

POLYCYTES AND PROPOLYCYTES IN INFECTION

In acute infection, because of the concomitant marrow stimulation and the delivery of large numbers of young cells into the blood stream, the polynuclear count shows a large number of cells of class I and a left-handed deflection. As the cells of class I develop into cells of class II, and so on, the polynuclear count shifts to the right, and it is usually under such circumstances that I have observed the cells which I call polycytes and propolycytes.

1. *Polycyte*.—This is a polymorphonuclear leucocyte of the usual size, 10 to 14 μ in stained films,† but with a hypersegmented nucleus possessing from 6 to 12 lobes (Plate I). The lobes are often widely separated and joined by long chromatin filaments. One gets the impression that the lobes are unusually

*No macropolycytes were observed in the blood of 90 persons who formed the basis of Cooke and Ponder's (1927) average normal polynuclear count. Cooke subsequently found one macropolycyte in one person, and reported to Kennedy that he had seen one in another healthy person. Kennedy and Mackay (1937) reported 9 in a series of 690 healthy males living in Iraq, and as many as 21 in 487 cases of leprosy, phlebotomus fever, and malaria.

†The size of the polymorphonuclear leucocyte in stained films depends very much on the method of fixation. Most of my material was stained by Giemsa after methyl alcohol fixation, but corrosive sublimate fixation and Heidenhain's iron alum is preferable for the study of polycytes and propolycytes. The cells are distinctly larger after corrosive fixation.

small, and some of the lobes may be very small indeed, looking like buds from larger lobes and connected to them by fine chromatin filaments.*

One frequently sees in polycytes an arrangement shown diagrammatically in Fig. 2 A, in which a fairly large lobe is joined by a chromatin filament to a very small lobe, which in turn is joined to another large lobe by another filament, apparently a continuation of the first. The separation of two pieces of nuclear material with a small piece left between them reminds one of the familiar Plateau's spherule, a very small drop of water which is formed between two larger drops as they separate (Edser, 1933) and which, when it occurs in a viscous fluid, is related to the phenomenon of "beading" in threads. It must be borne in mind that when two nuclear lobes separate, they do not move apart of themselves, but are drawn apart by some force, possibly the forces resulting from their movements through the fluid surrounding them. Given the proper relations of surface tension and viscosity necessary for beading, the appearance of the small lobe in the line of the filament joining two larger lobes is to be expected, and in this connection it may be observed that the appearance of polycytes is often associated with an amoeboid appearance of the polymorphonuclear leucocytes, as if their cytoplasmic viscosity were reduced.

Fig. 1.—Diagrammatic representation of the life history of the polymorphonuclear leucocyte in the blood stream. For explanation, see text.

One also sees an arrangement, such as is shown in Fig. 2 B, in which one lobe is connected to two others by a branched filament. It is difficult to see how this can come about during the process of segmentation of the nucleus, and the possibility must be considered that the branching may be nothing more than an appearance, the "branches" being really two separate filaments lying close together for some distance from the lobe of origin. The filaments are so fine that two of them lying side by side may be impossible to resolve; nevertheless, there is often seen a barely recognizable speck of material at the junction of the branches, and the part of the filament which branches does not seem to be thicker than the filaments which proceed from it.

*In Osgood and Ashworth's *Atlas of Hematology* there are two cells which resemble those described in this paper. No. 84 (neutrophile lobocyte) has 7 lobes and is from a case of myelogenous leucemia. Osgood says that some authors believe that such cells occur only in pernicious anemia and use this as a diagnostic criterion, but that they are also found in granulocytic leucemia, and occasionally in conditions in which the rate of leucocyte destruction is reduced. The cytoplasm is bluer than in the typical polymorphonuclear leucocytes, i.e., more like that of the "toxic" neutrophile as described by Osgood. No. 85 is from a case of pernicious anemia. Osgood describes this as the same as Cooke's macropolycyte, although the "macro" element is missing (the size is 15 by 12 μ , while that of a normal polymorphonuclear leucocyte at the upper limit of size, No. 83, is 15 by 15 μ). Osgood suggests the term polylobocyte, and says that the size of such cells is often larger than that of the typical polymorphonuclear leucocyte. Since the distinguishing feature of Cooke's macropolycyte, type I, is its size, this illustration (No. 85 of the *Atlas*) is probably one of what I call a polycyte. Cooke's macropolycyte of type I would be similar in appearance, but larger (20 by 20 μ).

In my experience polycytes are found in about 10 per cent of cases in which there has been a left-handed deflection of the polynuclear count followed by a commencing right-handed shift, i.e., at the stage of commencing recovery from a marrow stimulation. The following cases illustrate their appearance.

Case 1.—Traumatic amputation of arm and leg. Shock. Overwhelming toxemia from tissue injury. Patient died.

	AFTER ACCIDENT		
	1 HR.	5 HR.	18 HR.
White blood cells per cubic millimeter	13,725	31,900	5,600
Polymorphonuclear leucocytes per cubic millimeter	2,750	30,000	4,050
Polynuclear mean	1.84	1.40	1.31
Polycytes, per cent	0	Propolycytes	2

Case 2.—Pulmonary tuberculosis. Thoracoplasty. Patient recovered.

	BEFORE OPERATION	AFTER OPERATION	
		12 HR.	24 HR.
White blood cells per cubic millimeter	19,978	21,500	21,125
Polymorphonuclear leucocytes per cubic millimeter	14,600	18,900	17,900
Polynuclear mean	1.86	1.38	1.34
Polycytes, per cent	0	6	7

Case 3.—Perforated duodenal ulcer. Shock. Operation ten hours after perforation. Patient recovered.

	BEFORE OPERATION	AFTER OPERATION	
		19 HR.	6 DAYS
White blood cells per cubic millimeter	3,725	13,000	10,775
Polymorphonuclear leucocytes per cubic millimeter	3,150	11,700	10,100
Polynuclear mean	1.04	1.32	1.54
Polycytes, per cent	0	4), and 2 macro-polycytes

2. *Propolycyte*.—This is a polymorph of the usual size, characterized by a nucleus with several lobes, but of a quite unusual degree of complexity. These cells have, indeed, all the characteristics of polycytes, except that their nuclei are not sufficiently hypersegmented. The arrangement of the nuclear lobes, however, is like that seen in the polycyte; the lobes are often small and joined by conspicuously long chromatin filaments, and with respect to one another they lie in patterns not seen in the typical polymorphonuclear leucocyte. Some examples are shown in Plate I.

In health typical propolycytes are rarely seen, but between them and the typical polymorph there exists a whole series of forms, usually referred to as "complex forms" (Ponder and Flinn, 1926). Certain apparently normal persons show few polymorphonuclear leucocytes with three, four, and more nuclear lobes, and yet have a great many complex forms which have to be grouped in classes I and II if Cooke's criterion is adhered to strictly. The same condition is met with in certain animals.*

*In the mouse the polymorphonuclear leucocytes are complex forms, although by Cooke's criterion, they fall into classes I and II. In the guinea pig, cells with as many as 10 lobes occur, and the polynuclear mean is about 5.0. In some of the marsupials, e.g., the wombat, the mean is as high as 5.0 if all cells with more than 6 lobes are considered as cells of class VI. It would be still higher if proper weight were given to cells of the higher classes.

In conditions of abnormal marrow activity propolycytes occur under the same conditions as do polycytes, and are almost certainly a stage in the development of the latter. Thus in Case 1, above, propolycytes preceded the appearance of polycytes, just as in Case 3 polycytes preceded the appearance of macropolycytes.

A CASE OF THE DEVELOPMENT OF POLYCYTES IN VITRO

The phenomenon of polycyte development in vitro deserves a detailed description because the possibility of its occurring has not hitherto been suspected.

The blood was that of a man, aged 53 years, who later had a partial gastrectomy performed for ulcer. In heparinized venous blood withdrawn at 1:20 P.M. on Feb. 26, 1941 (a week before operation), he showed a total white blood cell count of 13,375, with 96 per cent polymorphonuclear leucocytes, and a polynuclear count of

I	II	III	IV	V
10	38	44	6	2

with a mean of 2.52. For a reason entirely apart from the subject of this paper, films were made on both slides and cover slips at 2:30 P.M., 4:00 P.M., and 6:15 P.M., during which time the small bottle containing the heparinized blood stood on the laboratory bench at a temperature which varied between 22.3° C. and 22.7° C. Subsequent counts on the stained films showed polycytes in the following numbers:

TABLE I

TIME (t)	NO. ON SLIDES	NO. ON COVER SLIPS	MEAN NO. IN 400
1:15 P.M.	1 in 400 2 in 400	- -	1.50
2:30 P.M.	3 in 400 2 in 400 5 in 400 3 in 400	- - - -	3.25
4:00 P.M.	1 in 400 6 in 400	1 in 400 6 in 400	3.50
6:15 P.M.	19 in 400 9 in 400 9 in 400 11 in 400	- - - -	12.00

The most convenient way of deciding whether or not the numbers found at the various times can be accounted for by variations in a random sample is to use a method employed in testing defective production of materials (American Society for Testing Materials: *Manual on Presentation of Data*, Section 17). The mean number of polycytes (5.57) and its standard deviation (± 2.34) are calculated for the 5,600 cells counted, and the distribution of the polycytes, with lines marked for the mean number and for 2σ , 3σ , etc., are plotted in Fig. 2. The odds for points lying between the 2σ lines are 20 to 1 or better that they are the result of random sampling of one uniform population of 5,600 cells, the odds corresponding to 3σ about 300 to 1, to 4σ , 10,000 to 1, and so on. The odds that 19 polycytes would be found in a sample of 400 cells taken at random from the blood under consideration are those corresponding to 5.7σ , or about 1 in a hundred million.

Looking at the figure, the trend toward larger numbers of polycytes at the later times is apparent, and the solid central sloping line is that of the equation $N = 1.82t + 1.5$, drawn by the method of least squares. On either side of it are two parallel lines for twice the standard deviation (± 1.46) of the points about this line. All the points lie between these two lines, except the very high point ($N = 19$) at 6:15 P.M. and the two low points ($N = 1$) at 2:30 P.M. Even in the case of these three points the deviation is in the right direction; hence the trend is a real one.

Fig. 2.—Diagrammatic representation of two polymorphs, one showing a small lobe (*P*) between two large lobes, and the other showing a branched filament *B*. For discussion, see text.

This is the only case in which I have followed an *in vitro* development of polycytes in sufficient detail to be certain of it, but on several occasions I have observed (without statistical proof) an *in vitro* increase in the number of propolycytes. The process is all the more remarkable in view of the difficulty encountered in showing any development from class to class in the blood stream of the normal animal (Climenko and Ponder, 1934). Finally, reference should be made to an observation (Ponder and MacLeod, 1938) in which, on one occasion, the blood stream of a rabbit injected with nucleic acid became flooded with macropolycytes within two hours.

DISCUSSION

It is apparent that the propolycyte, the polycyte, and the macropolycyte have a place in any scheme which describes the maturation of the polymorphonuclear leucocyte, and also that the present scheme (Fig. 1) requires some essential modification. I worked out this life history in 1926 by observing the effect of thyroid injections on the polynuclear count in rabbits; the progressive development from class to class was demonstrated, and the whole development from class I to class V was found to take from two to three weeks (Ponder, 1926). This result was confirmed, in general, by Ponder and Flint (1927, deflection with various drugs and extracts, including nucleic acid); Kennedy and Grover (1927, deflection with x-rays); Kennedy and Thompson (1927, deflection by ultraviolet light); Charipper (1928, deflection by thyroid extract in *Necturus*); Danzer (1930, deflection by tissue extracts); and Climenko (1930, deflection by ergosterol and ultraviolet light). In all these cases it was found that the polynuclear count returned to its original steady state after from fourteen to twenty-one days. All these experiments were on rabbits.

MacLeod and I have recently found that the production of sterile peritoneal exudates in rabbits results in a deflection of the count, and that a return to the original steady state takes about seven days, while the return takes only about four days when the deflection is the result of the injection of nucleic acid (1 mg. per kilogram). We explained this on the basis that the polynuclear counts in the rabbits we used were more left handed than those of the animals in the experiments conducted from 1926 to 1930, but the fact is that the time required for a return to the steady state is more variable, and often shorter, than the early experiments indicated.

Fig. 3.—Number of polycytes plotted against time. For explanation, see text.

The simplest way of reconciling these various observations is to suppose that the rate of maturation of the polymorphonuclear leucocyte, as measured by the lobulation of its nucleus, may vary. Cooke (1934) did not consider this possibility specifically in his two suggested explanations for the presence of macropolycytes, the first being an escape from the destructive processes which usually dispose of the cell at the stage of class IV or V, and the second being an altered development due to exposure to an abnormal environment during early development. This second suggestion might cover an increased rate of lobulation. I have considered the converse situation, a decreased rate of maturation, in connection with the steady state in chronic infections, and have dismissed it as applying to that state (Ponder, 1927). An increased rate of passage from class to class, however, would obviously account for the appearance of polycytes and their predecessors, propolycytes. This is what appears to occur in about 10 per cent of the type of case referred to above, and in some cases segmentation is so rapid as to produce polycytes within a few hours.

It should be borne in mind, however, that the macropolycyte of Cooke is unusual because of size as well as hypersegmentation (which may or may not be present in macropolycytes of types II and III; Cooke, 1934). This element of size, without the hypersegmentation, appears in the polymorphonuclear

leucocytes of rabbits with sterile peritoneal exudates and after the injection of nucleic acid (Ponder and MacLeod, 1938), whereas it is more usual in cases of infection to find the appearance of the element of hypersegmentation without that of size. Two factors thus seem to influence the development of the polymorphonuclear leucocyte in the blood stream, and these may operate while the cell is in its early stages, perhaps as early as the stage of the hemocytoblast: the factor for segmentation, and the factor for size. The former is involved in the production of propolycytes and polycytes; the latter, in the production of the kind of polymorphonuclear leucocyte found after peritoneal exudates and the injection of nucleic acid in the rabbit. Both, acting together, are involved in the production of macropolycytes of type I.

The idea of a change in the rate of maturation of the polymorphonuclear leucocyte may be applied to the regional and seasonal variations in the polynuclear count described by MacLeod (1935, 1938), and to the unusual degree of segmentation found in the polymorphonuclear leucocytes of some animals, such as the guinea pig (Curphey and Ponder, 1941) and the wombat (Ponder, Yeager, and Charipper, 1928). The extraordinarily rapid return of the polynuclear count in the guinea pig to its initial steady state after a deflection produced by nucleic acid is strong enough evidence that the life history of the polymorphonuclear leucocyte in this species is different from that of the rabbit and of man.

SUMMARY

1. This paper discusses the relation of two types of polymorphonuclear leucocytes, the polycyte and the propolycyte, to the typical polymorphonuclear leucocyte on the one hand and to the macropolycyte on the other. Polycytes and their precursors, propolycytes, are characterized by hypersegmented or complex nuclei, but are of the usual size (about $15\ \mu$ diameter).

2. Polycytes and propolycytes are probably the result of an increase in the rate of maturation of the polymorphonuclear leucocyte, and a case of their development in vitro is described.

3. These cells make their appearance in about 10 per cent of cases with acute or chronic infection, usually when the polynuclear count is returning, or about to return, to its normal steady state. In general, they are of favorable prognostic significance, and their appearance in states of infection suggest that under such circumstances the rate of segmentation of the polymorphonuclear leucocyte may be markedly increased as a result of factors acting on the cells at some earlier stage of their development.

RECOVERY FROM EXPERIMENTAL POLYCYTHEMIA*

ELIZABETH LOWENHAUPT, M.D., SAN FRANCISCO, CALIF.

POLYCYTHEMIA is generally conceded¹ to be due to increased bone marrow activity. However, in 1929 (Goldbloom and Gottlieb² in their studies on icterus neonatorum reported increased serum bilirubin and raised icterus indices in guinea pigs returned to normal atmospheres after being made polycythemic by exposure to low atmospheric pressures. This, apparently, confirmed observations on hemolysis of blood in plethora due to transfusion³ and seemed to indicate a regulatory, hemolytic control of the level of circulating erythrocytes. It would suggest that a derangement of this mechanism is a requirement for chronic polycythemia vera. An attempt was made to study the site of this hemolysis, but the report indicates failure to verify the fundamental observation of Goldbloom and Gottlieb.

METHODS

Twenty-one male guinea pigs, weighing 550 to 880 Gm., were used. Erythrocyte counts, hemoglobin in grams (by Evelyn photoelectric colorimeter⁴), and reticulocyte counts (brilliant cresyl blue on dry smear) were made at the outset, blood being obtained by pricking a small ear vein. The animals were then placed in the low pressure chamber, where the pressure was reduced gradually over the first week to 350 mm. Hg below atmospheric pressure, i.e., 410 mm. Hg, corresponding to an altitude of 16,000 feet⁵ and maintained at this level for the ensuing two weeks. The apparatus was that described previously.³ The animals were removed daily for perhaps fifteen minutes for cleaning of the chamber and introduction of fresh food, and weekly for about an hour for the above blood determinations. At the end of this period the animals were returned to atmospheric pressure, hematologic determinations were made, one animal of each group was killed as control, and the remainder were sacrificed in series during the next week, or during longer time in a few cases. Blood studies were made every forty-eight hours on the whole group, or just before death when one animal was killed on an alternate day. About 5 c.c. of blood for bilirubin determination were withdrawn by cardiac puncture, after which the animal was

*From the Department of Pathology, Stanford University School of Medicine, San Francisco.

killed and the spleen, liver, and femoral bone marrow were removed. The spleen was weighed fresh, and sections of spleen and liver were fixed and stained for iron. Sections of bone marrow were stained by Giemsa's method. Bilirubin readings were made on the Evelyn photoelectric colorimeter by the method given by Malloy and Evelyn.⁶

Since Goldbloom and Gottlieb removed 0.5 c.c. of blood every forty-eight hours, it was thought that the reticulocytosis dependent on chronic blood loss might have contributed to hemolysis in their experiments. Accordingly, 5 guinea pigs were so treated at low atmospheric pressure. It was also considered possible that their pigs had a larval anemia due to diet, so that 4 guinea pigs were placed on the diet described by Jacobson.⁷ These animals responded to low pressure as did normal controls, previously observed.⁸

Fig. 1.—Averaged responses of 16 guinea pigs. Those on the diet responded as did normal guinea pigs. Hemoglobin values were parallel to red blood cell counts and are not shown.

RESULTS AND DISCUSSION

It is seen that in all types of experiment the red blood cell count and hemoglobin were sharply elevated in response to low pressure. A reticulocyte peak occurred somewhat before the peak of this response. Upon return to normal pressure red blood cell count and hemoglobin fell gradually to normal, preceded by a decrease of circulating reticulocytes. These results are shown in Figs. 1 and 2. The experiment was terminated too early to observe the anemia described at about one month in guinea pigs by Gordon and Kleinberg,⁹ and in rats by Tyler and Baldwin.¹⁰ The bone marrow from marked hyperplasia became more quiescent, a few fat vacuoles becoming evident in section, and circulating reticulocytes practically disappeared, except after chronic blood loss, while erythrocytes and hemoglobin levels were still elevated. At no time was any increase in serum bilirubin demonstrable. The spleen and liver showed no histo-

logic increased iron content during recovery. No quantitative urobilin excretion studies were undertaken, since the more easily obtained and negative evidence was considered to preclude the necessity for this. No explanation is offered as to why none of the animals showed the rise in serum bilirubin which Goldbloom and Gottlieb observed in similar experiments, and which they interpreted as explaining *icterus neonatorum*.

Fig. 2.—Averaged responses of 5 guinea pigs bled every forty-eight hours. Hemoglobin values were parallel to red blood cell counts.

This "physiologic" *icterus* has presented an interesting problem, beyond the scope of the present discussion. Goldbloom and Gottlieb¹¹ considered it due to increased fragility of infants' blood, dependent on high per cent of reticulocytes, which cells they thought particularly fragile. However, increased fragility of the blood of the newborn or of reticulocytes was verified neither by Whitby,¹² using precise methods, nor by Mitchell.¹³ The latter found bilirubin raised at birth and abundant iron in the placenta, but none in the reticulo-endothelial system, this iron appearing later. He concluded that the process producing bilirubinemia must start before birth. A possible explanation of this process is afforded by Barcroft,¹⁴ who showed that fetal hemoglobin has a different dissociation curve, with a slightly greater affinity for oxygen than that found after birth. This observation is corroborated by chemical analysis and by spectroscopy.¹⁴ A process might occur whereby fetal hemoglobin is replaced by an adult type, excess iron being eventually stored in liver and spleen. Waugh, Merchant, and Maughan¹⁵ have recently reviewed this subject and have shown that in the newborn, in whom there is normally accelerated blood destruction, there is no correlation between the rate of fall of blood levels and the degree of bilirubinemia. They consider their evidence consistent with a hepatic origin of the *icterus*. At any rate, *icterus neonatorum* and normally rapid blood destruction in the newborn are not examples of a reaction which in adults might

cause bilirubinemia after previous exposure to low oxygen tension. Acceleration of blood destruction or rise in serum bilirubin has not been demonstrated in adult mammals changed from low to normal oxygen tension.

CONCLUSIONS

In the guinea pig recovery from polycythemia induced by low atmospheric pressure appears dependent on subsidence of increased bone marrow activity rather than on excess peripheral destruction of erythrocytes. No rise of serum bilirubin was found, even in animals in which blood regeneration had been altered by bleeding or by special diet while at low oxygen tension.

STUDIES ON VASODILATATION TESTS IN PERIPHERAL VASCULAR DISEASE*

ABRAHAM GOOTNICK, M.D., HAMIEL SALAND, M.D., CHARLES KLEIN, M.D., AND
HERMAN ZURROW, M.D., NEW YORK, N. Y.

THE fact that functional states may simulate organic involvement of the peripheral arterial tree has long been recognized. This has led to the devising of various tests for differentiating organic narrowing or occlusion of peripheral vessels (a permanent, nonreversible change) from narrowing due to vessel spasm (a transient, reversible change).

This differentiation, moreover, is important not merely for diagnostic reasons, but for its prognostic and therapeutic implications as well. Organic involvement, as in arteriosclerosis obliterans or thromboangiitis obliterans, implies a long-drawn, laborious effort to establish and to extend collateral circulation. The prognosis, even in cases of moderate involvement, is not too bright. In functional cases, however, the problem of releasing vessel spasm can be solved in most instances by physical or chemical means; in any case, the possibility of the involvement progressing to the death of tissue is less likely.

In addition there is the large group of cases where spasm and organic encroachment on vessel lumen coexist to varying degrees, and here the problem has been to establish the respective roles of the two causative mechanisms. The three tests here reported on are (1) the thermal reflex vasodilatation test; (2) the peripheral nerve block; and (3) the sodium nitrite test.

The thermal reflex vasodilatation test is based on the physiologic fact that when excessive heat is applied to a part of the body, the body attempts, through a compensatory generalized cutaneous vasodilatation, to dissipate this heat. The mechanism appears to be a reflex release of sympathetic vasoconstrictor influence. This vasodilatation, manifested peripherally by elevation in skin temperature of the extremities, is measured with a thermocouple.

Complete vasodilatation, under the standard conditions of the test,¹ is taken to indicate normal patency of peripheral arteries in the extremity tested, with no appreciable organic encroachment on the lumen of these vessels. However, we have found that failure of an extremity to show maximal vasodilatation is not invariably due to organic obliterative involvement; it may be an expression of a degree of vasoconstrictor tone (spasm) so high that the thermal stimulus is not sufficient to undo it. Every such failure in a proved nonorganic case of vessel spasm is, of course, a mark against the reliability of the thermal test.

Peripheral nerve block is a direct attack on the sympathetic innervation of the foot or hand, aiming at local vasodilatation. In the lower extremity the posterior tibial nerve at the ankle and the common peroneal nerve at the neck

*From the Department of Peripheral Vascular Diseases, Bronx Hospital.
Received for publication, May 8, 1941.

of the fibula are blocked with novocain. In the upper extremity the median nerve at the wrist and the ulnar nerve at the elbow are similarly blocked. The resulting abolition of sympathetic control manifests itself in vasodilatation distal to the level of block, and the rise in skin temperature is again measured as in the thermal test.

The sodium nitrite test² exploits the well-known relaxing effect of nitrites on the smooth muscle of peripheral blood vessels generally. The dose of sodium nitrite given intravenously is kept small enough to obviate any secondary vasoconstrictor manifestations: 1 c.c. of $\frac{1}{4}$ per cent sodium nitrite for the adult of average size. The major peripheral effect in this test is not an increase in blood flow, as in the thermal test and in peripheral nerve block, but an increase in pulsating volume of the limb, and a pooling of blood in the venocapillary bed.² There is thus no rise in skin temperature suitable for thermocouple determinations. The effect is tested with the oscillometer, which records the increased amplitude of pulsation when this occurs. The increase in oscillations is taken as a measure of the degree of spasm present before the test, and the failure of oscillations to increase indicates advanced organic involvement, with little or no coexisting vessel spasm.

The object of this study was to investigate the capacity of each of these three procedures to abolish vessel spasm and to induce in the limbs tested the maximal vasodilatation of which they were capable. We wished to establish the relative dependability of these tests as indicators of vessel spasm, and hence to derive definite impressions of the place of these tests in the study of peripheral vascular disease.

Our clinical material included 75 patients with a variety of peripheral vascular disorders. Each of these patients, in addition to a clinical estimate of his peripheral vascular status, was subjected to at least two of the foregoing tests *one or more times*. The clinical evaluation was arrived at on the basis of a complete history and physical examination, and a comprehensive examination of the extremities, including observations on rubor, pallor, temperature, peripheral pulses, nutritional changes, oscillographic determinations, claudication studies, and x-rays. The cases were, with few exceptions, reviewed at staff conferences, so that the clinical classification represented the consensus of the clinical staff.

In correlating with these clinical findings the results of the thermal, nerve block, and nitrite tests, we have found etiologic distinctions alone unsatisfactory. We have grouped the patients on the basis of the degree of vascular impairment,³ since the value of these tests lies not in differentiating between the various peripheral vascular ailments, but in indicating the latent vascular reserve of the patient.

Of the 75 patients included in this study, 15 were in the IIA group, i.e., they had organic involvement with minimal symptoms, with varying degrees of associated vessel spasm; 32 were in the IIB group, i.e., they had more advanced organic involvement with moderate symptoms, but were short of open lesions or gangrene; 28 were in the functional group (class IV),³ with normal vascular reserve and no demonstrable organic disease. In the latter group the symptoms were entirely due to vessel spasm.

Table I represents in summary the relative dependability of the three tests. Of 35 thermal tests done on patients in the functional group, only 11 revealed the full degree of the vascular reserve in the limbs tested. Twenty-four of the 35 thermal tests (69 per cent) failed to induce the maximal vasodilatation which was attained in response to other tests. Thus, in one patient after another whose symptoms, from a clinical viewpoint, seemed due solely to vasospasm, reliance on the thermal test alone would have led to the wrong conclusion that organic vascular disease was present.

TABLE I

GROUP	THERMAL			NITRITE			BLOCK		
	NO. OF TESTS	NO. WITH MAX. VASO-DILATATION	% SUC-CESS	NO. OF TESTS	NO. WITH MAX. VASO-DILATATION	% SUC-CESS	NO. OF TESTS	NO. WITH MAX. VASO-DILATATION	% SUC-CESS
Functional	35	11	31	17	12	70	24	24	100
IIA	23	6	26	6	3	50	13	13	100
IIB	37	20	54	23	10	43	29	28	96

It may be seen at a glance that the best showing of the thermal test was in the group IIB cases. In this group patients with advanced organic obstruction of vessels showed a minimal capacity for vasodilatation to begin with, and hence the inconstancy of the thermal stimulus to release spasm is obscured. In the IIA and functional groups, however, this weakness of the thermal test becomes conspicuous. For patients in these groups latent capacity for vasodilatation is high, and inadequate response to the thermal test repeatedly was followed by complete, or almost complete, vasodilatation after peripheral nerve block.

The reliability of the nitrite test paralleled roughly that of the thermal test in the IIB group, but was considerably ahead of the thermal test in the functional group. The greater incidence of failure in the subjects with advanced organic involvement may be due to the fact that the nitrite test measures increase in pulsating volume; and sclerotic, rigid, inelastic vessels are less capable of enhanced pulsation than the structurally normal arteries of the functional cases. In cases with no organic disease, where spasm alone was the cause of symptoms, the nitrite test was more dependable, and gave accurate indication of the actual vascular reserve in 70 per cent of cases.

Peripheral nerve block, properly performed and confirmed by the development of anesthesia or paralysis along the distribution of the nerves, was, in our experience, by far the most accurate and dependable test for vasospasm. With the exception of only one case, we found no instance where vasodilatation in response to any other measure exceeded the vasodilatation following nerve block.

Table II represents the results in a number of patients, each of whom was subjected to thermal test and nerve block done in a parallel fashion, i.e., under similar conditions and within several days of each other, to obviate the possibility of a change in vascular status between tests. Again, whereas the thermal test was accurate in only 30 per cent of the functional cases, and in 46 per cent of the IIB cases, nerve block was almost unfailingly effective in inducing the maximal vasodilatation possible in the limb tested.

TABLE II

GROUP	NO. OF PARALLEL STUDIES	THERMAL		BLOCK	
		NO. WITH MAX. VASO- DILATATION	% SUCCESS	NO. WITH MAX. VASO- DILATATION	% SUCCESS
Functional	23	7	30	23	100
IIA	13	3	23	13	100
IIB	28	13	46	27	96

In Table III are summarized parallel studies of nitrite test and nerve block. The results once again confirm the consistent accuracy of peripheral nerve block.

TABLE III

GROUP	NO. OF PARALLEL STUDIES	NITRITE		BLOCK	
		NO. WITH MAX. VASO- DILATATION	% SUCCESS	NO. WITH MAX. VASO- DILATATION	% SUCCESS
Functional	10	6	60	10	100
IIA and IIB	17	5	29	16	95

Table IV shows the results of thermal and nitrite test studies done in parallel manner. While in the patients with organic damage the nitrite test falls below the thermal test in dependability, it is approximately twice as accurate as the thermal test in functional cases.

TABLE IV

GROUP	NO. OF PARALLEL STUDIES	THERMAL		NITRITE	
		NO. WITH MAX. VASO- DILATATION	% SUCCESS	NO. WITH MAX. VASO- DILATATION	% SUCCESS
Functional	16	7	43	13	81
IIA and IIB	29	16	55	12	41

SUMMARY

In the study of the patient who presents himself with symptoms referable to the peripheral arterial tree, all three tests discussed have a place. The place for each is indicated in the results we have summarized in the accompanying tables.

Sodium nitrite injected intravenously and the hot water bath are both useful as preliminary tests for vasospasm. Of the two, the thermal test is better suited to patients with organic vascular involvement when we wish to discover the degree of associated vessel spasm. In patients who give the clinical impression of nonorganic vasospastic involvement the nitrite test is considerably more dependable. It is also more feasible for patients prone to syncope in a hot bath.

In our clinic a patient whose vasodilatation in response to either of these tests reaches normal values is then regarded as possessing normal vascular reserve. Those who respond to either of these tests with subnormal vasodilatation are then tested with peripheral nerve block. The advantage of this scheme is that in a considerable proportion of patients a simple, nonmanipula-

tive procedure serves adequately to reveal the intensity of spasm and the vascular reserve of the limb in question. Nerve block is reserved as the test of last appeal for those patients in whom either the thermal stimulus or the sodium nitrite failed to induce fully normal vasodilatation.

We wish to acknowledge the participation of Dr. Abraham Kahane and Dr. Abraham Katz in the performance of the tests described.

PRIMARY AMYLOIDOSIS OF THE LUNGS*

S. W. SAPPINGTON, M.D., JOHN H. DAVIE, M.D., AND J. ARTHUR HORNEFF, M.D.
PHILADELPHIA, PA.

AMYLOID disease, as is well known, usually follows certain chronic diseases, such as tuberculosis, and is characterized by massive and easily recognized lesions of the spleen, liver, kidneys, and adrenal glands. This is the secondary and typic form. It is less well known that there are rare, atypic, so-called primary forms of this disease which are seldom recognized clinically. The criteria for this atypic group were pointed out by Lubarsch¹ and are (1) Almost complete absence of amyloid in organs most involved in typic amyloidosis, such as spleen, liver, and kidneys. (2) Presence of amyloid in organs and parts not usually involved, such as heart, lungs, and skin. (3) The occasional occurrence of tumor-like nodules of amyloid. (4) The frequent failure of the deposits to react to the specific stains or tests for amyloid. (5) The absence of a preceding or concomitant disease to which the presence of amyloid may be ascribed. The case report herewith cited is an excellent example of the primary or atypic form and illustrates the lack of clinical awareness of this condition.

REPORT OF CASE

The patient was a woman, aged 51 years, who had three outstanding complaints: extreme fatigue on the least exertion, dyspnea even at rest, and upper abdominal distress.

*From the Department of Pathology, Hahnemann Medical College and Hospital, Philadelphia.

Received for publication, May 9, 1941.

Her family history was unimportant. She had had no chronic illness of any sort or any previous serious acute illness. She had no peculiarities of appetite, and no drug habits. She at no time had any symptoms referable to her tongue. In 1925 she had a tonsillectomy. In 1927 she received radium treatment for uterine fibroid. Menstruation continued until 1935.

Three years ago she noticed some thickening of the eyelids, and subsequently a similar condition involving the external auditory canal. Next there was thickening of the skin in the groin, which extended down to the vulva and rectum. In September, 1939, she was treated by a physician for arthritis involving the right knee and received four injections of lipoid iodine solution into the joint. Since April, 1940, she suffered from increasing dyspnea, and until near her death she was quite dyspneic when at rest in bed. She was hospitalized in September, 1940, for a study of the skin lesions. In the hospital these lesions were observed as yellowish brown elevations or infiltrations involving both upper and lower eyelids on both sides; as yellowish brown thickenings narrowing the lumina of the auditory canals almost to complete closure; and in the groins, not as nodular or glandular enlargements, but as wide areas of infiltration extending around to the rectum. The dermatologist made a diagnosis of xanthoma, and a biopsy was done on the eyelid and groin lesions. The pathologic report on these tissues was not definite. It was stated "that the tissue was probably originally xanthomatous but did not show that condition clearly now." The hyaline or homogeneous appearance of the subepidermal tissue in both eyelid and groin tissues was noted, but the real condition was not recognized. In October, 1939, a biopsy was done on the occluding lesion of the ear canal. The pathologist who examined the specimen also consulted a dermatologic pathologist on the diagnosis, and the joint opinion was colloid degeneration of the skin.

In the interval between April, 1940, and January, 1941, the patient consulted many physicians without diagnostic satisfaction, though she was assured she had no heart trouble. She became steadily worse, and a nonproductive cough was added to her increasing dyspnea. She was again hospitalized on Jan. 14, 1941, when the following data were recorded:

The patient was a large woman, about 6 feet tall, weighing over 200 pounds. She exhibited no cyanosis or jaundice, but was patently dyspneic at rest. She presented a pale and waxy appearance, with some swelling of the feet. Her mouth was clean and her teeth were good. Her tongue was moist and subjectively and objectively negative. Her heart sounds were weak but regular, and no murmur was detected. The systolic pressure was 134 mm. but the diastolic pressure could not be satisfactorily read. The electrocardiogram showed coronary T-waves in Leads I and II. No rales or other abnormalities were detected over the lungs. The roentgenogram showed some enlargement of the cardiovascular silhouette, and the lung fields were indefinitely hazy. There was some tenderness over the gall bladder and duodenum, but the liver and spleen were not palpable and there was no abdominal mass. The urine on all occasions showed considerable albumin and hyaline and granular casts. Urinary concentration was good. The hemoglobin was 12.8 Gm., the red blood cell count was 4,160,000, and the white blood cell count was 6,900. The differential count was normal. Blood sugar was 105 mg., blood urea 14 mg., blood creatinine 1.2 mg., and cholesterol 187 mg. The Wassermann and Kahn tests were negative.

After five days in the hospital the patient died suddenly and quietly without fever, rise of pulse rate, or signs of heart failure.

Autopsy.—Body that of an obese, white female of about 50 years. Nodular infiltrations of eyelids and groins, and slight edema of lower extremities, were noted.

The pericardium was normal in appearance. The heart was generally enlarged, weighing 510 Gm. There was moderate hypertrophy of both ventricles, the left ventricle measuring 18 mm. and the right 8 mm. in thickness. Otherwise auricles and ventricles appeared normal. There was no scarring grossly apparent, and there was no stiffening or fixation of the auricular walls. The orifices and valves were normal. The coronary arteries showed some atherosclerosis but no occlusion. The ascending portion of the thoracic aorta showed minimal atheromatous change; the abdominal aorta exhibited a moderate amount.

The lungs, in situ and on removal from the body, presented an expanded appearance without any tendency to the usual post-mortem collapse. The right lung weighed 860 Gm. and the left lung 810 Gm. They were dry, pinkish in color, and showed no focal changes, no areas of pneumonic consolidation or tuberculosis, and no edema. The cut surface had a fine honeycombed appearance, the empty alveoli remaining expanded. In appearance and consistency the lungs resembled a fine rubber sponge. Pleural cavities were normal. Tracheal and bronchial passages were free.

The spleen (150 Gm.) and the liver (1,810 Gm.) were without noteworthy gross changes. The gall bladder and ducts were normal. The pancreas was unchanged. The adrenal glands were apparently normal. The kidneys were embedded in considerable fat, each weighing 100 Gm. and showing some surface-pitting. The capsules stripped easily, revealing slight granularity. On section the cortex-medulla ratio was about normal. No abnormal findings were noted in the ureters or bladder. The uterus presented on the posterior surface a subserous fibroid, 1.8 cm. in diameter; uterine cavity and cervix showed no special change. Tubes and ovaries were unnoteworthy. Esophagus, stomach, and intestines gave negative findings, except a segment, about 100 cm. proximal to the ileocecal valve, which exhibited a peculiar honey-brown color not due to fecal staining or circulatory block, and not explained by observation of the opened gut.

Fig. 1.—Amyloid infiltration of arteries of *a*, liver; *b*, uterus; *c*, adventitia of aorta; *d*, heart.

Microscopic Examination.—The findings with the exception of the amyloid change were insignificant, and will only be mentioned incidentally in discussing in detail the more important amyloidosis. Sections were stained with hematoxylin and eosin, Mallory's connective tissue stain, Weigert's elastic stain and van Gieson, Congo red and methyl violet, and sudan III.

The liver was normal, except for amyloid infiltration involving branches of the hepatic artery; these were uniformly amyloid throughout. The hyaline appearance of the arteries was in contrast to the branches of the portal vein which were entirely uninvolved (Fig. 1*a*). In the spleen the pulp was congested, and the Malpighian follicles were inconspicuous. The amyloid change here was the slightest, and consisted only of partial involvement of the central arterioles of the follicles; even these responded poorly to the Congo red and methyl violet stains. The pancreas showed no amyloid whatever in the vessels or elsewhere. The kidneys likewise contained no amyloid in any part of many sections examined. There was a minimum amount of cortical sclerosis and moderate congestion of the glomerular and intertubular capillaries, but no capsular thickening and no hyalinization of the arterioles. There was some degeneration of the tubular epithelium, but no fat reaction with sudan III. There was slight proliferation of the endothelium of the glomerular capillaries. Sections of the intestine from the discolored segments showed necrosis involving the entire wall. The mucosa presented only smudged shadows of the epithelium and lymphoid tissue. The

submucosa still showed structural integrity of the small arteries and veins; the former were amyloid and the latter were unaffected. These intestinal arterioles stained perfectly for amyloid with Congo red and methyl violet. Sections of the subserous myoma of the uterus showed some hyalinization of the fibromyomatous tissue, but these did not react to amyloid stains. All arteries in the section, however, were amyloidized with extreme thickening in some vessels almost completely occluding the lumen (Fig. 1b). The veins again were uninvolved. There was a very small amount of amyloid in the tissues about some of the arteries.

In the heart there was seen a small amount of necrosis and fibrosis in the subendocardial fields, involving especially the papillary muscles, but there was no amyloid here or elsewhere, except in the walls of the small arteries of the parenchyma (Fig. 1d) and the epicardium, and these were uniformly involved. Again there was contrast in the freedom of the veins from amyloid change. In the aorta the arterioles of the adventitia showed amyloidosis, and the veins were free (Fig. 1c).

Fig. 2.—Amyloid infiltration of the pulmonary alveoli.

The lungs showed extreme amyloidosis. In addition to the practically universal involvement of both arteries and veins there was almost complete amyloid infiltration of the alveolar walls (Fig. 2). The great thickening of the vessel walls thus induced reduced the lumen markedly and in the smaller vessels to a minimum (Fig. 3). The amyloid of the alveolar walls was presumably related to the capillary wall, but the thickening was relatively so great, and various nodular enlargements so numerous, that fine distinctions could not be made. It is difficult to conceive of much function in lungs so altered. The bronchioles were inconspicuous with lining epithelial cells desquamated and lumina compressed by the swelling of the neighboring vessel walls. There was no amyloid in the bronchial walls. In the few fields where the alveolar walls showed little amyloid, the alveolar spaces contained monocytic cells, but there was no inflammatory exudate or edema. The only demonstrable lesion in the lungs was amyloidosis, and this was diffuse and almost complete. The response to amyloid stains (Congo red and methyl violet) was perfect.

In sections of the various organs stained with Weigert's elastic stain, it was noted that the site of amyloid formation was apparently primarily the media, later extending to the intima. This was well seen in vessels of the uterus and lungs. The intimal involvement tended to close the lumen, while the medial lesions thickened the wall and distended the adventitia but did not seem to involve it.

When the nature of lesions in this case was apparent, we looked for, and fortunately were able to find, the paraffin blocks made from the biopsies of the eyelid and groin done four months previously. Sections of the skin of the eyelid showed a thin epidermal layer, and immediately beneath it and extending through the entire section clumps and masses of tissue containing one or more vessels of capillary or precapillary size. These tissue masses looked like hyalinized or relatively acellular fibrous tissue, but they took the amyloid

stains throughout (Fig. 4a). The vessel walls did not take any amyloid stain. A similar appearance and reaction was noted in the sections of the skin of the groin. In one field of these sections were arterioles, showing hyalinized walls quite like those in the same vessels in the viscera. These vessels, however, did not give the amyloid reaction as did the extravascular homogeneous tissue in the eyelid sections (Fig. 4b).

Fig. 3.—Amyloidosis of the pulmonary vessels. Note the marked narrowing of the lumen.

Fig. 4.—*a*, Skin of eyelid showing amyloid in corium and subcutaneous tissues. *b*, Skin of groin showing hyalinization of vessel walls and amyloid of the mesodermal tissues.

The final pathologic diagnosis was primary systemic amyloidosis with maximum concentration in the lungs, moderate involvement of the skin, and involvement limited to the small and medium-sized arteries systemically. Moderate cardiac hypertrophy.

COMMENT

Here is a case of primary amyloidosis with lesions in the lung quite as great quantitatively as those found in a tuberculous or pneumonic infection of the organ, and yet unrecognized clinically as have been the great majority of atypic

amyloidoses in the past. The failure of the clinical diagnosis in this condition is probably dependent upon (a) the retention of the old conception of amyloid disease as exclusively a secondary condition with massive lesions in the spleen and liver; (b) the rarity of the atypic forms; (c) the variations in the dominant lesions and consequent clinical phenomena in primary amyloidosis; (d) unfamiliarity with diagnostic leads, such as the condition of the tongue; (e) the failure to be amyloid conscious with respect to skin lesions.

The rarity of primary amyloidosis is indicated in Reimann's² statement in 1935 that up to that time about 35 cases had been reported. Reimann's case, reported at that time, is apparently the first to be diagnosed clinically. Of these 35 cases, 17 were systemic with general distribution of the amyloid; the remaining were primary, with the localization of the amyloid largely in one or two organs. Using this classification, Koletsky and Stecher³ in 1939 were able to find only 23 cases of primary systemic amyloidosis in the literature, and added one of their own. Most of the cases have been reported since 1929, when Lubarsch's⁴ article aroused interest in the condition. Very few of them have been reported in medical journals dealing with general or internal medicine: most of them have appeared in publications devoted to pathology or dermatology, all of which helps to account for the general unfamiliarity with the subject. Atypic or primary amyloidosis should not be confused with cases of secondary amyloid presenting lesions in unusual situations, as in multiple myeloma. Nor should cases of atypic amyloidosis be considered good examples of the primary form when presenting massive lesions of the spleen, liver, or kidneys, in addition to deposits elsewhere.

In the cases of primary localized amyloidosis there is considerable variation in the distribution of the amyloid deposit, so that the concentration may be dominant in one or two organs or parts, such as the tongue, heart, skin or lungs, and less frequently in the gastrointestinal tract, female genitals, joints, muscle, bone marrow, or even the nervous system. Though such cases are reported as atypic, local, or primary amyloidosis of the heart,⁴ lung,⁵ skin,⁶ or tongue,⁷ there may be actually a systemic or diffuse distribution of amyloid scant enough in other parts to be only recognized by the microscope, as in the case reported here. Few cases in the literature show the dominant pulmonary lesion seen in our case. In either the local or systemic form of primary amyloidosis the tissue affected is mesodermal and usually intimately related to the vascular system.

Primary amyloidosis is slowly coming into recognition as a clinical entity, and ante-mortem diagnoses of the condition, now relatively few, may be increased by attention to certain clinical phenomena. Unexplained fatigue and dyspnea are common nonspecific symptoms marked in major involvement of the heart or lungs. Gastrointestinal complaints may actually be amyloid in nature, as may be joint symptoms. The leads which may indicate the specificity of other symptoms and make the diagnosis possible are found in the tongue and skin.

Involvement of the tongue is one of the most common and most suggestive signs of atypic amyloidosis. This organ was the seat of amyloid deposit in 20 of 24 cases reported by Koletsky and Stecher.³ The macroglossia may be

so great as to cause dysphonia and dysphagia, and even lead to the diagnosis of malignancy, as in one of Lubarsch's¹ cases which was diagnosed as carcinoma of the tongue. In Gerstel's² case the swelling was so great that the patient could not close her mouth, and sarcoma of the tongue was suspected. Warren,³ in a discussion of a case reported by Robertson and Brunsting,¹⁰ cites two cases and states that the patients in both instances complained that their tongues were too large for their mouths and that they had difficulty in swallowing. Their tongues had the characteristic rubber feel of amyloid spleen or liver. Warren was able to make a diagnosis in the second case from the tongue lesion. The part may be deeply furrowed and fissured. Our patient made no complaint at any time referable to the tongue, and we unfortunately did not examine tongue sections after death. It is not unlikely that had we done so we would have found amyloid. Robertson and Brunsting's¹⁰ case did not have symptoms referable to the tongue, but showed amyloid involvement post mortem.

Amyloid lesions of the skin are not as common as those of the tongue, and amyloid skin lesions may be of the purely local type and not indicative of systemic amyloidosis. Schilder¹¹ examined post mortem the skin of 14 patients showing advanced secondary amyloidosis and was able to demonstrate amyloid deposits in seven, including amyloid lesions in the sweat and sebaceous glands. The skin, however, showed no clinical change. When a case presents an obscure clinical complex and skin lesions are found, they may be of the utmost diagnostic importance, especially in conjunction with tongue symptoms. Amyloid skin lesions are described¹² as small papules, yellowish, yellowish brown, or brown in appearance. In our case they were yellowish brown and somewhat nodular. The injection of Congo red intravenously in cases of primary amyloidosis has not yet been properly evaluated. The test was negative in the cases of von Bonsdorff,¹³ Reimann,² and Nomland.⁶ Nomland⁶ has injected Congo red subcutaneously or intracutaneously in the region of the lesions with success, and his results have been confirmed by Robertson and Brunsting,¹⁰ and Philpott and Freshman.¹⁴ In such injections the first diffuse red staining of the skin and lesions later fades, leaving the amyloid lesions a rose red, and this may persist for days or even months. The specific staining of the amyloid lesions with Congo red was later proved by biopsy in Nomland's⁶ case. This test, if reliable, should prove of great diagnostic value.

Finally, the diagnosis may be definitely made by biopsy of the skin or glossal lesions. Such sections usually give typical amyloid reactions with methyl violet and other specific stains. The importance of the amyloid-conscious state in such examinations is evident, however, as is seen by the failure of three pathologists to recognize the amyloid in our case, and the fact that the amyloid nature of the sections was not realized in Koletsky's and Stecher's³ case until the third biopsy had been done.

SUMMARY

A case of primary amyloidosis is reported in which the distribution of amyloid was systemic but massive only in the lungs, and to some extent the skin. The condition is rare and is seldom diagnosed clinically. The diagnostic importance of lesions of the tongue and skin is stressed.

EXPERIMENTALLY INDUCED HEMATOPOIESIS IN ANEMIC RABBITS*

HAROLD GORDON, M.S., M.D., F.A.C.P., CHARLES H. CRUDDEN, A.B., A.M., Ph.D.,
AND ARTHUR K. LAMPTON, A.B., M.S., LOUISVILLE, KY.

HEMORRHAGE is a well-recognized stimulus of hematopoiesis. The following experiment was accordingly devised to determine whether or not posthemorrhagic hematopoiesis is due to a stimulant circulating in the blood of animals subjected to a single large hemorrhage.

MATERIAL AND METHODS

Fifteen healthy rabbits of comparable age and weight were kept under observation for a week or longer. During this time three or four determinations were made of their erythrocyte and leucocyte counts and hemoglobin percentages. These varied only slightly and were within the accepted limits of normal.¹ The average of the values obtained for each rabbit was accordingly accepted as the "normal" for that animal. Following this preliminary period of observation, the rabbits were rendered anemic by removing blood from the heart. The erythrocyte and hemoglobin values in each case were reduced as rapidly as possible to about 60 per cent of the normal, and maintained by repeated bleeding at approximately this level for variable periods. The amount of blood removed and the frequency of bleeding varied considerably, the erythrocyte counts and hemoglobin value being the sole determining factors in each case. After the anemia had been maintained for ten to fourteen days, the animals were divided into three groups, as follows: (1) A control group, comprising 4 rabbits, received no transfusions. (2) A second control group of 5 rabbits received transfusions intravenously with blood removed by cardiac puncture under sterile conditions from healthy rabbits. (3) A group of 6 rabbits received transfusions from "prepared" donors. Preparation of the donors consisted of preliminary bleeding in order to stimulate hematopoiesis. The bleeding was performed by cardiac puncture, from 15 to 20 c.c. of blood being removed by a single puncture, about three to five days before it was planned to use the blood of these rabbits for transfusion purposes. The resulting degree of hematopoietic stimulation was judged by repeated reticulocyte counts. Blood was removed from the stimulated donors by cardiac puncture and injected intravenously into the anemic rabbits when the reticulocyte response of the donors was judged to be at its peak. (Subsequent reticulocyte counts on the stimulated donors showed that the peak was judged correctly in all but one instance. The donor in this case showed a moderate increase of its

*From the Department of Pathology, School of Medicine, University of Louisville, Louisville.

Received for publication, May 12, 1941.

reticulocytes the day after its blood was used for transfusion.) A distinct reticulocytosis occurred in all the prepared donors. Determinations were made of the reticulocytes, erythrocytes, leucocytes, and hemoglobin at frequent intervals until the erythrocyte counts were at or above normal.

All the rabbits used in this experiment received the same general care. They were housed in well-aired metal cages in a large, well-ventilated animal room, and allowed a balanced commercial ration and water *ad libitum*.

TABLE I

SUMMARY OF EFFECTS ON ERYTHROCYTES AND HEMOGLOBIN OF RABBITS COMPOSING THREE EXPERIMENTAL GROUPS

EFFECTS	NORMAL CONTROLS	RABBITS GIVEN TRANS- FUSIONS FROM	
		HEALTHY DONORS	PREPARED DONORS
<i>On Erythrocytes</i>			
Number of animals	3.0 ^a	5.0	6.0
Average duration of anemia, days*	13.7	11.0	11.5
Average degree of anemia, per cent†	56.5	58.4	60.0
Average total amount of blood removed, c.c.	175.0	140.0	185.0
Average amount of blood transfused, c.c.		38.0	33.0
Average recovery time, days‡	18.0	10.8	8.0
<i>On Hemoglobin</i>			
Number of animals	3.0 ^a	3.0 ^b	5.0 ^c
Average duration of hemoglobinemia, days	10.3	14.0	10.6
Average degree of Hb. deficiency, per cent†	61.0	68.0	63.0
Average total amount of blood removed, c.c.	175.0	152.0	177.0
Average amount of blood transfused, c.c.		46.0	37.0
Average recovery time, days‡	19.3	9.0	6.8

*The average duration of the anemia was determined by computing the time in days during which there was a severe deficiency of erythrocytes and hemoglobin.

†The average degree of anemia was computed by determining the period during which each animal showed its most severe erythrocyte and hemoglobin deficiency.

‡The average recovery period represents the time taken for the restoration of the erythrocytes and hemoglobin to normal values.

^aOne control rabbit died before the erythrocyte count and hemoglobin returned to normal and is, therefore, not included in the summary.

^bThe hemoglobin of two rabbits in this group remained subnormal during the experimental period. They are omitted from the summary.

^cOne rabbit in this group still had a hemoglobinemia when the experiment was discontinued. It is not included in the summary.

RESULTS

The individual protocols are illustrated graphically in Charts 1 to 6. These show the amount of blood removed, the resultant degree of anemia, the amount of blood transfused, and the recovery period for each rabbit. The untransfused control group recovered very slowly and imperfectly, as judged by both the erythrocyte and hemoglobin determinations. One animal in this group died six days after the last bleeding. The day before death its erythrocyte count was still only 40 per cent of the pre-experimental level. At autopsy it showed severe anemia, dehydration, and emaciation. Another rabbit in this group required a month for the restoration of its erythrocyte count to normal. During all this time it was in poor condition. The remaining two in this group recovered in ten and sixteen days, respectively. It is interesting that neither the total amount of blood removed nor the frequency of bleeding influenced decisively the time required for recovery, since Rabbit No. 11‡ recovered the most rapidly, in spite of having been bled more severely than any of the other

Chart 1.—Control group, not given transfusions. Erythrocyte counts, expressed in percentage of the normal. Arrows pointing downward represent bleeding from the heart.

Chart 2.—Control group, not given transfusions. Hemoglobin, expressed in percentage of the normal. Arrows pointing downward represent bleeding from the heart.

Chart 3.—Control group, given transfusions from healthy donors. Erythrocyte counts, expressed in percentage of the normal. Arrows pointing downward represent bleeding from the heart. Arrows pointing upward represent intravenous transfusion.

Chart 4.—Control group, given transfusions from healthy donors. Hemoglobin, expressed in percentage of the normal. Arrows pointing downward represent bleeding from the heart. Arrows pointing upward represent intravenous transfusion.

Chart 5.—Experimental group, given transfusions from "prepared" donors. Erythrocyte counts, expressed in percentage of the normal. Arrows pointing downward represent bleeding from the heart. Arrows pointing upward represent intravenous transfusion.

Chart 6.—Experimental group, given transfusions from "prepared" donors. Hemoglobin, expressed in percentage of the normal. Arrows pointing downward represent bleeding from the heart. Arrows pointing upward represent intravenous transfusion.

rabbits in this group. This was true with respect to the restoration of both the erythrocyte and the hemoglobin values. The average recovery period for this group was eighteen days for the erythrocytes, and 19.3 days for the hemoglobin.

The second control group, transfused from healthy donors, recovered more rapidly than the group receiving only routine care (Table I). The erythrocyte recovery period for all 5 rabbits composing this group averaged 10.8 days, recovery being uninterrupted. The immediate hemoglobin recovery period was complete in only 3 of the 5 animals composing this group, and averaged nine days. All 5 survived the experiment and showed definite clinical improvement the day after one transfusion, with complete clinical recovery within a week after the termination of the experiment.

The rabbits transfused from stimulated donors recovered in an average of eight days with respect to their erythrocyte counts. All but one showed a satisfactory restoration of the hemoglobin content of the red blood cells within an average period of 6.8 days. The clinical recovery of the rabbits in this group was slightly more prompt than that of the group transfused from healthy donors.

The reticulocyte counts of all rabbits varied considerably. In general, there was a distinct reticulocytosis in all rabbits after the first bleeding. This declined irregularly after the third or fourth hemorrhage. A secondary increase in the reticulocytes appeared in all three groups when the bleeding was discontinued, although it was later in the untransfused group than in the two transfused groups. No significant difference in the degree or in the promptness of this secondary reticulocytosis was noted in the two transfused groups.

COMMENT

The number of animals used is too small to permit the drawing of sweeping conclusions. There is justification for the general statement that the rabbits receiving blood from stimulated donors recovered more rapidly and satisfactorily than either of the control groups. This is borne out both by the data summarized in Table I and by the clinical behavior of the animals. The two groups receiving transfusions gained weight and strength much more rapidly than the group receiving only routine care, and the group given transfusions from prepared donors improved more rapidly than the group given transfusions from healthy donors. There was some parallel in the restoration of the erythrocytes and that of the hemoglobin, but the restoration of the latter, with respect to the individual animals in each group, was less constant and returned more slowly to normal levels.

The question arises whether the erythrocytes of the "stimulated donors," being relatively young, may have been more viable than those of the healthy donors, thus accounting to some extent for the more rapid recovery of the rabbits in the one group. This does not seem a reasonable explanation, because the total amount of blood injected was comparatively small. Furthermore, the three rabbits in this group receiving only one transfusion recovered about as promptly as the three rabbits given transfusions on two occasions.

It may appear anomalous that a hematopoietic stimulant was apparently not formed in the rabbits rendered anemic by repeated bleeding. However, it is a well-confirmed observation in man that repeated hemorrhages are unaccompanied by evidences of regeneration of erythrocytes, whereas a single hemorrhage is succeeded by evidences of erythropoiesis (reticulocytosis and polychromatophilia). The reason for this is not evident. It is worth emphasis that the bone marrow of rabbits has an enormous "reserve," as judged by the large number of fat cells normally present in rabbit bone marrow.² These, presumably, are capable of metaplasia with transformation into hematopoietic foci.

Additional experiments along similar lines have been planned. The present experiment is being reported now because it is felt that clinical application may be made of the method of "donor stimulation"; that is, both on theoretical and experimental grounds, the conclusion seems justified that blood from human donors, shortly after a small phlebotomy, may act as a hematopoietic stimulant if administered to patients with hypoplastic, aplastic, or "refractory" anemia.

SUMMARY

1. Fifteen rabbits rendered anemic by repeated bleeding from the heart were divided into three groups.

2. One group received only routine care. A second group received routine care and intravenous transfusions from healthy donors. The third group was given routine care plus intravenous transfusions from donors previously stimulated by the removal of a small quantity of blood from the heart.

3. The two groups given transfusions improved more rapidly, both clinically and hematologically, than the group receiving no transfusions.

4. The group receiving transfusions from prepared donors improved more rapidly, both clinically and hematologically, than either of the two control groups.

5. It is suggested that preliminary phlebotomy of human donors may provide an effective method of treating hypoplastic, aplastic, and refractory anemia in man.

CLINICAL AND LABORATORY INVESTIGATIONS ON THE EXTRACT OF THE EUROPEAN MOUNTAIN ASH BERRY, WITH PARTICULAR REFERENCE TO ITS ANTIHEMORRHAGIC ACTIVITY*

GEORGE Y. SHINOWARA, PH.D., C. JOSEPH DELOR, M.D., AND
JOHN W. MEANS, M.D., COLUMBUS, OHIO

THE berry of the European mountain ash, *Sorbus aucuparia* L., has reportedly been used as a "spring tonic" by the Laplanders of the northern Scandinavian countries for many years.¹¹ Traditionally, the products obtained from the berry are consumed in the spring in the belief that they have some beneficial action, particularly on the liver. It has been suggested that the change from the high fat diet of winter to one containing more green vegetables in the spring, results in some type of biliary stasis. Folklore led to the assumption that the berry acted as a "flushing agent."

The United States Dispensatory⁹ describes the *Sorbus* fruit as having been "used in scurvy, and in infusion, as a remedy in hemorrhoids and strangury." It further states that the fruit contains a nonfermentable monosaccharide, sorbinose, $C_6H_{12}O_6$, isomeric with levulose; the crystalline saccharine principle, sorbitol, $C_6H_{14}O_6$, isomeric with mannitol; sorbic and parasorbic acids, $C_6H_8O_2$; malic acid $C_4H_6O_5$. The seeds of the fruit contain 22 per cent of fixed oil. The Biologic Research Division, Philadelphia College of Pharmacy and Science,² has confirmed these analyses and in addition has reported the definite presence of appreciable amounts of ascorbic acid.

A clinical and laboratory investigation of the *Sorbus* berry as to its mode of action and possible therapeutic value in hepatobiliary disease has been undertaken. In this paper are described experiments conducted to determine the antihemorrhagic activity of the extracts of this fruit.

EFFECT ON THE COAGULATION TIME IN HEMORRHAGIC CHICKS

Method.—Since the existence of vitamin K deficiency was first suspected in chicks by Dam³ in 1929, the chick has been employed in the assay of the natural and synthetic antihemorrhagic substances. The biological assay method of vitamin K employed in this study was that of Ansbacher.¹ The clotting time was determined as described by this author, except that larger test tubes (1 by 7.5 cm.) were used. Ration K-1 was fed to all the test animals. Although the quantitative determination of the plasma prothrombin level would have been preferable to the gross clotting time, attempts to apply both the method of Quick⁶ and that of Smith⁷ to the small volume of blood obtainable from chicks were without success.

*From the Gallbladder Clinic, a joint project of the Departments of Medicine, Pathology, and Surgery, and the Laboratories of the University Hospital, Ohio State University College of Medicine.

This study was made possible by a grant from the Comly Fund for Medical Research.
Received for publication, May 23, 1941.

Results.—In an attempt to produce the hemorrhagic syndrome typical of avitaminosis K, 920 chicks were placed on Ansbacher's basal ration K-1.² The syndrome developed more often in the White Rock than in the White Leghorn chicks. Some animals on this diet retained normal coagulation time for periods as long as three weeks. This emphasized the necessity of a freshly prepared diet. Ration K-1 contains 17.5 per cent of ether-extracted fish meal. Since putrified fish meal is known to be an excellent source of vitamin K₂, great care must be exercised to minimize bacterial action in this basal diet.

The alcoholic extract of the dried berry (Sorparin) was not sufficiently concentrated to be administered satisfactorily to the animals. This alcoholic extract was, therefore, subjected to rapid extraction with petroleum ether (b. p. range, 30° to 60° C.); 1 Gm. of this latter extract represented approximately 20 Gm. of Sorparin or 50 Gm. of the dried berry. Furthermore, the dried Sorbus berry was ground and extracted in a similar manner; 1 Gm. of this extract was equivalent to approximately 40 Gm. of the original material.

TABLE I
BIOLOGICAL ASSAY

EX- PERI- MENT	SUBSTANCE	DOSE	NUM- BER OF CHICKS	AVERAGE BLOOD CLOTTING TIME	
				BEFORE TREATMENT (MINUTES)	AFTER 24-HOUR TREATMENT (MINUTES)
A	2-methyl-1,4-naphthoquinone	0.25γ	5	greater than 30	6 (1-15)
	2-methyl-1,4-naphthoquinone	0.50γ	6	30	2 (1-4)
	Petroleum ether extract of Sorparin	20.0 mg.	5	30	2 (1-3)
	Petroleum ether extract of Sorparin	10.0 mg.	5	30	2 (1-3)
	Sorparin	75.0 mg.	6	30	5 (2-8)
B	2-methyl-1,4-naphthoquinone	0.25γ	8	30	10 (2-90)
	2-methyl-1,4-naphthoquinone	0.50γ	8	30	2 (1-4)
	Petroleum ether extract of Sorparin	20.0 mg.	8	30	1 (½-3)
	Petroleum ether extract of Sorparin	10.0 mg.	8	30	2 (¾-4)
C	2-methyl-1,4-naphthoquinone	0.50γ	8	30	3 (1-4)
	Petroleum ether extract of Sorparin	20.0 mg.	6	30	1 (½-2)
	Petroleum ether extract of Sorparin	10.0 mg.	6	30	2 (1-3)
	Petroleum ether extract of Sorbus berry	40.0 mg.	5	30	4 (1-9)
	Petroleum ether extract of Sorbus berry	20.0 mg.	6	30	18 (2-90)

The experiments reported in Table I are those in which there was the successful production of the hemorrhagic syndrome and in which sufficient depression of the clotting time was obtained for approximate comparison with the positive synthetic vitamin K controls. The extracts were administered in 0.1 c.c. amounts of cod-liver oil to 17-day-old White Rock chicks on ration K-1. After twenty-four hours of the test period blood clotting time determinations were made.

Experiment D was performed in an entirely different manner: 52 one-day-old White Rock chicks were placed on Ration K-1. After eleven days the blood clotting time on six chicks averaged eighteen minutes. The remaining chicks were separated into two groups of 23 each. Group 1 was continued on ration K-1 *ad libitum*. Group 2 was fed ration K-1 with a known amount of dried Sorbus berry added. Seven days later blood clotting times were taken on these

18-day-old chicks. The average clotting time of the control group 1 was sixty-two minutes (23 chicks: range four to ninety minutes). The average clotting time in group 2, fed dried berries, was two and one-half minutes (23 chicks: range one to eleven minutes). Two hours after the clotting times were taken, the mortality in group 1 was 35 per cent, in group 2, 5 per cent. During the seven-day test period the 23 chicks in group 2 consumed 300 Gm. of the dried Sorbus berry. Blood, bile, and livers were obtained for study. Our preliminary biochemical studies show a marked increase in the neutral fat content of the livers in group 1 in contrast with group 2, which was normal.

The results obtained in this preliminary investigation must be regarded as qualitative or, at the most, semiquantitative. It is apparent from the data of Table I that there is present at least one Ansbacher unit¹ of vitamin K potency in 10 mg. of the crude petroleum ether concentrate of Sorparin. This may be further interpreted to mean there are more than 5 units present in one gram of Sorparin, or the minimum of 2 units in one gram of the dried berry of the European mountain ash. Quantitative biological assays are now being carried out in our laboratory to determine the optimum potency of this drug with highly refined concentrates.

EFFECT ON THE PLASMA PROTHROMBIN LEVEL IN MAN

The 14 cases to be reported here include those patients on Sorparin therapy alone, or those with other medications, on whom prothrombin determinations were done before and after treatment.

Method.—Quick's⁶ prothrombin technique was employed throughout this study. The results obtained by this relatively accurate, rapid, and simple procedure in more than 2,000 tests in our laboratories have been generally satisfactory only when carried out with strict adherence to the following: (a) the careful preparation and standardization of thromboplastin; (b) the use of "proved" normal controls; and (c) the titration of undiluted and diluted concentrations of freshly obtained plasma or plasma preserved by freezing.

The drug was administered orally in tablets containing 3 grains of the solid alcoholic extract of the European mountain ash berry. Three grains of this extract is equivalent to approximately 7.5 grains of the dry berry.

Results.—The data on 8 of the 14 cases studied are presented in Table II. The data on the remaining 6 cases on which more intensive observations were made are recorded in Graphs 1 to 6. Table III is a summary of the results obtained in all 14 cases.

The results of this investigation on the prothrombin response to Sorparin medication present several interesting observations. Irrespective of the diagnosis in each of the 14 cases studied, in only one (Case 31, Graph 5) was the prothrombin level diminished further after Sorparin medication. In this particular case (biliary dyskinesia with persistent fistula) the decrease in prothrombin was noted only when bile acids were administered with Sorparin. When Sorparin was given alone, the prothrombin level rose in each of two periods of medication. From the data summarized in Table III, it may be concluded that the plasma prothrombin showed some decrease in 8 per cent, "no change" in 20 per cent, and a definite increase in 72 per cent of the 25

TABLE II
PROTHROMBIN LEVEL BEFORE AND AFTER MEDICATION

CASE NO.	SEX AGE	MEDICATION			PROTHROMBIN		DIAGNOSIS
		DURATION WEEKS	SORPARIN GR./DAY	BILE ACID GR./DAY	BEFORE TREATMENT (%)	AFTER TREATMENT (%)

U.K.C. = Unconjugated-ketocholanic acids.

a = First period of medication.

b = Second period of medication.

TABLE III
SUMMARY: PROTHROMBIN RESPONSES TO SORPARIN ALONE AND WITH BILE ACIDS

DIAGNOSIS (14 CASES)	PROTHROMBIN RESPONSE TO MEDICATION					
	PERIODS ON SORPARIN ALONE			PERIODS ON SORPARIN WITH BILE ACIDS		
	DECREASED	"NO CHANGE"	INCREASED	DECREASED	"NO CHANGE"	INCREASED
Cholecystitis and/or cholelithiasis (7 cases)	0	0	4	0	0	7
Postsurgical biliary syndrome (2 cases)	0	2	0	0	0	1
Intermittent common duct obstruction (1 case)	0	1	0	0	1	0
Hepatitis (syphilis) (1 case)	0	1	0	0	0	0
Carcinoma of pancreas with metastasis to liver (1 case)	0	0	0	0	0	2
Biliary dyskinesia with persistent fistula (1 case)	0	0	2	2	0	1
"Hypoprothrombinemia" (1 case)	0	0	1	0	0	0
Total	0	4	7	2	1	11
Percentage based on 25 periods of medication	(0%)	(16%)	(28%)	(8%)	(4%)	(44%)

Decreased = Prothrombin level after medication less than before medication.

"No change" = Prothrombin level increased less than 15 per cent after medication.

Increased = Prothrombin level increased greater than 15 per cent after medication.

periods of medication in 14 cases. "No change" is statistically reported when an increase of less than 15 per cent in the prothrombin level was recorded. On the basis of less rigid requirements, it may be stated that some increase in prothrombin was observed in 92 per cent of the 25 periods of medication of Sorparin with or without bile acids and salts.

In the 7 cases of cholecystitis and/or cholelithiasis there was an elevation in prothrombin following four periods of Sorparin treatment and during seven periods of Sorparin-bile acids treatment. Medication was without appreciable effect relative to prothrombin in hepatitis with syphilis (Case 43, Table II) and in intermittent common duct obstruction (Case 30, Table II). Of the two cases (Cases 16 and 46, Table II) of postsurgical biliary syndrome, a marked elevation in prothrombin was observed only in Case 46, and then when iron bile salts were administered with Sorparin. Apparently in the case of carcinoma of the head of the pancreas with metastasis to the liver (Case 49, Graph 3), there were sufficient functioning liver cells for prothrombin production in response not only to vitamin K, but also to Sorparin with bile acids. Case 50 is diagnosed as "hypoprothrombinemia" for want of a better terminology. The case is that of a healthy medical student with no symptoms or demonstrable pathologic dyscrasia except his persistent low basal prothrombin level. Another study of this patient is presenting similar results.

The question may arise as to the effect of bile acids and salts alone on the prothrombin level. Cases 49, 21, and 22 (Graphs 3, 4, and 6), indicate that no elevation can be attributed to bile acids and bile salts therapy alone. This was observed in 5 other patients not included in this series of 14 cases. The foregoing statements and data submitted cannot necessarily be interpreted to mean that bile acids and salts alone cause either a depression or no increase in prothrombin, since similar results are possible without any medication whatsoever.

CASE REPORTS

Case abstracts of 6 patients investigated for their prothrombin response to Sorparin medication follow:

CASE 50 (Graph 1).—In a group of approximately 50 normal healthy men and women, a 25-year-old white, male, medical student, was one of only two to show a plasma prothrombin level below 70 per cent. His initial prothrombin of 60 per cent fell to 45 per cent one week later. A bromsulphthalein test was normal. One milligram of synthetic vitamin K daily for three days increased his prothrombin from 36 to 95 per cent. Upon cessation of therapy the prothrombin level fell to 80 per cent in three days, and to 52 per cent in a week. Two weeks of Sorparin treatment (18 grains daily) brought the prothrombin level again to 95 per cent.

CASE 10 (Graph 2).—A white female, aged 60 years, had a history of cholecystitis and cholelithiasis for twenty years. She began to show symptoms of hypertension and of occipital headaches, and her menses ceased. After one month of Sorparin therapy the relief from her biliary symptoms was complete. The basal prothrombin level averaged 45 per cent. When the patient was placed on 18 grains of Sorparin daily, the prothrombin level was between 70 and 80 per cent; on Sorparin with bile acids, it rose to 105 per cent.

CASE 49 (Graph 3).—A white female, aged 76 years, had jaundice with itching and acholic stools for two weeks. The laboratory data revealed the serum bilirubin 6.7 mg. per cent, hippuric acid 1.35 Gm., nonfilling gall bladder, and prothrombin 32 per cent. Gall bladder drainage showed that the common bile duct was not completely obstructed. Surgery was

refused. A diagnosis of carcinoma of the head of the pancreas was made. Two milligrams of synthetic vitamin K with 7.5 grains of bile acids daily elevated her prothrombin level to 120 per cent in two weeks. Eighteen grains of Sorparin with 7.5 grains of bile acids daily raised the prothrombin level from 35 to 120 per cent, and from 30 to 120 per cent in two subsequent periods of medication. After twenty-two weeks of observation the patient's condition

became progressively worse. She died four months later. During the four-month period she was given very little bile acid, vitamin K, or Sorparin. Her prothrombin level averaged 39 per cent. The chief findings at autopsy were mixed squamous-cell carcinoma and adenocarcinoma of pancreas with compression of normal bile duct and metastases to liver and obstructive biliary cirrhosis of liver.

CASE 21 (Graph 4).—A 55-year-old white female had a cholecystostomy. On her first postoperative visit to the Gallbladder Clinic four months later, the prothrombin was 55 per cent. She was given Sorparin and bile acids, and her prothrombin gradually rose to 93 per cent. She was taken off of Sorparin and the bile acid dosage was doubled. In three weeks the prothrombin was down to 55 per cent. The same bile acid therapy was continued, but in addition she was placed on a high fat diet, and the prothrombin level averaged 76 per cent.

She was then placed on iron bile salts and Sorparin. There was an initial moderate fall in prothrombin followed by an increase (85 per cent). During the thirty-four weeks' study this patient had no complaints referable to the gall bladder.

CASE 31 (Graph 5).—A 72-year-old white female with obstructive jaundice was admitted to the hospital. A cholecystostomy with removal of stones was done, and she slowly recovered. The gall bladder was drained for ten weeks. She was discharged and remained asymptomatic

for four months, when she had an attack of nausea, vomiting, and chills. She was readmitted to the hospital with sharp pain over the upper abdomen, jaundice, acholic stools, and deeply colored urine. Laboratory tests showed a moderately diminished liver function. A cholecystogastrostomy was performed because of a beginning stenosis of the common duct. The patient's convalescence was rather slow, but she was discharged markedly improved. Except for a slight distress in the epigastric region, her condition was excellent and she gained 60

Graph 5. BILIARY DYSKINESIA with PERSISTENT FISTULA (Case #31)

Graph 6. CHOLELITHIASIS (RECURRENT) (Case #22)

pounds. Prothrombin studies were begun at this time. On 18 grains of Sorparin daily the prothrombin level was elevated from 52 to 96 per cent. When bile acids supplemented this therapy, the prothrombin level dropped to 64 per cent. It rose again on Sorparin alone to 90 per cent. The patient was then placed on 12 grains of Sorparin and 15 grains of bile acids daily. The prothrombin level was first decreased to 55 per cent, and then rose to from 80 to 100 per cent.

CASE 22 (Graph 6).—A white female, aged 42 years, had a cholecystostomy with removal of stones in 1936. Her symptoms recurred, and three years later a laparotomy was performed and the gall bladder region was explored. The gall bladder was found imbedded in a dense mass of adhesions, making it impossible to do any operative procedure. Gradually there was a recurrence of nausea, occasional vomiting, and recurrent, transient jaundice. She was admitted for the third time. Laboratory examinations at this time revealed normal serum bilirubin, hippuric acid, and galactose tolerance. However, her prothrombin level was diminished to 52 per cent. She was placed on 6 grains of Sorparin with 11.25 grains of bile acids daily for one week. Her prothrombin increased to 75 per cent. When next seen in the Gall-bladder Clinic one month later, the prothrombin level was 37 per cent, and she was on bile acids only. She was placed on Sorparin along with bile acids, and the prothrombin rose to 105 per cent in two weeks. At this time bile acid therapy was discontinued, and on Sorparin alone she maintained a prothrombin average of 70 per cent.

TABLE IV
CLINICAL RESULTS OF THERAPY WITH SORPARIN, KETOCHOL, AND BILRON

NUMBER OF CASES	DIAGNOSIS	SORPARIN		KETOCHOL		BILRON	
		RELIEF (%)	NO RELIEF (%)	RELIEF (%)	NO RELIEF (%)	RELIEF (%)	NO RELIEF (%)
22	Chronic cholecystitis	72	28	70	30	77	23
13	Cholelithiasis	86	14	72	28	85	15
2	Cholecystopathy	50	50	100	0	100	0
20	Endocrinopathy	60	40	70	30	80	20
6	Hepatitis	85	15	75	25	100	0
4	Postcholecystectomy	50	50	100	0	100	0
5	Postcholecystostomy	60	40	100	0	100	0
1	Avitaminosis "A"	100	0	100	0	—	—

MISCELLANEOUS CLINICAL FINDINGS

In chronic cholecystitis (proved by cholecystography, duodenal intubation, and surgery) complete relief of symptoms with Sorparin was obtained in 36 per cent, partial relief in 36 per cent, and no relief in 28 per cent of the cases receiving 18 grains daily. When these patients were given unconjugated-ketocholic acids (Ketocho), 7.5 to 22.5 grains daily, or iron bile salts (Bilron), 5 to 15 grains daily, the incidence of relief from symptoms was approximately the same. In some instances Sorparin gave relief when Ketocho and Bilron did not, and in some patients the reverse was true. When given alone, without antispasmodics or special diets, Sorparin produced satisfactory results in half of the patients who obtained relief. However, its action was enhanced when the diet was regulated,⁴ and antispasmodics and sedatives were administered. Patients who had been subjected to cholecystectomy or cholecystostomy, and who had recurrence of their symptoms, obtained partial or complete relief in a slightly lower (10 to 20 per cent) percentage of instances than when no surgery was done. Sorparin will give relief in cholecystopathic dyskinesia, but it is not as effective as bile salt and/or bile acid preparations. It is an interesting fact that patients in menopause experience considerable relief when Sorparin or bile acids or bile salts are given for their associated biliary complaints, an observation in this series of cases for which an explanation is not forthcoming at this time.

The length of time Sorparin must be administered before symptomatic relief is obtained is variable, but usually results are noticeable in seven to fourteen days. But as in any other type of medical therapy no permanent cures can

be obtained. These patients need controlled supervision, re-education as to diet and habits, and correction of infections, metabolic dyscrasias, and the like, which are so common in patients suffering from biliary disease. In short, Sorparin, like bile salt and bile acid preparations, is not a panacea for chronic gall bladder and liver disease, but it does dispel the symptoms in many patients who suffer from these diseases.

No toxic symptoms attributable to any of the drugs discussed in this paper were encountered.

COMMENTS

The extensive literature in the field relating to prothrombin and vitamin K has been reviewed by Smith and co-workers⁷ and Warner.¹⁰ That vitamin K is necessary for the production of prothrombin has been definitely established. Warner¹⁰ cites as natural sources of this vitamin, green vegetables, such as alfalfa, spinach, and kale, and putrified fish meal. There have been no reports of its occurrence in fruits. McKee and his associates⁵ found that the active principles, vitamins K₁ and K₂, isolated from alfalfa and putrified sardine meal, respectively, have a quinoid structure. Of the numerous quinoid compounds which have been synthesized, the most potent biologically has been found to be 2-methyl-1,4-naphthoquinone.¹⁰ This compound was employed in this study for comparative purposes.

Little is yet known concerning the optimum dosage of vegetable and animal concentrates or synthetic compounds of known vitamin K activity to be employed clinically. In the cases reported here 1 Gm. of the alcohol extract (Sorparin), equivalent to 2.5 Gm. of the dried berry of the European mountain ash, was the maximum daily dosage. Similar studies with extracts from other natural sources in their effects on the prothrombin level in man have been made by others. Smith and co-workers⁷ administered extracts, representing 300 to 400 Gm. of alfalfa meal daily, and obtained a rapid rise (three to eight days) in the prothrombin level. Stewart³ gave his patients a daily dosage of extracts equivalent to from 140 to 700 Gm. of spinach.

In the hemorrhagic chicks comparable results in the lowering of the clotting time were obtained by feeding one part by weight of 2-methyl-1,4-naphthoquinone to 400,000 parts of Sorparin. In respect to the prothrombin level in man the ratio by weight was one part of the pure synthetic compound to 400 parts of Sorparin. This variance in activity in the human being and in the chick is significant.

In another section the approximate analyses of the extract of the European mountain ash berry was presented. Among the known constituents of this extract are rare carbohydrates and dibasic acids and their derivatives. Information is limited concerning the degree and mode of bacterial synthesis from other materials of vitamin K in the intestinal flora of mammals. Accordingly, until adequate chemical identification and biological assay of the active principle or principles of this extract are completed, no definite reference of its activity in coagulation can be made to the presence of Vitamin K compounds with or without a quinoid configuration.

Aside from raising the plasma prothrombin level, Sorparin produced symptomatic relief of subjective complaints in a large percentage of patients (up

to 72 per cent). This observation is interesting in that Sorparin has no known cholagogic or choleretic activity. The exact mode of action is not clear, since the known vitamin K compounds do not produce similar results.

CONCLUSIONS

1. The administration of the dried berry of the European mountain ash, *Sorbus aucuparia* L., and its extracts to hemorrhagic chicks significantly reduced their clotting time. A synthetic vitamin K compound, 2-methyl-1,4-naphthoquinone, was employed as control.

2. Fourteen patients with various types of biliary and hepatic disease were investigated for their plasma prothrombin response to the alcohol extract (Sorparin). In the total of 25 periods of medication in these patients, of this extract, with or without bile acids and salts, 72 per cent showed marked increase in the prothrombin level; 20 per cent, slight increase; and 8 per cent, decrease. Significant elevation of the plasma prothrombin was observed after Sorparin therapy in all 7 cases of cholecystitis, with or without cholelithiasis. A case of idiopathic hypoprothrombinemia is reported.

3. Clinical studies reveal that approximately 72 per cent of the patients in this series afflicted with chronic cholecystitis, with or without stone, post-surgical biliary disease, and hepatitis obtained symptomatic relief when given 18.0 grains of Sorparin daily. This compares favorably with the results obtained with bile acid/salt preparations, such as Ketochole and Bilron.

We are indebted to the McNeil Laboratories for the extract of the European mountain ash berry (Sorparin); to G. D. Searle & Co. for the unconjugated-ketocholanic acids (Ketochole); to Eli Lilly and Company for the iron bile salts (Bilron).

LESIONS IN THE SUPERIOR MEDIASTINUM WHICH INTERFERE WITH VENOUS CIRCULATION*

H. CORWIN HINSHAW, M.D., PH.D., AND DAVID I. RUTLEDGE, M.D.
ROCHESTER, MINN.

THE superior mediastinum is the great transportation center of the body. Through it passes all food on its way to the gastrointestinal tract, all air which enters and leaves the lungs, all lymph in the thoracic ducts, all blood which leaves the heart and which returns to it from the superior half of the body. It is surprising that obstructive symptoms do not develop more frequently than they do in this crowded region. It is more surprising still when the frequency with which the numerous mediastinal lymph nodes are involved in tumefactive processes due to inflammatory, tuberculous, and neoplastic lesions is recalled.

The anterior and posterior boundaries of the superior mediastinum are firm and unyielding parts of the thoracic wall. The lateral boundaries are elastic, being separated from the spongy lungs by nothing more than the pliable pleural layers. Space-occupying lesions can thus expand laterally.

The trachea is well protected by its cartilaginous rings. Although frequently displaced, it is rarely collapsed by extrinsic pressure sufficient to produce obstructive symptoms. The esophagus lies in a somewhat protected region, and its elasticity and power of independent motility make serious functional impairment from extrinsic pressure rather uncommon. The great arterial trunks not only have firm walls, but the contained blood is under pressure sufficient to prevent interruption of the flow by any external force of reasonable intensity.

The large mediastinal veins, on the other hand, are thin-walled, and the blood flowing through them is under very low pressure. Furthermore, these veins are anteriorly situated nearer the unyielding bony thoracic cage, against which they may be compressed by expanding mediastinal lesions. These veins drain blood from the upper half of the body only: from the upper extremities, the head, neck, and thoracic wall. Obstruction to flow of blood in these important channels will produce localized symptoms and signs pathognomonic of a mediastinal lesion. Since these vessels are readily compressed, such manifestations may be early indications (sometimes even initial symptoms) of serious mediastinal disease. These phenomena may be ascribed to delayed circulation time, increased venous pressure, and collateral diversion of the blood stream. All these factors are amenable to objective study and graphic demonstration. They are not uncommon, but they are frequently overlooked and are not adequately stressed in medical literature.

*Before roentgenologic treatment, June 29, 1938.

†After roentgenologic treatment, July 11, 1938.

‡After roentgenologic treatment, August 15, 1938.

This paper is based on a study of 31 cases of obstruction to the large thoracic veins. Condensed summaries of pertinent data in a few cases will be found in Tables I and II. We shall record and illustrate certain clinical aspects of mediastinal venous obstruction, with objective measurements of the circulatory phenomena demonstrated. We have seen all the patients in consultation. No effort has been made to study cases in the clinic files in which the patients were examined by other physicians.

Total	22	9	31

METHOD

The venous pressure was measured by the direct method. For this purpose a point of reference was taken 5 cm. below the fourth interspace at the right border of the sternum. The vein was placed at this level by means of a T-square arrangement with a carpenter's spirit level. A three-way stopcock was used between the syringe and the needle. A manometer tube graduated in millimeters was attached to the upright portion of the stopcock, and the direction of flow was controlled by means of a three-way valve. A 3 per cent solution of sodium citrate was placed in the syringe to prevent clotting of the blood. Venipuncture was made in the ordinary manner, after which the mixture of blood and citrate was forced up into the manometer tube. When the manometer tube was connected directly with the vein, the fluid fell in the manometer tube until its pressure equaled that in the veins. By this method the normal venous pressure was found to vary from 40 to 120 mm. of water. Clinically, it was found that the pressure in the veins could be simply estimated by observation of the level above the heart at which the veins on the dorsum of the hand would collapse when the arm was raised.

The circulation time was measured by injection of 5 c.c. of a 20 per cent solution of sodium dehydrocholate* into the antecubital vein; the time that elapsed before a bitter taste was noted in the patient's mouth was checked by a stop watch. This procedure constituted rough measurement of the pulmonary circulation time; normally, it varies from twelve to seventeen seconds.

Infrared photographs were made by the Mayo Clinic Department of Photography under the direction of Mr. Leonard A. Julin. Films sensitive to infrared rays and a suitable filter were used.

SYMPTOMS OF MEDIASTINAL OBSTRUCTION

The symptoms commonly produced by compression of the great veins of the thorax are characteristic. In most of our cases the lesion had developed

*Decholin (Riedel-DeHaen, Inc., New York N. Y.)

rather slowly and had been present long enough to permit fair circulatory compensation to develop. If obstruction develops more rapidly, alarming edema of the upper half of the body may occur.

Most patients in our series were relatively comfortable as long as gravity was aiding the return flow of blood. Distress was manifest chiefly on stooping or bending forward, or when exertion accelerated the flow of blood beyond the capacity of the anastomotic vessels. Undoubtedly, temporary increased cerebral congestion occurred at such times to explain the vertigo, throbbing sensations, and sometimes confusion and headache of which the patients complained. In one instance, syncope was frequent, and in another instance, convulsions occurred. Externally, suffusion and cyanosis of the face were seen, with very prominent engorgement of the veins of the forehead, face, and neck, and sometimes apparent prominence of the eyes. On the patient's resuming erect posture,

Fig. 1.—*a*, Infrared photograph of thorax; superior vena caval obstruction; note anastomoses between jugular veins, cephalic veins, and perforating branches of the internal mammary veins. *b* (Case 2), Mediastinal fibrosis; Infrared photograph showing anastomotic veins on anterior thoracic wall caused by superior vena caval obstruction.

many seconds might pass before circulatory conditions became stabilized. Although moderate orthopnea frequently was mentioned, the symptoms were minimal at night, when the circulatory rate was slowed naturally because of inactivity. Dyspnea was a frequent complaint and was thought to be caused more by circulatory embarrassment than by obstruction of the air passages.

LOCALIZATION OF THE OBSTRUCTING LESION

Blood from the upper extremities drains into the subclavian veins. These are joined by the jugular veins to form the innominate veins. The right and left innominate veins unite to form the superior vena cava. Near the upper end of the superior vena cava the azygos vein contributes blood from the thoracic wall. The superior vena cava ends in the right auricle.

If the superior vena cava is obstructed above the level of the azygos vein, the latter may serve as an important collateral channel. In this instance, blood from the head and neck will follow the external jugular veins to a plexus on the anterior thoracic wall. Blood from the arms will reach the same plexus by way of the cephalic veins. This plexus may form prominent anastomoses with the perforating branches of the internal mammary veins, and thence to the intercostal veins which are drained into the azygous system (Fig. 1*a* and *b*).

If surgical treatment is being considered, it is desirable to localize the site of obstruction accurately. In other cases it is interesting to do so, and prognosis may be affected by the findings.

Simple inspection and the determination of direct venous pressures should be adequate to localize obstruction of high degree. If a subclavian vein is involved, the phenomena of distention and increased pressure will be limited to the veins of one arm. If the veins of one side of the neck, especially the external jugular vein, and the veins of the arm on the same side also are involved, the innominate vein on that side also will be involved (Fig. 2a). The left innominate vein is much more frequently involved because of its longer course.

Fig. 2.—a (Case 20). Carcinoma of the bronchus, left upper lobe of lung and metastasis with obstruction of the left innominate vein; note asymmetric distribution of anastomotic veins. b (Case 18). Mediastinal lymphoblastoma; the superior vena cava is obstructed below the level of the azygos vein; note lateral abdominal veins.

If the veins of the neck on both sides and in both arms are similarly involved, the lesion may be considered to be situated in the superior vena cava. We believe that it is possible to determine further whether the obstruction is situated above or below the level of the azygos vein in certain instances of obstruction of high degree. A prominent plexus of large veins may be seen over the sternum, often clearly connecting with perforating branches of the internal mammary vein. It becomes obvious that blood is seeking a route to the intercostal vessels which drain into the azygous system. It, therefore, may be concluded that the obstruction is situated above the level of the azygos vein. Because of the relative efficiency of this route of communication, in these cases venous pressures are not so high, symptoms are not so severe, and external appearances are most striking.

If the entire superior vena caval system, including the azygos tributaries, is obstructed, blood must return to the heart through the inferior vena cava. Large veins in such circumstances cross the costal margin, and blood flows downward over the abdominal wall (Figs. 2b, 3a and b and 4). Venous pressures are high and symptoms are severe. If obstruction is situated in the superior

vena cava below the entrance of the azygos vein, establishment of effective collateral channels becomes much more difficult. It then becomes necessary for blood to seek a route to the inferior caval system. The resultant collateral channels resemble those which are formed in portal and inferior vena caval

Fig. 3 (Case 1).—*a*, Mediastinal sarcoma; the superior vena cava is obstructed below the level of the azygos vein; note the anastomotic veins on the abdominal wall. *b*, Roentgenogram of the thorax of the same patient.

Fig. 4.—Specimen of superior vena cava obtained at necropsy in Case 1. The photograph has been retouched. Extrinsic pressure had compressed the vein, producing intimal adhesions which partially blocked the channel. Point *a* was adherent to *a*, leaving vessel open only from point *a* to point *b*.

obstruction, except that blood flows in the opposite direction. Prominent tortuous vessels cross the costal margin and pass downward, chiefly in the lateral epigastric region on either side. These vessels may be traced toward the groin. It is possible to determine the direction of flow by compression of both ends of a segment of the vein with the fingers after the blood has been pressed out. If the lower finger is released, the vein refills slowly or not at all, whereas if the upper finger is removed, the vein refills almost instantly.

Fig. 5 (Case 4).—Infrared photograph of left side of thorax; carcinoma of bronchus with superior vena caval obstruction. Note dilated veins and fine superficial varicosities in the inferior midaxillary region.

COMMENT

There is another type of visible vascular change that is produced by mediastinal lesions. It is unlike the large, tortuous varicosities previously described and illustrated. It consists of small, superficial, rather tortuous groups of dilated, purplish venules, closely grouped in bunches and invariably situated along the anterior costal margins. The blood contained within these venules appears to be under increased pressure. It is difficult to photograph these vessels except with the aid of color films, but they are shown fairly well in Fig. 5 in contrast to the large veins. They are somewhat similar to the fine venules situated across the costal margins of normal persons, especially elderly men, and those who have a thorax of the shape of a thorax affected by emphysema. When a mediastinal tumor is present, these venules have a much more engorged appearance, and the vessels are larger, more numerous and more tortuous. They have a dark purplish appearance, unlike the fine pink or light blue hairline vessels situated along the costal margins of apparently normal persons. When the venules are associated with progressive mediastinal lesions, they usually appear rather suddenly, attracting the patient's attention. We have seen a few instances in which these small varicosities in the costal margins constituted the first objective evidence of mediastinal disease, and their significance was not realized by either patient or physician. We believe that the

rapid development of such vessels in this situation constitutes definite indication for roentgenographic study of the structures within the thorax.

Circulatory disturbances were the most prominent clinical features in many cases in this series. In more than a third (12) of the cases the chief disturbance which persuaded the patient to seek medical aid was of circulatory origin. In about a fourth (9) of the cases there was definite circulatory embarrassment, but this condition was secondary in importance to others. In the remaining cases minimal or no subjective discomfort was reported, despite objective evidence of impaired circulation.

It is important to note that the circulatory phenomena may be the earliest manifestations of mediastinal disease. They were noted as prominent early symptoms in at least half (16) of the cases of this series. In several instances experienced physicians had failed to recognize these symptoms as early evidences of mediastinal obstruction. In other instances it was possible to predict that malignant disease had already metastasized to mediastinal lymph nodes because of the circulatory disturbances noted. This conclusion afforded valuable evidence of inoperability in cases of malignant thoracic disease.

The duration of symptoms previous to diagnosis naturally depended somewhat on the nature of the obstructing lesion. In cases in which lesions were caused by malignant tumors, symptoms were of recent origin and of progressive severity. In cases of "mediastinal fibrosis" symptoms often had been present for years without evidence of progression. In 5 cases symptoms had been present for only a few weeks; in 8 additional cases symptoms were first noted within six months of the time we examined the patients. Eight other patients had noted circulatory disturbances for periods of from one to eight years. Ten patients had minimal symptoms or none at all.

Although prolonged duration of symptoms is convincing evidence of a benign lesion, a history of recent progressive symptoms does not exclude the presence of a benign inflammatory lesion. When symptoms were of recent origin, progressive and severe, with tumor not demonstrable in roentgenograms, we were inclined to regard the lesion as being inflammatory, and in three such cases, in which the patients underwent surgical exploration, such a conclusion proved to be correct.

The objective circulatory measurements recorded appear in Table I. Photographs made by infrared radiation show a striking exaggeration of the visible venous collateral channels. In no instance did infrared photography establish a diagnosis which could not have been made by easier methods. The value of this procedure is apparently limited to the production of illustrations for studies such as this one.

The clinical diagnoses and distribution of cases according to sex of patient are summarized in Table II. The great preponderance of men is due in part to the well-known fact that carcinoma of the bronchus is encountered much more frequently among men than among women.

The term "mediastinal fibrosis," as we have employed it, is not entirely satisfactory and deserves explanation. We have used it to denote cases in which tumor could not be demonstrated roentgenographically and in which duration of symptoms or surgical findings appeared to exclude malignant disease. In 3 cases in which the patients underwent surgical exploration the obstruction ap-

peared to result from fibrosis, and the fibrotic process probably surrounded healing tuberculous lymph nodes of the mediastinum. In 2 other cases roentgenographic evidence of unusually prominent calcified lymph nodes in the superior mediastinum was noted. In the remaining 3 cases long-standing symptoms of obstruction for periods of years made this clinical diagnosis appear probable. Measurements of circulatory changes were obtained in 6 of the 8 cases (Table I).

In the 2 cases in which the condition was recorded as being caused by pericardial constriction, such constriction was not proved to exist. Evidence indicated the obstruction to be situated below the entrance of the azygos vein into the superior vena cava, and in both cases severe rheumatic heart disease was present. In the remaining cases the diagnosis was based on results of bronchoscopy, biopsy, necropsy, or roentgenography.

The therapeutic test of roentgenologic irradiation frequently was employed when types of lymphoblastoma were suspected to be present. It was realized that such treatment might increase the harmful effects of mediastinal fibrosis if undertaken too vigorously; hence, the treatment usually was restricted to dosage considered adequate to accomplish the therapeutic test.

SUMMARY AND CONCLUSIONS

Simple inspection is adequate to reveal evidence of serious venous blockage in the superior mediastinum and to indicate the probable site of the lesion. Infrared photography will produce a striking record for illustrative purposes, but it is not necessary for diagnostic purposes. The increase in venous pressure in the arms can be roughly shown by determination of the level at which the veins empty on elevation of the arms. Direct measurement of venous pressure affords a much more nearly accurate record. Accurate measurements of venous pressure have practical value when it is desired to know whether a lesion is progressing or regressing, especially following irradiation therapy, or when surgical intervention is contemplated. The circulation time may be greatly prolonged beyond the point of obstruction in the vein.

The prominence of collateral veins bears no close relationship to severity of symptoms. As collateral varicosities increase in size, symptoms may regress. The height of venous pressure is not so closely correlated with symptoms as might be expected. Symptoms are more severe if the superior vena cava is obstructed below the point at which the azygos vein enters it, although visible varicosities may be less striking. When obstruction develops above the level of the azygos vein, symptoms are milder and collateral channels are more impressive than they are when obstruction occurs below the level of the azygos vein.

Prognosis is dependent strictly on the nature of the lesion. If it is not progressive, a degree of compensation is likely to develop; this may permit the patient to live indefinitely in fair comfort.

CLINICAL CHEMISTRY

ANDROGENIC AND ESTROGENIC SUBSTANCES IN URINE OF EUNUCHOID AND CASTRATE MEN*

CHANGES FOLLOWING ADMINISTRATION OF TESTOSTERONE PROPIONATE

JAMES B. HAMILTON, PH.D., RALPH I. DORFMAN, PH.D., AND
GILBERT R. HUBERT, M.D., NEW HAVEN, CONN.

METHODS, MATERIALS, AND SUBJECTS

THE present use of castration as a therapeutic procedure in men with metastatic prostatic carcinoma (Huggins and associates, 1941) has led us to summarize our studies and to review the literature pertaining to biological assay of androgens and estrogens in castrate and eunuchoid men and to indicate changes in these values found upon administration of exogenous androgens.

All samples of urine were collected over periods of twenty-four consecutive hours, usually four or more days being included in each specimen. The exact number of days is listed for each subject in Table I. Urine was preserved with toluene and extracted within two weeks, except that of Case 7, the extraction of which was delayed for four weeks. Extraction was done with benzene in a continuous extractor by the method of Gallagher and others (1937). A minimum of 15, and usually 20, chicks were used for each androgenic assay which was made according to the method of Dorfman and Greulich (1937). Determinations are held to be accurate within ± 25 per cent but their accuracy is probably greater. Values are expressed in international units (I.U.), one I.U. being equivalent to the increase in comb weight evoked by 0.1 mg. of androsterone.

After extraction of the urine with benzene in a continuous extractor, the alkali-soluble fraction of the urinary extract was separated and assayed for estrogenic activity in adult spayed mice. Ten or more mice were used for each estrogenic assay. The results were expressed in international units (I.U.), one I.U. being equal to the estrous growth of the vaginal epithelium evoked by 0.1 μ g of estrone. The accuracy of the method is probably at least ± 50 per cent.

The subjects were 4 castrated men, 2 oöphorectomized women, and 7 hypogonadal men. Five hypogonadal men are prepubertal eunuchoids; two (Cases 1 and 6) were deprived postpubertally of adequate testicular function in attempted surgical repair of hernia. The term *eunuchoid* is applied to men who, although possessing testes, do not have adequate testicular function. Brief description has been given of Case 4 (Hamilton, 1937). For each patient the age and number of years since castration are listed in Table I.

	52		7 (day)						
	42		16,0,10 (day)						

The techniques of assay and extraction are listed in instances where the data are available. Only values convertible to I.U. are used. Apparently castrate men rarely excrete more than 20 I.U. of urinary androgens a day, whereas eunuchoid men usually have higher levels, and a range extending from that of the castrate to the lower limits found in normal men. Values for urinary estrogens are also lower than those observed in normal men, but errors inherent in assay preclude strict definition of these values.

*Values corrected as of a fifteen minute period of boiling.

†Extracted by boiling with solvent; continuous extraction used by all other authors.

Twenty milligrams of testosterone propionate* in 1 c.c. of peanut oil were administered intramuscularly from three to seven times weekly, as described individually for each patient in Tables I and II.

RESULTS AND DISCUSSION

Urinary Androgens and Estrogens in the Eunuchoid and Castrate.—(1) *Androgens.* Until recently androgens have been reported to be absent in urine of castrate men (McCullagh and Renshaw, 1934), but with the use of better methods positive findings have been recorded. Data from studies in which the excreted substances were calculated in international units of activity are abstracted and compared in Table I, together with the additional cases reported at this time.

*Case 8 received only six injections per week.

In our series the eunuchoids have levels of urinary androgenic activity in the lowest part of the range found in normal young men, and the values for urinary androgenic activity of every eunuchoid are greater than in any castrate except Case 2 (Fig. 1). It is noteworthy that despite these facts all persons classified as eunuchoid had organic evidence of continuously inadequate testicular secretion. For example, Case 3, who excreted 20 I.U. of androgens daily, presented the most severe state of genital underdevelopment that we have observed in an adult male. The scrotum was a small, flat band of tissue without pendulous form. The penis was 2 cm. in length, 0.5 cm. in diameter, and the prepuce was undetached from the glans penis. As estimated from roentgenographic study of the wrist the osseous age was many years less than the patient's actual age.

Although strict comparability is not to be expected among studies made in different laboratories, since the methods employed differed in several details, the various data are uniform in suggesting that the castrate rarely excretes more than 20 I.U. of androgenically active material daily, whereas the levels in the eunuchoid are usually higher than in castrates and may be within the lower limits found in normal men. The daily values in normal men have been stated by Gallagher and co-workers (1937) to be 22 to 132 I.U., by Dingemanse and associates (1937), 15 to 170 I.U., and by Callow and co-workers (1938), 20 to 110 I.U.

*Testosterone propionate was furnished through the courtesy of the Ciba Pharmaceutical Company Products, Inc., Summit, N. J., under the trade name Perandren.

(2) *Estrogens.* The presence of urinary estrogens has been demonstrated for castrate men and oöphorectomized women (Bingel, 1935; Hansen, 1936a; Kenyon and associates, 1937). In the patients reported by the present authors the range of values is 5 to 28 I.U. for castrates, 8 to 50 I.U. for eunuchoids (Table I). These titers are less than those reported for normal men whose range in daily values is 20 to 290 I.U. according to Gallagher and associates (1937).

Fig. 1.—Daily excretion of urinary androgens in four castrate and eunuchoid men. All men excrete appreciable quantities of androgens, but the output of the castrate man (average 7.5 I.U.) does not fall within the range, much less the average of normal men (range from about 20 to 120 I.U., average about 60 I.U.). The range of excretion among the eunuchoid group extends from that of the castrate to the lower limits of the range in normal men. Data for men with testicular insufficiency are from cases reported by Hamilton and Dorfman in Table I.

COMMENT

The testes play a major role in men in the production of both androgens and estrogens. Orchidectomy or hyposecretion of the testes is accompanied by subnormal levels but not by absence of sex hormone activity in the urine. Extragonadal sources of these urinary steroids or their precursors may be the adrenal glands, as indicated by the excretion of large quantities of steroids in

certain patients with adrenal tumors (Slot, 1936; see Dorfman and co-workers, 1940), but specific designation of these glands as the sole source is not warranted by available data.

EFFECT OF ADMINISTRATION OF ANDROGENS UPON URINARY LEVELS OF GONADAL SUBSTANCES IN THE EUNUCHOID AND CASTRATE

Urinary Androgens.—In 1937 Koehakian reported that after injection of male hormone extracts from urine and of androstendione, about 2 to 6 per cent of the activity represented in the administered substances could be recovered from the urine. Callow (1938) found that after injection of testosterone propionate there was very little additional or even less urinary androgenic activity save in the case of two eunuchs who received fairly large doses. In 1939 (Dorfman and Hamilton) assays of urine from eunuchoids receiving testosterone propionate showed considerable increase in androgenic titers, which in one instance in terms of molecular conversion of testosterone to androsterone, amounted to approximately 41.4 per cent. In man conversion of testosterone to androsterone has been demonstrated by the isolation of large quantities of androsterone from urine of patients receiving testosterone (Callow, 1939; Dorfman, Cook, and Hamilton, 1939).

CASE	RECOVERY AS ANDROGENS (CALCULATED AS ANDROSTERONE)		RECOVERY AS ESTROGENS (CALCULATED AS ESTRONE)	
	TOTAL EXCRETION (%)	WITH ALLOWANCE FOR POSSIBLE ENDOG- ENOUS ANDROGEN (%)	TOTAL EXCRETION (%)	WITH ALLOWANCE FOR POSSIBLE ENDOG- ENOUS ESTROGEN (%)
1	41.4	32.9	0.03	0.02
2	43.1	37.7	0.06	0.04
3	39.5	27.6	0.05	0.03
8	48.3	46.1	0.02	0.02
4	53.2	44.8	0.01	0.01

The above figures were computed from data in Table II; the following instance of Case 2 illustrates the method of calculation:

Daily injection of 20 mg. of testosterone propionate = 16.7 mg. of testosterone.

Average daily androgenic excretion in days tested = 72 I.U.

72 I.U., calculated as androsterone = 7.2 mg. or 41.3% recovery.

If endogenous androgen were still excreted at levels observed prior to therapy, 72 I.U. minus 9.4 I.U. = 62.6 I.U. net excretion = 37.7% recovery.

Average daily excretion of estrogen in days tested = 100 I.U.

100 I.U. calculated as estrone = 0.01 mg. = 0.06% recovery.

If endogenous estrogen were still excreted at levels observed prior to therapy, 100 I.U. minus 31 I.U. = 69 I.U. net excretion = 0.04% recovery.

Probably the chief androgenically active compound in these urines is androsterone, as computed; but the urinary estrogenic substance, although phenolic, may not be estrone. Calculated as estriol, figures for percentage recovery are increased by a multiple of 50.

The relatively high percentage recovery in Case 4 may be due to the fact that the assays were made only after therapy had been given for several weeks. The figures would be higher also in the other cases if allowance had been made for the quantities excreted after cessation of therapy.

Values for Case 1, taken from other studies (Dorfman and Hamilton, 1939), are included in Tables II and III since these data were not calculated in the form used here.

The figure for percentage recovery (calculated as androsterone) reported previously is substantiated by data from four additional cases which are summarized in Table III and confirmed by the observations made independently by Hoskins and others (1939), and by McCullagh (1939). It is interesting that the percentage recovery is highest with subcutaneously implanted pellets of

testosterone propionate (Dorfman and Hamilton, 1941), less with intramuscular injections, and apparently even lower with oral administration (Dorfman and Hamilton, 1940).

In addition to androsterone there has been recovered from the urine of eunuchs and eunuchoids given testosterone propionate, etiocholanol-3(α)-17-one (Callow, 1939; Dorfman, 1940). and etioallocholanol-3(β)-17-one (iso-androsterone) (Dorfman, 1941). Another androgen of human urine, dehydro-iso-androsterone, has not been demonstrated to be a metabolite of testosterone.

From the foregoing comments it is evident that androsterone is very largely responsible for the androgenic activity of substances found in the urine after administration of testosterone to eunuchoids. The values observed are listed in Table II, from which it will be seen that in all of these instances 20 mg. of testosterone propionate injected intramuscularly seven times (six times in Case 8) weekly sufficed to maintain during the period of treatment urinary levels of androgens of approximately the average seen in normal young men. This is in agreement with the earlier report of Dorfman and Hamilton (1939), with daily intramuscular injections of 20 mg., and is in general agreement with the findings of Hoskins and co-workers (1939), with injections of 25 mg. daily.

TABLE IV

CASE 8 SHOWING EXTREME LOWERING OF LEVELS OF URINARY ANDROGENS WHEN WEEKLY INJECTIONS OF TESTOSTERONE PROPIONATE ARE 60 MG. INSTEAD OF 120 MG.

TREATMENT WITH 120 MG. OF TESTOSTERONE PROPIONATE WEEKLY	DAYS SINCE BEGINNING OF THERAPY	TREATMENT WITH 60 MG. OF TESTOSTERONE PROPIONATE WEEKLY
URINARY ANDROGENS (I.U./24 HR.)		URINARY ANDROGENS (I.U./24 HR.)
	2	9.2
	3	5.2
52	4 and 5	
	4	15
47	6 and 7	
89	9 and 10	
70	11 and 12	
	21	13
89	54 and 55	

If the dose is only about one-half of the amount (20 mg. of testosterone propionate daily) usually used in the treatment of eunuchs and eunuchoids of this series, that is, if injections of 20 mg. are given only three times per week, values of urinary androgenic activity were only slightly higher than observed before treatment and strikingly reduced from values observed with double the therapeutic dose (Table III). This observation requires confirmation, for only one person was studied in detail.

Urinary Estrogens.—Man excretes relatively large quantities of urinary estrogens, about 90 to 120 I.U. daily, in comparison with 180 to 360 I.U. excreted by women (Gallagher and co-workers, 1937). The source of these estrogens is in part the testis, as indicated by the low estrogenic values in castrated men.

Thus it was logical to ascertain whether or not there was conversion of androgens to estrogens. Steinach and associates (1936) found that the estro-

genic activity in the urine of normal and castrate male rats was greater after administration of urinary extracts and of androsterone; Steinach and Kun (1937) observed that injection of men with 1,000 mg. of testosterone propionate in doses of 50 mg., three times weekly, resulted in increased urinary estrogenic activity from values of 0 to 36 R.U. per liter found before injections to titers of 1,200 R.U. per liter of morning samples after seven weeks of injection. Hoskins and co-workers (1939), write, "These high values are especially remarkable in view of the almost casual extraction conducted by shaking the urine twice with benzene and the absence of hydrolyzing procedures usually necessary to secure maximum yields of estrogens from urine."

Kochakian (1938) detected no augmented estrogenic activity in the urine of one normal dog and of four castrate dogs which received several testosterone compounds, androstendione, and urinary androgens. Nevertheless, despite the above evidence to the contrary, it now appears certain that in man, testosterone can be converted to a substance (s) that is active estrogenically (Hoskins and co-workers, 1939; Dorfman and Hamilton, 1939; Callow and co-workers, 1939).

Table III shows the excretion of increased amounts of estrogenic substances during the period of treatment and for a short while thereafter. Amounts much larger than those in the normal young man were not encountered under the conditions employed. The values of 0.06 and 0.02 per cent from five cases, calculated on the basis of estrone, stated independently by Hoskins and others (1939), and by Dorfman and Hamilton (1939) are in agreement, and are substantiated by data from four additional cases listed in Table III.

The question arises as to the possibility of estrogenic action exerted directly by androgens or indirectly by substances converted from testosterone. Many androgenic compounds induce uterine and mammary growth, and one, trans-androstenediol, has marked estrogenic activity (Emmens and Parkes, 1938). Tenderness and swelling of the subareolar area occur in the eunuchoid receiving testosterone (Hamilton, 1937) and spontaneously in the boy at puberty (Jung and Shafton, 1937), but a variety of substances exert an effect on the mammary glands, and there is no proof as to whether or not the estrogenic action necessarily either precedes or follows conversion of androgen to estrogen.

SUMMARY

The levels of androgenic and estrogenic substances in the urine of 7 eunuchoid and 4 castrate men are presented in Fig. 1 and Table I. Data existent in the literature on this subject are summarized and listed in Table I.

In the present series of cases the average daily androgenic activity of the urine of eunuchoids (18.8 I.U.) was slightly less than one-third that of normal young men, and that of the castrates was still lower (7.7 I.U.). The average daily estrogenic activity of the urine was also less than in normal young men, being 27.4 I.U. in the eunuchoid, and 14.7 I.U. in the castrate.

Daily injection of 20 mg. of testosterone propionate resulted in elevation of values for urinary androgenic activity to the range in normal young men. Urinary estrogenic activity was also increased as a result of conversion of testosterone to phenolic estrogenic substances. Upon the cessation of injections of testosterone the values for urinary androgens and estrogens returned to those found before the employment of therapy.

In terms of molecular conversion to androgens and estrogens, the percentage recovery in the urine of the administered androgen is appreciable and comparable from person to person (Table III). Apparently, recovery following intramuscular injections in oil is less than that obtained upon implantation of pellets of testosterone propionate, but is in turn greater than that occurring after ingestion.

LABORATORY METHODS

GENERAL

HEMATOCRIT TUBE BALANCING RACK*

ARTHUR C. STIRLING, M.D., ROCHESTER, N. Y.

IT IS recognized that when in use, the various sedimentation instruments for determining the sedimentation rate of whole blood must be as nearly vertical as it is possible to attain in order to prevent an increased settling rate caused by slight inclination of the tube.

Most devices to aid in securing this vertical position require either a perfectly flat surface for mounting, or incorporate a system of levels which are adjusted by a system of screw legs. The former is unsatisfactory because of the difficulty in finding a perfectly level laboratory table. The latter method is relatively complicated and requires frequent adjustments if the device is moved from table to table.

The device herein described and illustrated permits the Wintrobe type of tubes to rest within fractions of a degree of the vertical position. The balance rack may be placed on any smooth top table with disregard for the level of that table, and with one simple motion of the damping stage, fixed into a true vertical position. Tubes may then be placed into or removed from the rack without disturbing the balance. This type of balancing device is satisfactory for all styles of laboratories; for example, research, arthritic clinics, sanatoriums, and ward laboratories in hospitals. We have used it with satisfaction in this hospital in connection with further research on the problem of sedimentation.

The instrument consists essentially of (1) a rack for holding the tubes (this is supported on a pivot in pendulum fashion) and (2) a damping device for stopping this rack and holding it in a fixed position.

The *rack* is constructed of three parts. The upper part (A) is composed of a lightweight material, such as aluminum, plastic, or wood. It is circular in cross section and deep enough to contain several drilled holes into which the hematocrit tubes may be lowered about 3 cm. These holes are centered by machine to give necessary accuracy (the whole rack must, of course, be accurately machined in order to maintain a vertical position) and placed in such positions as to aid balance; this is done by placing one hole in the center, then an even number of holes at the periphery. The bottom of this piece is drilled and tapped to receive the middle part.

*From the Strong Memorial Hospital, Department of Surgery, Obstetrics and Gynecology, Rochester.

Received for publication, September 15, 1941.

The middle part (*B*) of the rack consists of a threaded joint which holds the two other parts together and serves as the fulcrum for the pivot.

The lower part (*C*) of the rack simply consists of a heavy mass of iron (1 pound or so) which receives the joint at one end; it is rounded at the lower end to offer a constant surface to the damper. The rack hangs on the pivot which is mounted on a scaffold-like arm. This is mounted on the same base as the damper.

Fig. 1.—Hematocrit tube balancing rack in use.

The *damping device* consists of (1) a soft sponge rubber block mounted on a stage which in turn is attached to a strip of sheet spring metal, and (2) an off-center cam which when worked by a suitable handle raises the stage and rubber cushion against the bottom of the rack.

The rubber block must be soft in order to press equally in all directions against the rack and to prevent lifting of the rack off the pivot; it is cemented to the stage. The stage is riveted to the strip of spring. The spring is attached firmly at one end and loosely at the other to permit up and down motion; the stage moves vertically.

The cam is half rounded at opposite edges to permit smooth and steady setting against the spring plate. A handle is joined to the cam via a shaft.

Fig. 2.—Details of construction of the rack and damping device.

When it is desired to balance one or several filled Wintrobe tubes, the tubes are placed in the rack either before or after setting; any number from one to seven (or more if more holes are drilled) may be so balanced. Being mounted on a circular rack, the tubes may be read from all sides. The rack is allowed to swing freely on the pivot, and is gradually damped down as it assumes the vertical position (regardless of the level of the base). When the vertical point is reached, the handle is snapped completely over to fix the rack in this position. There are thus no adjustments of levels to be made at any time; gravity does the balancing job, and a single turn of the thumb fixes the rack in a perfectly vertical position.

A SIMPLE MECHANICAL FEEDING DEVICE⁸

EDGAR J. POTH, PH.D., M.D., BALTIMORE, MD.

IN THE course of experiments which required that dogs be administered a drug at four-hour intervals day and night it became imperative that an automatic feeding device be employed. After several designs had been considered and rejected, the rather simple arrangement illustrated in Fig. 1 was improvised.

Fig. 1.—This illustration shows the position of the 2 inch iron pipe placed through the top and fastened to the side of an animal cage.

Fig. 1 requires but little explanation. A small, 1,750 r.p.m. electric motor designed for continuous operation is connected in series with two 1 to 400 reduction gears mounted in series. This arrangement will give a speed of one revolution every ninety minutes for the low-speed shaft of the second gear. On this shaft is mounted a reel onto which rope *a* will be wound to advance the chain *c*.

⁸From the Surgical Hunterian Laboratory, Department of Surgery, Johns Hopkins University School of Medicine.
Received for publication, September 10, 1941.

The travel of this chain in a given interval of time will determine the spacing of the pins. The device as used here was designed to feed every four hours. In order that the feeder need attention only once daily, five pins were incorporated in the design. Pull cord *b* is adjusted so as to throw the motor switch after the last pin has been withdrawn. Rope *a* is attached to chain *c* by a hook to facilitate unwinding the rope at the completion of a twenty-hour run.

The daily dosage of drug was mixed with a portion of ground meat which was divided and made into six similar balls. Five of these balls are skewered with the pins and are released to fall into the animal's cage as each pin is withdrawn. An economical feeding mixture consists of ground, boiled lungs cemented together with a small amount of admixed tallow. The animal's total daily food ration can be incorporated in these meat balls. To insure the administration of the drug at the desired time the animals are kept slightly hungry and they eat the food immediately when it is delivered.

Two tiers of cages arranged on three walls of a room were operated by a single mechanism. If the animal is given a feeding when the feeder is loaded, it will demand attention once daily. With slight changes the device can be altered for feeding different types of food.

PREPARING PARAFFIN FOR IMBEDDING PURPOSES*

WALTER KOCH, M.D., PH.D., JERUSALEM, PALESTINE

FRESH paraffin is unfit for microtechnical purposes, since it contains volatile admixtures which make the paraffin brittle, thus rendering sectioning difficult. Besides, fresh paraffin often crystallizes. Therefore Apathy advised that fresh paraffin be left for about one week at 70° to 80° C. and filtered several times. Spee mentioned that overheating renders paraffin fit for sectioning in ribbons. Other authors (Schulgin, Brass, Altmann, Pohlmann, van Walsem, Kabsch) advocated the admixture of wax, ceresin, myrtle wax, mastix, vaseline, etc.

The following is a procedure for rendering paraffin suitable for sectioning. It combines the advantages of overheating, as advocated by Spee, with those of the addition of wax, as suggested by Brass, van Walsem, and Kabsch, the disadvantages of the various methods being as far as possible eliminated.

The paraffin is purified through prolonged heating (see *A*) and made smooth through the addition of beeswax. The wax is heated for a short time in order to prevent the surface of the compound from becoming greasy. Thus, 10 per cent of beeswax may be added. It is an advantage that the melting point of the compound is almost the same as that of the original paraffin. If

*From the Zoological Institute of the Hebrew University, Jerusalem.
Received for publication, March 20, 1941.

"a" gram paraffin of the melting point T_1 is mixed with "b" gram of the melting point T_2 , the melting point T_x of the resulting mixture is:

$$T_x = \frac{a \cdot T_1 + b \cdot T_2}{a + b} \quad \text{Example: } 100 \text{ parts paraffin } 62^\circ \text{ mixed with } 10 \text{ parts beeswax } 54^\circ =$$

$$T_x = \frac{100 \cdot 62 + 10 \cdot 54}{100 + 10} = 61. \quad \text{Heating raises the melting point about } 1^\circ, \text{ thus:}$$

$$T_x = \frac{100 \cdot 63 + 10 \cdot 55}{100 + 10} = 62.$$

Used paraffin is less contaminated by volatile substances. On the other hand, it contains tiny water droplets left over from the cooling procedure, as well as glycerin (boiling point 290° C.), which is used to prevent the block from sticking to the imbedding dish (see *B*).

PROCEDURE

A. Fresh Paraffin. (1) Fresh paraffin is weighed, put in a shallow enameled dish (as used in photography), and heated on an electric plate. At about 80° C. benzol evaporates. If the liquefied paraffin begins to boil at 100° to 110° C. , this proves the presence of water. In this case, splashing can be avoided by leaving the temperature below 120° C. until all the water is evaporated. The paraffin is then heated to 220° C. and kept at this temperature for about three to four hours. During this procedure disagreeable-smelling fumes escape; the paraffin, while absorbing oxygen, takes on a yellowish color. It is then cooled and left overnight. In the cooled paraffin no heterogeneous spots should appear. Otherwise the procedure should be repeated.

(2) Yellow beeswax is added in the proportion of 10 per cent of the weight of the paraffin. The mixture is kept at a temperature of 180° C. for thirty to forty-five minutes, then filtered and cooled.

B. Used Paraffin (Remainders of A). (1) The block rests are rinsed in water and dried. (2) The paraffin is heated to 180° C. for thirty to forty-five minutes, then filtered and cooled.

SUMMARY

A mixture of paraffin and beeswax is described which can be sectioned with ease, the melting point of which hardly differs from that of the original paraffin.

A SIMPLIFICATION OF BENHOLD'S TEST FOR AMYLOIDOSIS*

ADELE B. COHEN, M.D., NEW YORK, N. Y.

THE standard Congo red test, with or without acetone extraction, has two major disadvantages. (1) It is rather complicated, requiring one intravenous injection and two venipunctures and consuming more than one hour to perform. (2) There is a large range, say from 40 to 80 or 90 per cent dye retention, which is not diagnostic for amyloid disease but does not exclude it. This may possibly be due to the inability of slight amyloid deposits to fix a sufficiently large part of the Congo red injected.

It was observed during the performance of the standard test that in patients with amyloidosis the apparent dye content of the serum four minutes following the injection of Congo red was obviously considerably less than in normal patients.

In Fig. 1 the percentage of dye retention is plotted against time during the first hour following the intravenous injection of 10 c.c. of a 1 per cent solution of Congo red. Subject A had amyloidosis; Subject B did not. The calculations are based on the colorimetrically determined dye content and on the estimated total plasma of the respective patients. The vastly faster absorption of the dye in the amyloidotic patient is shown particularly in the early phase following injection. It would appear that this early phase allows a more reliable distinction between the presence and absence of amyloidosis. Since the estimation of the percentage retention of Congo red, as done in the standard test, increases the uncertainty of interpretation rather than adds a quantitative evaluation, the aim was to find a proper amount-time relation so that all persons not suffering from amyloidosis would show Congo red in the serum and patients with amyloidosis would not.

In preliminary experiments it was found that Congo red in a 0.00025 per cent solution can easily be demonstrated by the appearance of a blue color when one drop of this dilution is mixed with one drop of concentrated hydrochloric acid. When 2 c.c. of 1 per cent solution of Congo red are injected in a normal person weighing 150 pounds, the plasma (about 2,700 c.c.) would contain about 0.00074 per cent of Congo red, or three times the demonstrable concentration. Even with 10 or 20 per cent resorption during the first fifteen minutes, Congo red should still be demonstrable fifteen minutes following the injection.

The present modification is, then, based on (1) the rapid initial absorption of Congo red in the presence of amyloid, (2) the slow initial absorption of Congo

*From the Division of Pulmonary Diseases, Montefiore Hospital for Chronic Diseases, New York, N. Y.

Received for publication, September 22, 1941.

red in persons without amyloidosis, (3) the easy demonstrability of Congo red in a dilution as low as 0.00025 per cent.

TECHNIQUE

Two cubic centimeters of a 1 per cent Congo red solution are injected intravenously, and after exactly fifteen minutes a few drops of blood are withdrawn from a finger into a suitable tube with capillary mouth (Widal tube). After the blood has clotted, it is centrifuged at slow speed and one or two drops of clear serum are removed with a capillary pipette and placed into a small white porcelain dish. One drop of undiluted hydrochloric acid is added with another capillary pipette. If the serum contains Congo red, a blue, quickly fading color, appears at the moment of mixing.

Fig. 1.

RESULTS

A total of 245 persons who presented no evidence of amyloid disease and in whom it was not suspected were examined with this technique. All showed Congo red in their serum, with the exception of one patient. With the 10 c.c. method this patient had given the results shown in Table I. On March 13, 1939, he was positive for amyloid according to the 2 c.c. method. He had massive albuminuria, a fixed urinary specific gravity between 1.017 and 1.020. Liver and spleen were not enlarged. At autopsy on Feb. 18, 1940, no amyloid was seen. The kidneys showed a few areas of hyaline degeneration of glomeruli, and the

spleen contained minute hyaline, rounded bodies. Microchemically these hyaline areas could not be identified as amyloid. Since this patient had massive albuminuria, he might have excreted Congo red through his kidneys, thus giving a false positive test. The urine was not examined for Congo red at the time of the test.

TABLE I

DATE	PER CENT
2/24/38	15
10/20/38	100
12/30/38	40
4/ 7/39	44
4/11/39	33
9/18/39	75

A total of 33 patients with evidence of amyloid disease were tested, and all but one gave a positive test. The evidence for amyloid disease in these patients is as follows:

8: confirmation by autopsy.

32: 95 to 100 per cent Congo red retention by the standard test.

Many of these patients had the usual clinical and chemical evidence of amyloidosis.

The one patient with amyloidosis who yielded a negative test showed moderate amyloidosis of kidneys and spleen at autopsy on March 4, 1939. She had none of the usual clinical signs of amyloidosis, and a 10 c.c. Congo red test done on July 5, 1938, showed 20 per cent retention. The falsely negative 2 c.c. test was performed on Jan. 11, 1939.

DISCUSSION

According to this experience, the reliability of this modification is not less than that of the standard 10 c.c. method. However, many further observations are necessary to define its limit of reliability correctly.

This modification is so much simpler than the original test (requiring one venipuncture instead of three, and fifteen minutes observation instead of one hour) that it seemed justified to report it.

SUMMARY

1. A modification of the Congo red test for amyloidosis is reported.
2. It is simple in technique and requires only one instead of three venipunctures.
3. Its reliability, which needs further testing, appears to be of the same degree as that of the standard technique.

A COMPARISON OF CAPILLARY AND VENOUS RED BLOOD CELL COUNTS AND HEMOGLOBIN DETERMINATIONS IN PATIENTS WITH PERNICIOUS ANEMIA IN REMISSION UNDER TREATMENT*

MAURICE B. STRAUSS, M.D., AND JOSEPH H. BURCHENAL, M.D.
BOSTON, MASS.

IT IS generally believed¹ that in adult man the red blood cell count and hemoglobin content of blood obtained by puncture of the ear or finger and that obtained by venepuncture without stasis is the same, although Haden and Neff² found lower values in the blood obtained from central vessels than from skin capillaries in infants. In a recent article De Marsh and co-workers³ state in a footnote that they consistently find the sinus blood of infants to have lower values for red blood corpuscles and hemoglobin than blood obtained from puncture of the heel. Duke and Stofer⁴ demonstrated that in 8 patients with pernicious anemia, 5 of whom were in relapse, capillary red blood cell counts averaged 17.6 per cent higher than venous counts, whereas such differences were not encountered in 5 normal persons or in 4 patients with "secondary" anemia.

In the course of an analysis of the effect of treatment in maintaining blood levels in 80 patients with pernicious anemia, it became apparent that a decided difference existed between the results of blood counts and hemoglobin determinations made on venous blood and on capillary blood. A total of 2,139 blood examinations were analyzed. Approximately two-thirds of the examinations were made on capillary blood during the first years of this study; since January, 1938, all determinations have been made on venous blood. From 14 to 46 separate examinations were made on each of the 80 patients over a period of from five to nine years (average 7.1 years). All but 5 patients had both capillary and venous determinations, although, as indicated above, these determinations were not made at the same time. All patients were under constant treatment and in remission. The arithmetic means of the venous and capillary red blood cell counts and hemoglobin determinations were calculated for *each* patient. The distributions of these means have been plotted in Fig. 1.

The mean capillary red blood cell count of the 80 patients was 4.690 millions per cubic millimeter, and the mean venous red blood cell count of 75 of these 80 patients was 4.444 millions per cubic millimeter, a difference of 0.246 millions per cubic millimeter, a value which is distinctly significant, there being less than one chance in 1,000 of its being accidental ($t = 4.712$; $n = 153$; $p = < 0.001$).

*From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School, Boston.

Received for publication, September 22, 1941.

The mean of the hemoglobin determinations on capillary blood of the 80 patients was 91.8 per cent (15.6 Gm. per 100 c.c. = 100 per cent), and the mean of the hemoglobin determinations on venous blood of 75 of these 80 patients was 87.3 per cent. The difference 4.5 per cent is significant, there being less than one chance in 1,000 that it is accidental ($t = 4.657$; $n = 135$; $p = <0.001$).

Fig. 1.—The distribution of the average capillary and venous red blood cell counts and hemoglobin determinations in 80 patients with pernicious anemia in remission while under treatment. The solid lines in each curve represent the mean value, and the dotted lines represent the standard deviations.

CONCLUSION

Venous blood in patients with pernicious anemia under treatment has approximately 5 per cent less erythrocytes and hemoglobin than blood obtained from the capillaries. This may be true for normal persons as well, but we have insufficient data on this point.

It is a pleasure to acknowledge with thanks the technical assistance of Miss Eleanor Fleming, Miss Marjorie Jewell, Miss Florence Kelly, Miss Elizabeth King, Miss Harriet MacDonald, and Miss Charlotte Nicklin who performed the technical determinations.

A DEVICE FOR MARKING FIELDS ON MICROSCOPE SLIDES*

CARL OLSON, JR., D.V.M., AMHERST, MASS.

WHILE making a routine examination of histologic preparations, it is convenient, and sometimes necessary, to mark certain areas so that they may be readily found later. Among methods used for this purpose is one using a mechanical stage with vernier markings. A reading of the vernier markings will constitute a record of the location of the area to which future reference may be made. It is, of course, necessary that the same mechanical stage is used and that the slide stop remains unchanged. A second method utilizes a diamond point, placed in an eccentric position, attached to the rotating end of a blank objective. For operation, the regular objective of the microscope is replaced by the blank objective and, with the slide held firmly, the diamond point is lowered to contact the cover slip. A circle is described by turning the rotating end and scratching the cover slip with the diamond. Disadvantages of the method are that sometimes the cover slip is moved or broken and the permanent scratch mark may obliterate an area desired for study. A third and rather crude method consists simply of marking the area with a pen and India ink. A difficulty of this procedure is to center properly the desired area within the inked circle; usually several attempts are necessary to obtain the desired result. Failure of an attempt can be corrected by removing the ink mark with a dampened cloth.

The third method of pen and ink marking has been improved by incorporating a principle of the second method in a simple device that may be fitted in the place of an objective and act as a rubber stamp. It consists of a brass cylinder, knurled and threaded at one end to fit into the revolving nosepiece of a microscope. The other end is reduced to a cylindrical shaft, $\frac{3}{16}$ inch in diameter and about $\frac{3}{8}$ inch in length. A short length of rubber tubing is slipped over the cylindrical shaft and allowed to project a short distance beyond the end of the shaft. The gum rubber tube supplied with a blood cell counting pipette was used for this purpose. The free end of the rubber tube must be cut squarely across. The length of the entire device must be such that the free end of the tube will make contact with the surface of the slide when the microscope tube is racked down.

The marker may be fitted to an empty socket or a revolving nosepiece on the microscope and be ready for use at all times. For operation the area of a slide to be marked is centered in the field of the microscope, and the slide is allowed to remain in place on the stage of the microscope. The rubber tip

Contribution No. 416 of the Massachusetts Agricultural Experiment Station.

is inked with the quill of an India ink bottle. The marking device is then swung into the position formerly occupied by the objective, and the body tube is gently racked down until the inked rubber touches the slide. A ring of ink will be stamped on the slide to encircle the area desired. A little care is necessary to avoid application of excess ink on the rubber tip.

Fig. 1.—Device ready for attachment to nosepiece of microscope. The over-all length is slightly more than that of the longest microscope objective.

The diameter of the ink ring can be varied by having a larger or smaller shaft. The marker now in use was made with a detachable tip. Other tips of different diameters may be used.

The device has been in use for some time and found to be extremely useful in marking areas of slides to be studied or photographed at a later time. The inked ring mark is quite permanent under ordinary conditions and yet can be readily removed with a damp cloth.

CHEMICAL

THE EXTRACTION OF PROTEINS FROM AQUEOUS SOLUTION BY MEANS OF EMULSIFICATION WITH CHLOROFORM*

JAMES C. ANDREWS, PH.D., W. E. CORNATZER, M.S., AND A. B. SAMPLE, M.S.
CHAPEL HILL, N. C.

DURING the past fifty years there have been occasional references in the literature to the ability of chloroform to precipitate proteins more or less quantitatively from aqueous solution.¹⁻³ It is remarkable that such a method has not received closer scrutiny, particularly in view of the claims made in some of the earlier papers as to the completeness of removal attained. The method, furthermore, deserves investigation in view of its obvious advantage in not leaving behind in the aqueous layer an excess of a reagent that is difficult to remove and sometimes objectionable. This paper reports some systematic studies designed to evaluate the advantages and limitations of the procedure.

On shaking protein solution with chloroform there is quickly formed a heavy emulsion, which settles out readily on mild centrifuging in a compact cake below the supernatant water layer. A very satisfactory separation of this layer results even without centrifuging. The supernatant liquid can readily be decanted without disturbing the heavy emulsion, and the protein can be recovered by evaporation of the chloroform at room temperature in vacuum. Any foaming can be readily checked by the addition of a small amount of amyl alcohol;¹ its use, and that of ethyl alcohol, as noted below, have the further advantage of greatly increasing the completeness of protein removal.

Various forms of this method have been used by Tsuchihashi⁴ for the preparation of blood catalase extracts; by Zeile and Hellström⁵ for the preparation of liver catalase extracts; by Meldrum and Roughton⁶ for the preparation of protein-free carbonic anhydrase extracts from blood; by Sevag⁷ for the isolation of carbohydrates from egg albumin and pneumococci; by Sevag, Lackman, and Smolens⁸ for the isolation of the components of streptococcal nucleoproteins; and by Gurin, Bachman, and Wilson⁹ for the purification of the gonadotropic hormone of pregnancy urines.

EXPERIMENTAL

Kjeldahl determinations of total nitrogen made on the original protein solution and on the supernatant liquid after separation from the emulsion were used as the criterion of protein removal. The fact that different criteria, such as qualitative protein tests, were used by some of the earlier investigators,

*From the Department of Biological Chemistry, School of Medicine, University of North Carolina, Chapel Hill.

Received for publication, December 18, 1941.

Baker's isoamyl alcohol with boiling range of 128° to 132° C. was used. For the sake of brevity it will be referred to in the remainder of this paper simply as "amyl alcohol."

undoubtedly accounts for some differences in our conclusions. The percentage of free amino nitrogen to total nitrogen was used as the criterion of molecular size. In preliminary experiments, amino nitrogen was determined by the Sorensen method, but the work was later repeated using Van Slyke determinations. The relationship between ability to be precipitated by this method and molecular complexity will be discussed in detail below.

Colorimetric pH determinations were made in the preliminary experiments; the glass electrode was used in all final work on the effect of variation of pH.

A preliminary series of extractions of 0.5 per cent egg albumin solution, made with varying proportions of chloroform, showed that maximum removal is effected by a volume of chloroform 25 to 30 per cent that of the protein solution. Smaller proportions of chloroform reduced the percentage removal; higher proportions brought about no improvement. As a result the standard proportions adopted were 100 ml. of protein solution and 35 ml. of chloroform. To this were added 10 ml. of amyl alcohol when it became evident that this mixture produced the optimum results of any investigated. Later work showed that 95 per cent ethyl alcohol could be substituted equally well for the amyl alcohol.

TABLE I
EFFECT OF TIME OF SHAKING ON PERCENTAGE OF EGG ALBUMIN REMOVED

TIME (MINUTES)	PERCENTAGE PROTEIN REMOVED		
	NATURAL pH CHLOROFORM ALONE USED (%)	ISOELECTRIC pH CHLOROFORM ALONE USED (%)	ISOELECTRIC pH CHLOROFORM + AMYL ALCOHOL USED (%)
1	4.5		73.5
3	8.9	16.8	80.0
5	18.4	22.0	78.5
7	27.7	25.2	79.8
10	31.8	40.6	78.2
16	33.2		
20	38.1		

Comparisons of the effect of mechanical shaking versus hand shaking showed that one is as effective as the other. Previous investigators have used widely varying times of shaking, in some cases as much as ten or more hours. However, we find no evidence quoted in support of such lengthy periods. We find that the effect of increased time of shaking (by hand) depends upon two other factors: the proximity of the pH of the solution to the isoelectric point of the protein, and the presence of the added alcohol. Table I shows the relative percentages of the protein removed from approximately 1 per cent egg albumin solution under these different conditions. With chloroform alone and the protein not adjusted to its isoelectric pH, an irregular increase up to twenty minutes is observed. The use of isoelectric conditions increases somewhat the percentage removal but does not bring it to constancy within ten minutes. However, the use of both isoelectric pH and amyl alcohol gives practically constant removals from three minutes upward. For this reason, a five-minute period of vigorous shaking by hand was adopted.

Tests of the effect of shaking with successive portions of the emulsifying agent also showed marked differences between chloroform alone and chloroform plus 10 per cent amyl alcohol.

TABLE II
EFFECT OF SUCCESSIVE EXTRACTIONS OF THE SAME SOLUTION (APPROXIMATELY 1 PER CENT EGG ALBUMIN) AT ISOELECTRIC PH

NUMBER OF EXTRACTIONS	TOTAL PROTEIN REMOVED BY	
	CHLOROFORM (%)	CHLOROFORM + AMYL ALCOHOL (%)
1	15.4	84.5
2	24.7	86.8
3	32.4	87.3
4	37.5	
5	41.4	

In Table II are recorded the results of a series of successive extractions of the same 1 per cent egg albumin solution in which the two procedures are compared. Percentages of protein removed are cumulative. The much more rapid effect of the chloroform-amyl alcohol mixture is plainly evident.

Other organic liquids of limited miscibility with water have been suggested for this purpose, such as ethyl acetate by Marie,¹⁰ and bromoform by Formanek.² For this reason, a series of such liquids was investigated, employing the foregoing procedure described for egg albumin solutions of slightly under 1 per cent concentration. In some cases the test was made both at the natural pH of the protein solution (about pH 6) and at the isoelectric point (pH 4.8). A series of these results is recorded in Table III. In all cases the amount of the emulsifying agent used was one-third the volume of the albumin solution with, in some cases, addition of 10 ml. of the auxiliary agent (ethyl or amyl alcohols) per 100 ml. of the protein solution.

These results show the practical superiority of the chloroform-amyl alcohol and chloroform-ethyl alcohol mixtures over all other solvents investigated. We have not been able to correlate the low and irregular recoveries obtained with other liquids with any other physical property, such as boiling point, surface tension, water solubility, dielectric constant, etc. The surprisingly high removal effected by ethyl acetate prompted an examination of some homologous esters of different alcohols and acids. As will be noted, no benefit resulted.

Little has been done to investigate the colloidal properties of the protein-chloroform emulsion. Sevag, Lackman, and Smolens⁸ suggest a loose molecular combination or "adsorption compound." A few tests on our part showed that water is attracted to a fragment of the emulsion on a microscope slide and enters it whereas chloroform does not. This would seem to indicate that the external phase is aqueous.

Previous investigators have discussed the properties of the precipitated protein,^{3, 6-8} the consensus of opinion indicating more or less denaturation. Our own results confirm this. Egg albumin, precipitated by the above-described procedure, gave a product which, after washing out the chloroform and amyl alcohol with ether and drying at room temperature, was quite water insoluble.

After several days' shaking with water, the amount dissolved was insufficient to give biuret or sulfosalicylic acid tests. It was also insoluble in 0.1 N acid or alkali, salt solutions, and alcohol. Dried in vacuum to constant weight it had a nitrogen content of 14.5 per cent. Other methods of drying the emulsified protein gave a product similarly insoluble. The only case in which the precipitated and dried product was water soluble was when proteose-peptone solutions had been used as the starting point. In this case the fraction precipitated was correspondingly low (see below).

Contamination of the precipitated protein by dissolved salts is very slight. Experiments in which sodium chloride (about 1 per cent) was added to the aqueous protein solution showed that the presence of the salt did not appreciably affect the efficiency of removal by chloroform-amyl alcohol and that about 99 per cent of the salt remained in the water layer after emulsification.

TABLE III

EFFICIENCY OF VARIOUS ORGANIC LIQUIDS AS PROTEIN PRECIPITANTS FROM 1 PER CENT EGG ALBUMIN SOLUTION AT BOTH NATURAL AND ISOELECTRIC PH (4.8)

REAGENT	PERCENTAGE PROTEIN REMOVED	
	NATURAL pH	ISOELECTRIC pH

Ethyl butyrate	31.3	33.7
n-Butyl acetate	22.9	35.6
Isoamyl acetate	20.0	27.4

Effect of pH.—The data in Table III indicate that in some cases considerable differences in percentage removal of egg albumin from solution result from adjustment of the solution to pH 4.8 (isoelectric point). The column of values for the "natural pH" is included to illustrate the irregularities resulting when the protein solution is not adjusted to as near its isoelectric point as possible. In most cases, albumin solutions made from dried commercial preparations showed pH values of from 6.5 to 7.5. In some of the earlier papers,^{2, 8} causal reference is made to different recoveries having been obtained at different acidities, although Zeile and Hellström⁵ claim that the separation of hemoglobin from catalase is unaffected by pH variations between 4.5 and

9.0. We have not investigated hemoglobin in this regard but have made a systematic study of the effect of pH variations on percentage removal of egg albumin and serum albumin. Preliminary experiments were carried out using colorimetric determinations after titration with varying amounts of acid or alkali. Uniform extractions with either chloroform or chloroform-*amyl* alcohol were run on these solutions, and the percentage removal of the protein was determined as described previously. One outstanding difference between the use of chloroform alone and of the chloroform-*amyl* alcohol mixture was observed. In all cases, maximum precipitation occurs at or near the isoelectric point. However, with chloroform alone this maximum is a comparatively low one, whereas with either alcohol added, the curve, starting from about the same level, rises rapidly and sharply to a much higher maximum. At pH values, for example, two units above or below the isoelectric pH, only small differences were observed between the use of chloroform alone or with *amyl* alcohol; at the isoelectric pH, however, the difference was 30 per cent or more.

TABLE IV

VARIATION BETWEEN pH OF AQUEOUS PROTEIN SOLUTION AND PERCENTAGE PRECIPITATION BY THE CHLOROFORM-*AMYL* ALCOHOL PROCEDURE

Approximately 1 per cent solutions of all proteins were used.

				7.35	34.1		
				9.45	19.7		

*Chloroform-ethyl alcohol used.

A more accurate determination was then made of the curves of pH *versus* percentage protein removal for both egg albumin and blood albumin, all pH determinations being made by means of the glass electrode. The results are shown in Table IV. The sharp maximum obtained is obvious for both blood albumin and egg albumin, but it will be observed that this maximum is uniformly higher by several tenths pH than the isoelectric point usually accepted for egg albumin. We have not as yet redetermined the isoelectric point of this material and can, therefore, offer no explanation. However, it may be stated that this maximum roughly approaches the isoelectric point of the protein.

Effect of Molecular Size of Protein.—Preliminary experiments indicated that this method of precipitation is somewhat selective as regards the molecular

size of the protein. Using the ratio of free amino nitrogen to total nitrogen as a measure, it was evident that the larger aggregates were precipitated, leaving in the aqueous layer a residue of such high free amino nitrogen to total nitrogen ratio that it often failed to respond to qualitative precipitation tests for proteins. This circumstance no doubt accounts for the fact that some of the earlier investigators claimed complete precipitation.

TABLE V

RELATIONSHIP BETWEEN PERCENTAGE PRECIPITATION OF PROTEINS AND THE CHANGE BETWEEN FREE AMINO NITROGEN TO TOTAL NITROGEN RATIO OF THE ORIGINAL PROTEIN SOLUTION AND THAT REMAINING UNEXTRACTED IN THE AQUEOUS LAYER
All solutions at isoelectric pH.

SOURCE OF MATERIAL	CONC. OF PRO- TEIN PER 100 ML. (GM.)	PERCENTAGE PRECIPITA- TION	RATIO: FREE AMINO N TO TOTAL N \times 100

*Kindly prepared by Dr. Samuel Gurin, School of Medicine, University of Pennsylvania, Philadelphia, Pa.

To investigate this point, comparisons were made of the free amino nitrogen to total nitrogen ratio in the original protein solution and in the supernatant aqueous layer after precipitation. This comparison was applied to blood albumin and egg albumin from different sources as well as to some commercial proteose-peptone mixtures, from which very little precipitation could be accomplished. In Table V are given the results obtained from a number of different proteins. In these determinations the chloroform-amyl alcohol mixture was used throughout. Free amino nitrogen to total nitrogen ratios cannot be recorded for the precipitated protein because of its insolubility (see above). The only exception encountered was in proteose-peptone solutions. For example, the commercial proteose-peptone solutions are listed in Table V, which showed a very low percentage precipitation and a proportionately small rise in the free amino nitrogen to total nitrogen ratio, yielded a small amount of precipitate which was sufficiently water soluble to make possible Kjeldahl and Van Slyke determinations. These samples showed a corresponding decrease in the ratio from that of the original solution.

The data in Table V are presented as typical of a large number of such determinations. It is evident from these data that the higher the original ratio of free amino nitrogen to total nitrogen, the smaller the percentage of the total material removed by this treatment and the less selective the removal. Some samples of serum albumin purposely chosen were old and already partly hydrolyzed. The behavior of such samples, in comparison with some egg

albumin samples of a lower ratio of free amino nitrogen to total nitrogen is plainly evident. A number of such determinations were also made on protein solutions at pH values other than the isoelectric. Aside from small quantitative irregularities the same conclusion holds: in general, the higher the proportion of the protein precipitated, the more marked the change in free amino nitrogen to total nitrogen ratio between the original solution and the residual material.

It is evident that chloroform precipitation, while in many cases a useful tool for protein removal, has distinct limitations which should be recognized. Its chief advantage lies in the fact that the aqueous solution, from which the protein is being removed, remains uncontaminated by an excess of the precipitating reagent, as is the case when precipitation is accomplished by tungstic acid, trichloroacetic acid, etc. Furthermore, it is sometimes an advantage not to have changed the pH of the aqueous solution, and the precipitated protein, although denatured, is free from metallic contamination.

The chief disadvantage to be recognized is the failure of the method to effect a quantitative removal of the protein even under optimum conditions. It should, therefore, not be used if a small percentage of residual nitrogen in the aqueous solution is objectionable. Since, however, the unprecipitated fraction is of simpler structure with a high ratio of free amino nitrogen to total nitrogen, this may not always be an objectionable feature. The use of the chloroform procedure by other investigators,^{4,9} as mentioned above, exemplifies this.

Although most of our data have been collected on protein solutions approximating 1 per cent concentration, a number of determinations have been made on egg albumin solutions, ranging from 0.5 per cent to about 8 per cent. We have not found that the completeness of removal is appreciably affected by variations in concentration within these limits.

CONCLUSIONS

Studies of the removal of proteins from solution by chloroform emulsification have led to the conclusion that the procedure is a useful one for certain purposes and when certain limitations are recognized. The following is recommended as the optimum procedure:

The protein, in water solution, should be as near its isoelectric pH as possible. The most advantageous proportions studied were 100 volumes of the protein solution, 35 volumes chloroform, and 10 volumes of 95 per cent ethyl or of isoamyl alcohols. The mixture should be shaken vigorously for five minutes in a container of about twice its volume, then centrifuged for about five minutes at a speed of 2,000 to 2,500 r.p.m. Mechanical shaking is unnecessary.

Successive treatments of the aqueous solution with new portions of chloroform and alcohol cause no significant increase in the amount of protein removed.

Similar tests of a number of organic liquids of limited solubility in water have brought to light none approaching the chloroform-alcohol mixture in efficiency. The nearest approach is ethyl acetate. Homologues of this ester have all given much lower percentage removals.

The precipitated protein is denatured by the process to the point of being insoluble in water, salt solutions, and dilute acid and alkali. The only exception to this is in the very small amount of precipitate obtained from proteose-peptone solutions.

The presence of small amounts of salts in the protein solution does not appreciably affect the emulsification process nor the purity of the denatured protein.

When chloroform alone is used as the emulsifying agent, the curve of percentage removal *versus* pH reaches a low maximum at or near the isoelectric point of the protein. With the alcohol added this maximum becomes sharp and much higher.

In any protein solution investigated, the fraction of higher molecular weight is preferentially precipitated, leaving in solution a fraction with a ratio of free amino nitrogen to total nitrogen much higher than in the original solution. The lower this ratio is originally, the more effectively does this procedure remove the protein.

THE QUANTITATIVE DETERMINATION OF INDOXYL COMPOUNDS IN URINE*

ARNOLD P. MEIKLEJOHN, B.M., B.CH. (OXON.), AND FRANK P. COHEN, M.S.
BOSTON, MASS.

INTRODUCTION

FOR nearly a quarter of a century there has been a general absence of interest in the significance of the urinary excretion of indole derivatives. The doctrine established by tradition that urinary indoles are derived from putrefactive processes in the intestines apparently has made further investigation of this subject unprofitable.

Recent work, however,^{1, 2} has revived earlier observations³⁻⁵ that the presence of indoles may be demonstrated with unusual ease in the urine of pellagrins. This observation merits further investigation, since the doctrine of the intestinal derivation of urinary indoles was formulated at a time when biochemical and medical science was unaware of the importance of nutritional deficiency.

The most familiar indole derivative that may be encountered in urine is indican (indoxyl potassium sulfate). Several methods for the estimation of this substance in urine have been proposed in the past. Most of these methods are crude and inadequate to meet the demands of modern quantitative investigation. Part of the indole excreted in urine may occur in a form which is responsible for the uroscopin reaction,⁷ but for which no method of quantitative estimation has as yet been developed. This study is concerned with a discussion of the methods available for the quantitative determination of indican in urine, and the presentation of a procedure, modified from Sharlit's method,⁶ which has been found satisfactory for quantitative purposes.

EXPERIMENTAL

The qualitative detection of indican in urine depends on the reaction obtained by adding concentrated hydrochloric acid and an oxidizing agent (ferrie chloride or calcium hypochlorite) to urine. By this means indican undergoes oxidation and polymerization to form the characteristic blue pigment indigo, which may then be extracted from aqueous solution with chloroform. There have been various attempts in the past to utilize this reaction in the quantitative colorimetric estimation of indican. However, there are certain objections to methods based on this procedure.

(1) After the addition to the urine of hydrochloric acid and an oxidizing agent, a single extraction with chloroform may be insufficient to remove all the

*From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School, Boston. Received for publication, November 7, 1941.

indigo formed, particularly when the indigo is formed slowly, as sometimes happens. Occasionally, it is possible to extract more indigo after the reaction mixture has been subjected to an initial extraction and then allowed to stand for some minutes.

(2) The addition of a fixed amount of the oxidizing agent to some urine specimens results in overoxidation of the indican and a diminished yield of indigo, while in other urine specimens incomplete oxidation occurs.

(3) The oxidation by ferric chloride or calcium hypochlorite does not always yield indigo blue. Indigo red (indirubin), which may have a different color intensity, is sometimes obtained.

(4) The recovery of a known amount of indican from indican-free urine is frequently far from quantitative.

(5) Difficulties arise in the preparation of a suitable standard for comparison. The intensity of color obtained in the chloroform solution of indigo extracted from urine is frequently more intense than that of a saturated solution of synthetic commercial indigo. In our experience recrystallized synthetic indigo has a maximum solubility of approximately 2 mg. per 100 ml. of chloroform at room temperature. When a saturated solution of synthetic indigo is evaporated to dryness and then taken up in strong sulfuric acid, a marked intensification of color results, indicating that the color reaction of indigo can be modified by such procedure. Great caution is, therefore, necessary in the use of any artificially prepared standard for purposes of comparison with unknown indigo solutions.

These difficulties are largely overcome by Sharlit's technique.⁶ This method makes use of the formation of a condensation product of indoxyl with thymol in the presence of persulfates. The condensation product is extracted from aqueous solution by forming within the reaction mixture itself the organic solvent ethyl trichloroacetate, which slowly settles out, carrying the pigment down with it. Under these conditions both the reaction and the subsequent extraction can be carefully controlled. This procedure, when modified as described below, has been adopted as the method of choice.

PROCEDURE

Ten milliliters of unfiltered urine preserved under toluene are placed in a volumetric flask and diluted to 100 ml. with distilled water. Five milliliters of this diluted urine are measured into a 15 ml. graduated centrifuge tube. The reagents are added in the following order: 0.5 ml. of 1 per cent potassium persulfate solution, 0.5 ml. of 1 per cent thymol in 95 per cent ethyl alcohol, 5 ml. of 25 per cent trichloroacetic acid in concentrated hydrochloric acid. At the same time another tube is prepared for a blank determination; urine and reagents are added in the same quantities *except that thymol-free alcohol* is employed. After the solutions have been mixed, each tube is placed in a boiling water bath until the ethyl trichloroacetate has separated out, and the aqueous layer is essentially free from pigment. This ordinarily requires about twenty minutes. The tubes are then centrifuged briefly and as much as possible of the supernatant aqueous layer is removed with a pipette. The trichloroacetate layer,

together with the small volume of aqueous layer remaining in the centrifuge tubes, is taken up in sufficient glacial acetic acid to bring the volume to the 5 ml. mark; the solutions are then transferred to special tubes for use in a Klett-Summerson photoelectric colorimeter, and are thoroughly mixed by pouring back and forth between the centrifuge tube and the colorimeter tube. The intensity of color in the acetic acid solutions is read immediately in the photoelectric colorimeter, using a No. 540 filter. The logarithmic scale reading given by the blank determination is subtracted from the reading of the unknown solution. The concentration of indican in micrograms per milliliter of urine is calculated as given below. If the reading on the colorimeter is less than 200, or more than 400 scale units, greater accuracy is achieved by repeating the test, using appropriately greater or smaller amounts of urine.

DISCUSSION OF METHOD

Preservation of the Urine.—Estimations have been carried out on twelve- and twenty-four-hour specimens of urine. Although it is usually stated that the indican reaction must be performed on freshly passed urine, we have found that the addition of a few milliliters of toluene to the urine when first passed is sufficient to maintain the values obtained by this method for at least twenty-four hours. As pointed out by Sharlit, formaldehyde should not be used as a preservative.

Amounts of Reagents.—Using 0.5 ml. of urine, it was found that the amount of potassium persulfate could be varied considerably without affecting the results of the determination. We have used 0.5 ml. of a 1 per cent solution. The results were found also to be unaffected by increasing the volume of alcoholic thymol solution employed. In practice 0.5 ml. of a 1 per cent alcoholic solution of this reagent is sufficient. The 25 per cent trichloroacetic acid in concentrated hydrochloric acid used by Sharlit⁸ in his estimation of indican in plasma was employed successfully in urine estimations.

Time Necessary for the Various Stages.—It was not found necessary to allow the tubes to stand for fifteen minutes to cool after removal from the water bath, as recommended by Sharlit. Nor was any advantage gained by allowing the tubes to stand at various stages of the test, as Townsend⁹ recommended. Considerable saving of time is achieved by the omission of these steps.

Colorimetry.—Townsend⁹ has shown that the spectrum of the indoxyl-thymol condensate exhibits maximum light absorption at about 540 m μ . A No. 540 filter was, therefore, used in the colorimeter. The use of a Klett-Summerson photoelectric colorimeter has definite advantages over visual colorimetry. The personal factor is eliminated in making the readings. Furthermore, since solutions of the indoxyl-thymol condensate obey Beer's law reasonably well within the limits of the concentrations recommended in this procedure, the readings obtained on the logarithmic scale of the colorimeter can be converted directly into terms of a concentration of indican by simple multiplication of the reading by the same factor over the recommended length of scale.

The Standard.—The conversion factor was experimentally determined by carrying out the estimation on an indican solution of known concentration.

Obviously the validity of the standard depends upon the purity of the specimen of indican used for this purpose. It is possible that indican obtained from various commercial sources may vary appreciably in its degree of purity. This is suggested by the fact that the figures given by Townsend⁹ for the level of indican in normal plasma unaccountably disagree with those given by Sharlit.⁸ This discrepancy may be partly explained by differences in their standards, due to different degrees of purity in the specimens of indican they employed. For this reason, particular precautions were taken to ensure the purity of the indican used in obtaining the standard. A specimen of indican,^{*} manufactured by Fraenkel and Landau, was purified by recrystallization. The temperature of decomposition was checked and found to be 180° C. Micro-determinations for sulfur and nitrogen yielded the results given in Table I. These values show satisfactory agreement with the theoretical values when the errors of the methods are considered.

TABLE I

FOUND		THEORETICAL
Nitrogen	4.6 per cent	5.2 per cent
Sulfur	12.7 per cent	11.9 per cent

Further tests showed that this specimen of indican gave standard readings which agreed well with those obtained by Sharlit who used a specimen from a different source. He employed a solution of cobalt sulfate as a standard for use in a comparison colorimeter, and stated that a 1.5 per cent solution of $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$ matched the color given by 2 ml. of acetic acid solution containing indoxyl-thymol condensate derived from 0.0086 mg. of indican. We found that under our conditions 50 μg of indican gave the same colorimeter reading as a 3.5 per cent solution of $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$. This agrees with results of Sharlit to within 3 per cent.

Calculation of Results.—The colorimeter readings obtained with different amounts of indican were determined experimentally under the conditions of the test using standard aqueous solutions of indican. The results are given in Table II.

TABLE II
DETERMINATION OF THE CONVERSION FACTOR FOR INDICAN

INDICAN IN μg PER 0.5 ML.	NUMBER OF OBSERVATIONS	AVERAGE COLORIMETER READING	CONVERSION FACTOR
25	4	137	0.182
50	13	262	0.190
75	5	392	0.191
100	9	492	0.203
125	6	600	0.208

It will be seen from the figures in Table II that the factor necessary to convert colorimeter readings into terms of the amount of indican present varies somewhat over the range employed; or, in other words, when colorimeter read-

*Obtained through the courtesy of Dr. S. R. Townsend.

ings are plotted against concentrations of indican, the resulting calibration curve is not absolutely linear, as required to fulfill Beer's law exactly. However, the differences between the factors for each concentration of indican are so small that for practical purposes one factor may be used throughout. We have employed the factor 0.38 to convert colorimeter readings into terms of micrograms of indican per milliliter of solution. This factor is obtained from the equation:

$$\text{Factor} = \frac{\text{Indican in micrograms}}{\text{Colorimeter reading} \times \text{volume of indican solution}} = \frac{50}{262 \times 0.5} = 0.38,$$

substituting the values for the point of greatest experience, Table II. Use of this single factor for all concentrations introduces a possible error of not more than 5 per cent when the colorimeter readings lie between 200 and 400 scale units. The twenty-four-hour excretion of indican is calculated as follows:

$$24\text{-hour excretion of indican in mg.} = \text{Colorimeter reading} \times \frac{0.38}{1,000} \times \text{volume of urine.}$$

Since it is possible that there may be slight differences between individual colorimeters of this type, we suggest as a check the use of a 3.5 per cent $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$ solution to determine the colorimeter reading which should be given by 50 μg of indican under the conditions of this test.

Recovery of Indican Added to Urine.—We have found that on adding a known amount of indican to urine the recovery is quantitative.

Blank Determination.—Sharlit did not feel it necessary to carry out a blank determination as recommended here. However, we have found that in certain urine specimens (notably in specimens obtained from cases of liver disease) high blank readings are sometimes obtained with the use of thymol-free alcohol. This high blank is due to nonspecific substances which on oxidation by persulfate form colored products soluble in ethyl trichloroacetate. Such substances might include uroscopine and perhaps bile products. Contrary to Sharlit's statement, we have found that preliminary treatment of the urine with basic lead acetate may sometimes result in a significant reduction in the colorimeter reading, due to the removal of such interfering pigments. In theory a small part of the blank estimation may be due to indican itself, since in the presence of persulfate it could be converted to indigo which, dissolved in the trichloroacetate, may increase the reading on the colorimeter. However, in our experience the addition of indican to a number of urine specimens has resulted in no significant increase in the blank reading. In practice, therefore, the blank is subtracted from the reading of the unknown without correcting for a small error which occasionally may be introduced by the additional color added to the blank by the conversion of indican to indigo by persulfate.

If the persulfate is also omitted from the blank determination, very much higher readings may be obtained, which indicates that persulfate plays some part in the decolorization of pigments which would otherwise interfere still further with the estimation.

It is evident that any substance will interfere in this test if it can form a colored condensate with thymol in the presence of persulfate, which in turn

is soluble in ethyl trichloracetate and has an absorption band in the region of $540 \mu\mu$. Our own experience and that of Sharlit indicate that it is highly improbable that urinary constituents other than indican will contribute significantly to such color production. Sharlit showed that of a number of substances tested, only glucose, formaldehyde, and tryptophane produced any color under these conditions, and then only in insignificant amounts. In addition, we have investigated the effect of added indole and indole-3 acetic acid on the test. Two-tenths milligram of each of these substances when added to samples of urine taken for test failed to produce any significant increase in the colorimeter reading. It seems, therefore, that this reaction is sufficiently specific to exclude unsubstituted indole, and its simple substitution products, such as indole acetic acid. Hence it is probable that the test is, in fact, specific for indoxyl and its salts and just possibly a few other derivatives of indole so closely related chemically that they are indistinguishable from indican.

SUMMARY

The need for a reinvestigation of the significance of the urinary excretion of indole derivatives has prompted a consideration of the various methods available for the estimation of indoxyl compounds in urine. It has been found that Sharlit's method, with the modifications contributed by this investigation, yields quantitative results.

A MODIFICATION OF THE COLORIMETRIC PHOSPHORUS DETERMINATION FOR USE WITH THE PHOTOELECTRIC COLORIMETER*

G. GOMORI, M.D., CHICAGO, ILL.

THE two most widely used colorimetric methods for the determination of phosphorus are those of Fiske and Subbarow,¹ and of Kuttner and Cohen,² with minor adaptations of the techniques for specific purposes. The Benedict-Theis³ modification of Briggs'⁴ method, although highly praised for its accuracy by Bodansky,⁵ cannot be used in the presence of phosphoric esters because boiling, which is a part of the procedure, will hydrolyze them.

Both the Kuttner-Cohen and the Fiske-Subbarow methods have certain advantages as well as inconveniences. The one great advantage of Kuttner and Cohen's method is the excellent stability of the color. However, this advantage is more than counterpoised by two serious drawbacks: first, the extreme sensitivity of the method to interfering substances and to minimal impurities in the reagents; second, the narrow range of acid concentration within which colorless blanks and proportionate readings are obtained. A slight deviation from this concentration results in colored blanks or erratic readings, or both. A third much less serious disadvantage is that the stannous chloride reagent has to be diluted fresh daily. The Fiske-Subbarow method is far less sensitive to interfering substances and to the concentration of acid. However, it still requires the use of three different molybdate solutions for the use with samples containing various amounts of acid. The second drawback of the method is that the aminonaphtholsulfonic acid reducer does not keep well. Even in a well-stoppered bottle it becomes increasingly yellowish brown, and at the same time its reducing power slowly declines, especially if the sulfite used in preparing the solution is not absolutely fresh. A 14-day-old solution may give 10 to 15 per cent lower readings than a freshly prepared one, as found in our experiments. In addition, sometimes for no apparent reason it will precipitate in the test tube, making the liquid so turbid that it cannot be read without filtration. The third drawback of the Fiske-Subbarow method is that the intensity of the color produced increases continuously for several hours. If a visual colorimeter is used this will cause no complication, since the standard will darken at the same rate. However, with a photoelectric colorimeter, an instrument which is superseding the older visual types at a fast rate, the results may be considerably off if readings are not taken at a strictly specified time.

*From the Department of Medicine, the University of Chicago, Chicago.

This work has been done under a grant from the Douglas Smith Foundation for Medical Research of the University of Chicago.

Received for publication, January 13, 1942.

An attempt was made to develop a method which combines the advantages of the methods mentioned, with elimination of their drawbacks.

EXPERIMENTAL

In a first series of experiments the Benedict-Theis, Fiske-Subbarow, and Kuttner-Cohen methods were compared with respect to (1) their acid tolerance, and (2) the stability of the color produced. All readings were obtained with a photoelectric colorimeter.

Acid tolerance is defined as the permissible range of final acid concentration within which the method gives uniform readings at the optimum time suggested by the deviser of the method. It was found that within wide limits of molybdate concentration (0.1 to 1 per cent $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$) the acid tolerance of each method depends only on the proportion between molybdate and sulfuric acid in the final mixture. Acid tolerance will be expressed by the permissible range of cubic centimeters of normal sulfuric acid per 10 mg. of sodium molybdate under the conditions mentioned.

Acid Tolerance	
Benedict-Theis Method	0.9 to 2.2 c.c.
Fiske-Subbarow Method	1.1 to 2.1 c.c.
Kuttner-Cohen Method	1.3 to 1.45 c.c.

If the amount of acid present in the mixture is below the lower limit of tolerance, the readings will be too high and the blanks may be colored; if the amount of acid is above the upper limit, the readings will be too low.

As shown by the data, the range of acid tolerance of the Kuttner-Cohen method is very narrow. With the Fiske-Subbarow method the final concentration of acid is 2 c.c. per 10 mg. of molybdate. This is so close to the upper limit of tolerance that they realized the necessity of using special mixtures (molybdate II and molybdate III) with samples that contain additional free acid. Hydroquinone, used in the Benedict-Theis method, has an excellent acid tolerance. We found that boiling, an undesirable feature of this method, is unnecessary if the concentration of hydroquinone is increased to 1 per cent and that of the bisulfite is cut to 3 per cent. Although the color is somewhat slow to develop, it is extremely stable for a long period of time. This slow development of color is the main objection of Fiske and Subbarow to the Briggs method. However, it is hard to see why this should be considered a shortcoming as long as the method is satisfactory otherwise. In fact, slow development of color with sustained stability is a decided advantage, especially when a large number of determinations have to be done with a photoelectric colorimeter.

However, one of the objections of Fiske and Subbarow to hydroquinone is a valid one. It is the production of a brownish shade with molybdates.

The stability of the colors obtained with the methods mentioned is given in Table I.

Some other substances, part of which were tried previously by Fiske and Subbarow, were examined in order to find one that would give stable solutions and colorless blanks. Three of them, 2:4-diaminophenol hydrochloride (com-

mercial names, amidol, acrol), methyl-p-aminophenol sulfate (commercial names, metol, elon, graphol, etc.), and p-phenylenediamine were found to meet all requirements, in spite of the fact that Fiske and Subbarow were not satisfied with the first two. We are unable to explain why they did not find them satisfactory since they did not state their reasons.

Of the three substances mentioned, *elon* is the one of choice on account of its low price and its excellent keeping qualities. Unlike aminonaphtholsulfonic acid, it is readily soluble in a bisulfite solution. It can be kept almost indefinitely either in the crystalline form or in solution with 3 per cent sodium bisulfite.* The blanks produced with it are colorless. It is very insensitive to many common interfering substances. The following substances in the amounts stated per 15 c.c. of final mixture did not produce appreciable deviations in the readings in our set-up:

Sodium fluoride	15 mg.
Sodium oxalate	15 mg.
Sodium citrate	15 mg.
Sodium nitrite	3 mg.
Sodium nitrate	450 mg.
Sodium chloride	500 mg.
Ammonium sulfate	500 mg.
Ferric chloride	15 mg.
Trichloroacetic acid	750 mg.

In the case of large amounts of silicates special precautions, which will be mentioned later, have to be taken.

The acid tolerance of *elon* is 0.9 to 2.2 c.c. This considerable range of acid tolerance permits the use of a single molybdate-sulfuric mixture for all kinds of samples, with almost no regard for the amount of free acid they may contain. For instance, if in the set-up to be described later 5 c.c. of the molybdate-sulfuric reagent is used, an amount of acid equivalent to 0.5 c.c. of concentrated sulfuric acid will be tolerated.

The intensity of the color is practically the same as that obtained in the Fiske-Subbarow method. The stability of the color is given in Table I. The data were obtained by first calibrating the curves at the optimum times of reading, as specified by the authors or as found by us. Values at other times were read from these curves. The sample contained 0.04 mg. of phosphorus. Readings at optimum times are in italics.

TABLE I
1/100 MG. OF PHOSPHORUS

	5 MIN.	10 MIN.	30 MIN.	60 MIN.	120 MIN.
Kuttner-Cohen method	<i>4</i>	<i>4</i>	<i>4</i>	<i>4</i>	<i>4.06</i>
Fiske-Subbarow method	3.92	<i>4</i>	4.15	4.25	4.5
Hydroquinone (room temperature)	3.2	3.65	<i>4</i>	<i>4</i>	<i>4</i>
<i>Elon</i>	3.35	3.82	<i>4</i>	<i>4</i>	<i>4</i>

On the basis of the afore-mentioned data and of the constancy and proportionality of the readings obtained with *elon*, we are of the opinion that its use offers definite advantages over previous methods.

*Müller⁴ uses *elon* in a 5 per cent solution of neutral sodium sulfite. This solution keeps very poorly. The reading time proposed by Müller (fifteen minutes) is too low.

The following method was found to be simple and dependable. Its results in many hundred determinations on biological materials (serum, tissues, phosphatase) were compared with those obtained with the Fiske-Subbarow and Kuttner-Cohen methods, and proved to be in excellent agreement:

Solutions required.

1. 10 N sulfuric acid. Pour 282 c.c. of concentrated sulfuric acid into 600 c.c. of water. Cool and make up to 1,000 c.c.

2. Molybdate-sulfuric reagent. Mix 2 parts of a 5 per cent solution of sodium molybdate ($\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$), 1 part of 10 N sulfuric acid, and 1 part of water.

3. Reducing solution. Dissolve 1 Gm. of *clon* in 100 c.c. of a 3 per cent solution of sodium bisulfite.

Procedure. The method has been worked out for use with photoelectric colorimeters only.

1. Calibration of the curve. Prepare a standard solution of monobasic potassium phosphate, containing 0.01 mg. of phosphorus per cubic centimeter (110 mg. of the salt in 2,500 c.c., with 1 c.c. of concentrated sulfuric acid). Measure into each of 7 test tubes or volumetric flasks, as the type of the colorimeter may require, 2.5 c.c. of the molybdate-sulfuric reagent. Add 2 c.c. of the phosphorus standard to the first tube, and 1 c.c. more to each consecutive tube. The last tube will contain 8 c.c. of the standard. Add 1 c.c. of *clon* solution to each of the test tubes and fill them up to 15 or 25 c.c., respectively.* Read within from forty-five to ninety minutes. Use a red filter with transmission limits of about 600 and 750 $\text{m}\mu$. Plot readings on a semi-logarithmic graph paper. The readings should fall in a straight line.

If a range of much higher phosphorus values is required, the method of calibration will remain the same, except for proportionately larger amounts of reagents and final volumes.

2. Determination of phosphorus in sample. Measure 2.5 c.c. (or, if the sample is very acid, as after wet ashing, 5 c.c.) of molybdate-sulfuric reagent into a test tube or flask. Add about 5 c.c. of water. Add a measured aliquot of the sample, calculated to have a phosphorus content within the reading limits. Measure 1 c.c. of *clon* solution into the tube and fill up to the mark. Read as before.

If the amount of phosphorus in the sample is entirely unknown, one may proceed in the following way: Place 2.5 c.c. of the molybdate-sulfuric reagent in the test tube and dilute it with about 5 c.c. of water. Add first a small aliquot, say 1 c.c., of the sample, followed by 1 c.c. of *clon* solution. Wait a few minutes. With some experience it will be easy to judge whether the intensity of the color is within the range of readings. If it is, dilute to the usual volume. If the solution looks too pale, another measured aliquot may be added until the color seems to be of about the right intensity. On the other hand, if the solution is too dark, it should be diluted to a greater final volume

*With the Evelyn colorimeter the final volume should be 25 c.c.; with colorimeters using more narrow test tubes, such as the Lumetron apparatus, 15 c.c.

(up to 8 times). In our experiments we found that if such diluted solutions are read from a curve calibrated at a smaller volume, a correction of 1.75 per cent has to be added to the values for each 100 per cent of diluent; for instance, with a curve calibrated at 25 c.c., a reading at 50 c.c. requires a correction of +1.75 per cent; at 100 c.c., a correction of 3×1.75 or +5.25 per cent.

In the case of the presence of large amounts of silicate add 0.5 c.c. of 10 N sulfuric acid for each 2.5 c.c. of the molybdate-sulfuric reagent to the solution before adding the sample in order to depress the reduction of silicomolybdic acid. Take readings between forty-five and fifty minutes. The results of this slight modification of the *elon* method compare very favorably with those obtained with the Fiske-Subbarow technique. It was found that the latter method is far more sensitive to silicates than the data given by the authors would indicate.

Table II shows the results of the Fiske-Subbarow method, of the original, and of the modified *elon* method in the presence of sodium silicate. All samples contained 0.05 mg. of phosphorus in 15 c.c. of the final mixture. To one series of the tubes 2 mg. of sodium silicate ($\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$) were added; to the other series 10 mg. Readings were made in 1/100 mg. of phosphorus.

TABLE II

	5 MIN.	10 MIN.	30 MIN.	45 MIN.	60 MIN.	90 MIN.
Fiske-Subbarow						
Control	4.2	5	5.22	5.28	5.35	5.45
2 mg. silicate	4.2	5.1	5.7	5.86	6.2	6.5
10 mg. silicate	4.2	5.8	7.5	8.2	9.1	11.1
<i>Elon</i> , original						
Control	4.3	4.6	4.9	5.0	5.0	5.0
2 mg. silicate	6.3	7.25	9.25	11.1	14.5	
10 mg. silicate	14.5					
<i>Elon</i> , modified						
H_2SO_4 added						
Control	4.3	4.5	4.8	5.0	5.0	5.0
2 mg. silicate	4.5	4.7	5.0	5.0	5.1	5.16
10 mg. silicate	4.6	4.8	5.0	5.1	5.3	5.5

If the sample is alkaline, it must be neutralized or, even better, acidified with trichloroacetic or dilute sulfuric acid, since the acidity of the molybdate-sulfuric reagent is close to the lower limit of tolerance.

SUMMARY

The advantages and drawbacks of the Fiske-Subbarow and the Kuttner-Cohen methods for the colorimetric determination of phosphorus are evaluated. The use of *elon* as a reducing agent is suggested. A new method, adapted for use with the photoelectric colorimeter, is described. This method combines the advantages and eliminates the handicaps of the methods mentioned.

ADAPTATION OF THE SILVER COBALTINITRITE METHOD FOR POTASSIUM TO THE PHOTOELECTRIC COLORIMETER*

EARL H. WOOD, M.D., PH.D., BOSTON, MASS.†

THE silver cobaltinitrite potassium method was introduced by Breh and Gaebler (1930) as an improvement of the cobaltinitrite method of Kramer and Tisdall (1921). This procedure has been modified and its capabilities have been studied by Robinson and Putnam (1936), Truszkowski and Zwemer (1937), Ismail and Harwood (1937), Weichselbaum, Somogyi, and Rusk (1940), and Harris (1940).

The main advantages of this method over the more standard chloroplatinate method are: simpler analytical technique, lack of interference of sodium ion, decrease in the time required for an analysis, and the relatively small cost of the reagents used. However, the method has the serious disadvantage that it is based on reactions which do not occur in a strictly stoichiometrical basis.

Silver cobaltinitrite is formed by the interaction of silver nitrate and sodium cobaltinitrite. Silver cobaltinitrite forms highly insoluble salts with potassium. There reactions can be represented as follows (Burgess and Kamm, 1912):

As these reactions indicate, the composition of the precipitated potassium salt is not fixed and may vary under different conditions of precipitation; hence the potassium content of the precipitate cannot be calculated on a stoichiometric basis unless the precipitation is carried out under rigidly controlled conditions.

Chloride, silver, nitrite, and ammonium ions will interfere with potassium determination by this method. The chloride ion reacts with the silver of the silver cobaltinitrite reagent to form insoluble silver chloride. The amounts of silver and nitrite present influence the composition of the precipitated

Received for publication, February 16, 1942.

potassium salt (Weichselbaum and co-workers, 1940). If these two ions are present in relatively large amounts, they will precipitate out as silver nitrite crystals. The ammonium ion reacts with silver cobaltinitrite reagent similarly to potassium, forming an insoluble complex, which unless the ammonia has been previously removed would be determined as potassium.

The silver potassium cobaltinitrite complex decomposes and goes into solution when exposed to hot acid or alkali. The amount of silver, nitrite, or cobalt in the resulting solution can be determined and serves as an indirect measure of the amount of potassium in the solution from which the complex was precipitated.

The cobalt ion in relatively nonaqueous solutions, such as 95 per cent alcohol or acetone, reacts with ammonium thiocyanate according to the following reactions (Heinz, 1929; Steffen, 1932):

Breh and Gaebler (1930) used this reaction as a means of determining the potassium colorimetrically. This paper deals with the adaptation of this colorimetric method to the photoelectric colorimeter.

METHODS

The light transmission of alcoholic ammonium cobalt thiocyanate solutions from potassium analyses of standard potassium sulfate solutions was examined spectroscopically. The color of these cobalt solutions was found to be a mixture of red and blue, since the solutions absorb a relatively narrow band of light between 5,900 and 6,360 Å.U. The type of photoelectric colorimeter* used in this study measures the intensity of light transmitted through the solutions being analyzed, and in this sense might better be called a photometer. The instrument attains a high degree of sensitivity, and in a sense becomes a colorimeter when used with filters which absorb all light outside the absorption ranges of the solutions to be analyzed. A compound filter, which transmitted light between 5,800 and 6,560 Å.U., was found suitable for use with these cobalt solutions.

The silver cobaltinitrite reagent and the precipitation procedure used in the potassium analyses were as described by Truszkowski and Zwemer (1937).† By means of a stopcock-controlled siphon, equipped with a capillary tip bent up at the end and beveled at the same slope as the inside of the pointed tip

*The Evelyn Photoelectric Colorimeter, manufactured by the Rubicon Company, Philadelphia, Pa., was used in this study. The Klett-Summerson Photoelectric Colorimeter, manufactured by the Klett Manufacturing Company, New York, has been used in more recent experiments.

†In more recent experiments the precipitation procedure and wash reagent of Harris (1910) have been used, and 1.5 c.c. of 7 per cent sulfuric acid have been substituted for nitric acid as the solvent for the precipitated potassium complex. Such solutions made up to 10 c.c. photoelectric colorimeter show a straight line relationship between concentration and the galvanometer reading. The best sensitivity has been attained with a combination of Corning filters Nos. 245, 965, and 978.

centrifuge tube* in which the precipitation of the silver potassium cobaltinitrite complex is carried out, it has been found possible to withdraw the supernatant fluid completely enough so that the required number of washings and consequent centrifugings can be reduced from three to one without detectable loss in accuracy.

The procedure developed for the preparation of the potassium complex for photometric analysis was as follows: The supernatant wash fluid above the silver potassium cobaltinitrite complex was removed as completely as possible with the capillary siphon described above. One cubic centimeter of a 7 per cent† nitric acid solution was added, and the precipitate was dissolved by careful heating over a microburner. After cooling, the volume was made up to the 15 c.c. mark of the calibrated centrifuge tube with a freshly prepared 2 per cent ammonium thiocyanate solution in 95 per cent ethyl alcohol. A blank consisting of 1 c.c. of 7 per cent nitric acid made up to 15 c.c. with the thiocyanate solution was also prepared. The centrifuge tubes were closed with rubber stoppers previously washed with a nitric acid-alcohol solution with the same acid and alcohol content as the blank. The tubes were centrifuged for three minutes to remove any suspended particles. The solutions were then poured into the photometer tubes, the photometer tube shield placed at the 10 c.c. position, the zero point adjusted, and the rheostats set so that the galvanometer deflected to the 100 mark with the blank solution. The deflections of the cobalt solutions were then recorded. The photometer readings for alcoholic ammonium cobalti-thiocyanate solutions prepared in this manner and tightly stoppered will remain constant for several hours at room temperature and for days if kept at temperatures below 10° C.

The photometer was calibrated by running several series of analyses on known potassium sulfate solutions with potassium contents from 0.05 to 0.50 mg. by steps of 0.05 mg. A calibration curve was constructed by plotting the log of the galvanometer deflections against the potassium content.

RESULTS

The accuracy obtained in potassium analyses of dog whole blood and plasma with this method, using an ordinary colorimeter, has been previously reported (Wood, Collins, and Moe, 1940). Calculations based on 251 duplicate analyses indicated that the probable error of a single analysis was 1.2 per cent, or 2.3 μ g of potassium per cubic centimeter of plasma. The photoelectric colorimeter, if it is to be satisfactory for use with this method, must have a sensitivity which will allow detection of potassium content differences of less than 3 μ g. The standard deviation of a single photoelectric potassium analysis was calculated from 74 triplicate analyses of standard potassium sulfate solutions. The

*Very pointed tip centrifuge tubes similar to the Keys (1937) chloride tube, but made with a small glass foot to prevent perforation of shield cushions during centrifugation, have been found suitable for the accuracy of the procedure and greatly increase it.

†It was found that the alcoholic cobalt thiocyanate solution was not stable if the silver potassium cobaltinitrite complex was dissolved in 20 per cent nitric acid, as described by Breh and Gaebler. In the course of an hour or so, depending on the temperature, this solution turns green, and a yellow precipitate forms, probably due to the transformation of the thiocyanate to perthiocyanogen as a result of the oxidizing action of the nitric acid (McAlpine and Soule, 1933). This difficulty can be avoided by the use of 7 per cent nitric acid as the dissolving agent.

Fig. 1.—The relationship between the standard deviation of potassium analyses of standard potassium sulfate solutions and the potassium content of the sample.

*Number of triplicate analyses upon which each point is based. The calculated standard deviation for each point was corrected for the size of the sample.

Fig. 2.—Potassium analyses of standard potassium sulfate solutions: Variation of photometer calibration curves with aging of the sodium cobaltinitrite reagent (color: ammonium cobalthiocyanate blue).

*All standard potassium sulfate solutions were made up by dilution from the same stock solution. Each point is based on the averages of from 3 to 9 separate potassium analyses.

standard deviations have been plotted against the amount of potassium in the sample (Fig. 1). The average probable error in samples ranging from 50 to 500 μg of potassium was ± 1.1 per cent (0.9-2.0). This probable error for potassium analyses is acceptable for most biologic studies.

The photoelectric colorimeter calibration curve (Fig. 2) in the region from 50 to 300 μg of potassium was found to approach a straight line, the theoretical prediction for such an instrument. The slope of the calibration line in this region is such that 2.5 to 3.0 galvanometer divisions represent 10 μg of potassium. Since the galvanometer can be read accurately to somewhat less than one division, the sensitivity of the instrument will allow detection of concentration differences of less than 3 μg of potassium, or in terms of plasma concentrations, 0.3 mg. per 100 c.c.

Plasma potassium analyses by this method are carried out on 1 c.c. amounts of plasma; hence potassium analyses of from 50 to 300 micrograms are equivalent to plasma potassium concentrations of from 5 to 30 mg. per 100 c.c. This concentration range far exceeds the normal range of plasma potassium concentration found in man or in laboratory animals.

It was found that as the sodium cobaltinitrite reagent ages, the galvanometer deflections obtained from analyses of the same standard solution gradually decreases, i.e., an apparent increase in the potassium content of the standard solution. This finding was checked by determining a series of four calibration curves at intervals during a period of over six months. All standard potassium sulfate solutions used for the determination of these curves were made up by dilution from the same stock solution. The silver cobaltinitrite reagent was made up fresh on the day of its use by the addition of 5 c.c. of 40 per cent silver nitrate to 100 c.c. of the same stock solution of sodium cobaltinitrite reagent. The silver cobaltinitrite reagent was filtered by suction through a No. 4 sintered glass filter just prior to its use. A family of four separate calibration curves was obtained (Fig. 2). This change in the calibration curve apparently indicates that the cobalt content of the precipitated silver potassium cobaltinitrite complex increases as the sodium cobaltinitrite reagent ages. This constitutes a serious source of error in the use of the photoelectric colorimeter for this method. This source of error can be avoided to a large extent by running duplicate analyses of a standard potassium solution (containing 0.25 mg. of potassium) along with the analyses of unknown solutions. Since the calibration curves approach straight lines, the potassium content of the unknown solutions can be determined with reasonable accuracy by interpolation between the calibration curves on the basis of the deflection obtained with the standard solution.

The average results obtained for the potassium content of blood and tissue by the use of this method agree well with those reported from other laboratories using other methods (Wood and Moe, 1942; Wood, 1942).

Use of the photoelectric colorimeter is much less laborious and time-consuming than the use of the ordinary colorimeter. By means of the method described it is easily possible for a single analyst to complete fifty potassium determinations within ten hours, omitting the time required for precipitation of the potassium complex.

SUMMARY

(1) The adaptation of the silver cobaltinitrite method for potassium to the photoelectric colorimeter is described.

(2) The method is devoid of intricate technical procedures and substantially decreases the time required for a potassium analysis.

MEDICAL ILLUSTRATION

AGAR COMPOSITIONS FOR MOLDING: THE TECHNIQUE OF COMPOUNDING AND USING*

CARL DAME CLARKE, PH.D., AND ELIZABETH S. CONE
BALTIMORE, MD.

THE compounding and technique of using agar compositions for obtaining impressions of human tissue have been discussed at considerable length in previously published articles.^{1, 2} Recently a number of articles have appeared which add materially to the information on this subject. Most notable among these is the review by Paffenbarger,³ who considered in detail commercial agar preparations. This author has perfected devices for testing compositions as to their strength under pressure, their elasticity, and their flowing qualities. He presents a set of general specifications for making agar compositions suitable for use in dentistry as a material for intraoral impressions. However, he does not explain how agar compositions may be compounded or changed to suit specific cases. It is the purpose of our paper to include a discussion of this important subject.

Since the appearance of the afore-mentioned articles, Kaufman⁴ has devised a face mask of brass tubing through which cold water may be forced to facilitate rapid cooling of the negative, so that it may be removed from the tissue surface in a shorter period of time than was required previously. In this paper we shall also discuss the technique of preparing these molds in such a manner as to reduce the setting time of the agar composition.

In discussing the composition of agar molding materials, a basic formula may be considered. It should be realized that this formula is flexible and can be changed to suit specific requirements. Methods for changing the formula will be given following the reason for using each chemical.

Agar	4 ounces
Water	100 ounces
Zinc oxide	1 ounce
Oxyquinoline sulfate	10 grains
Cellucotton	$\frac{1}{2}$ ounce
Cotton	15 grains

Agar is the basic substance. When mixed with water it liquefies completely at 100° C. and does not jellyfy or start to set until it cools to about 40° C. Paffenbarger has found this setting point to vary from 36° to 44° C. in different batches of agar. It is this property of agar that makes it suitable as a molding material for use on living human tissue. The more serviceable

*From the Department of Art, University of Maryland School of Medicine, Baltimore.

composition should set at or near 44° C. If it sets below body temperature, 37° C., it is less satisfactory for use on living human skin. Agar differs greatly from gelatin or glue in this respect. It will adhere closely to the melting and setting points when mixed with water in spite of high or low concentrations. The amount of water in a gelatin or glue mixture plays a more important part on the temperature of its setting or jellying point. The higher the water content, the lower will be its setting point, and vice versa.

According to Paffenbarger, manufacturers report that they find it impossible to procure agar which is uniform from batch to batch. Agar from different species of seaweed from various parts of the world, or from different parts of the same country, shows varying characteristics.⁵ Therefore, it becomes necessary to refine the crude product before it can be used as an impression material. We have found that the commercial powdered agar has less strength in solution than either the granular or shredded agar. However, the powdered agar goes into solution more readily. The higher the agar content, the stronger the composition will be, but its flowing qualities will be reduced accordingly. The agar composition must possess a viscosity that will permit easy flow into the smallest details to obtain accurate impressions, such as the fingerprint pattern. If the flow is too sluggish, air bubbles and lap or border lines will be formed in the mold, which in turn will produce a defective cast. The agar content, as well as each of the other ingredients, must be balanced against one another to produce a composition suitable for making intraoral molds, molds of the skin surface, and molds of inanimate objects. For example, a mold of the gum surface is made by pressing a tray filled with agar composition against the gums. Its fluidity is more viscous because the pressure exerted in a comparatively small space has a tendency to reduce the possible formation of air bubbles. A composition suitable for application with a brush to the human skin, such as a face or hand, should be less fluid, since it must flow by gravity without pressure into every detail. However, it must be sufficiently viscous to remain where it is placed in adequate quantities to obtain a mold of the desired thickness. A less viscous composition may be poured over an inanimate protoplasmic specimen, such as a part of the viscera, or a nonprotoplasmic specimen, such as a plaster cast placed in a walled area. In many cases the viscosity of the agar may be controlled by the water content of the mixture. In other words, the same mixture may be used for all three purposes if the water content is changed to suit the specific case. However, this is not the ideal method. The mixture should be compounded to suit definite requirements, because the agar content of a mixture often determines its setting strength or elasticity. Other ingredients, such as an excess of alum and iron sulfate, will reduce this strength despite the small amount of water used.

Water is an important factor in the plasticity and friability of agar compositions, both in the liquid and set states. The water content must be balanced against all other ingredients. Regardless of the other ingredients, if there is too much water in the mixture it will lack strength and elasticity. The agar content imparts these desirable properties to the mixture. The remaining ingredients offset difficulties that can and do arise when an agar-water mixture is used for molding.

Zinc oxide, talc, whiting, and similar nonsoluble earths and minerals mix physically with agar but have little chemical effect upon the composition as a whole. They give the mixture bulk and weight. Their main use is to change the electrolytic action of a setting plaster cast that is made in an agar mold, or to absorb any substance that may be excreted from the agar during and after setting. Such a secretion can cause a softening of the surface of a plaster cast made in an agar mold. In other words, if these fillers or absorbing agents are not included, a plaster cast made in an agar mold does not set properly. There are other substances, such as borax, sodium chloride, and sorbitol which have a chemical action on agar compositions, materially toughening them and at the same time reducing the plasticity or flowing qualities of agar compositions as a whole. Borax may be substituted for zinc oxide; it causes the resulting mixture to be more elastic if the cast is to be of wax. Such a mold has a detrimental effect on the plaster cast. However, it is possible to balance the borax or sorbitol against the zinc oxide, talc, or similar earth pigments to prevent this softening or "skinning" of the resulting plaster cast, and at the same time produce a more elastic mold. In fact, concentrated sorbitol-agar mixtures have a strength that is a thousand times greater than that produced by ordinary commercial agar molding compositions. The latter compositions serve their purpose well in the *cire-perdue* or lost wax casting process as an intermediate step in making metal casts of sculptures. These mixtures will have to be perfected for use as a molding material for plaster casts.

Oxyquinoline sulfate is probably the best preservative for agar compositions because it prevents mold growth over a long period of time. It is not as volatile as thymol, nor is it as toxic as phenol or sodium fluoride, all of which have been used without complete success. Sodium fluoride is quite toxic in large quantities, but it has its place as a preservative for colloidal jellies that are applied to inanimate nonprotoplasmic subjects. Oxyquinoline sulfate is used in such small proportion that it has no effect on the plasticity of the agar in the prejelly state.

Cellucotton and *cotton* may be grouped together, since they have the same effect on agar mixtures, the effect being purely physical and not chemical. When these fibers are dispersed throughout an agar composition, they have a mechanical influence on the mixture, thereby holding it together. The cotton fibers are much longer than those of the cellucotton, which is a wood product. The amount of cotton fibers used must be kept low, for they tend to collect on the spoon during stirring and form in knots or clots throughout the mixture. These two substances, especially the cellucotton, increase the internal friction of the mass in both the liquid and set states. In other words, they give it body and reduce its flowing properties or plasticity.

Some manufacturers have incorporated rubber cement or para rubber dissolved into one of its solvents, such as benzine, into their agar compositions. After considerable experience in carrying out over two thousand experiments with such mixtures, we have come to the conclusion that the rubber, even when incorporated properly, is not only valueless in the mixture but is one of the most difficult ingredients to disperse evenly throughout the mass. It mixes only physically and not chemically, and provides thousands of tiny rubber

Fig. 1.—Making an agar mold of an inanimate object. An animate object, such as a hand, may be made in the same manner if a retaining wall of clay or cardboard is placed around the hand. A better method requiring less agar composition is shown in Fig. 3.

A, A cardboard or, preferably, a glass box is made as a retaining wall. The agar composition is poured into the box and allowed to set.

B, After setting, the specimen is removed.

C, The wax positive composition is poured or painted into the agar mold. If it is poured, the mold is turned until the composition covers all surfaces.

D, After the composition reaches a thickness of $\frac{1}{8}$ inch, gauze is applied with melted wax to reinforce the mold.

E, Pieces of wood are put in place to serve as anchors for mounting the specimen on a wooden base. The remaining mold is poured with melted wax. If the specimen is to be hollow, latter method requires less wax.

F, After the wax reproduction is removed, it is given a coating of shellac-alcohol fixative to make it suitable for coloring. If this fixative is not applied, the wax-resin mixture of the positive will mix with the oil paints used in coloring.

bands that in themselves exert less mechanical influence in holding together the particles than does the same amount of cellulocotton. We are inclined to believe that the commercial manufacturer includes rubber purely for its psychologic effect on the buyer. It is reasoned that since rubber is tough and elastic, it

Fig. 2.—The finished wax-resin casts.

B, Wax cast of a kidney made in the same manner.

should impart these qualities to agar compositions, but we have found no evidence of such effects. Our tests and analyses have shown that the commercial products containing rubber were less elastic than those without it.

Technique.—The basic formula mentioned in this text can be used for the various types of molding specified. However, as in all types of art work, the manner in which the formula is compounded and used determines the

Fig. 3.—The painting rather than pouring method of making an agar mold of an animate object. This method uses less agar and requires about the same amount of time to make.

- A, The hand is placed on a piece of glass.
- B, The agar composition is painted on the glass around the hand to anchor it into position. It is then applied over the hand.
- C, Rough edges of the agar are cut off and scraped away.
- D, Plaster which has been mixed in cold water is painted over the agar mold. If the mold has not completely set, the cold water-plaster mixture hastens setting for the agar mold.
- E, As the plaster thickens in setting, it is applied with the hands until sufficient thickness is built up.
- F, The top of the mold is scraped flat so that when inverted it will be level for pouring the positive.
- G, After the wax positive has been made, the agar mold may be taken from the plaster case.
- H, The agar mold is broken from the cast in removing the positive. This is given a coat of shellac fixative and colored.

quality of the finished product. For example, an impression of the hand may be made by painting or pouring the mixture over the skin surface, as seen in the illustrations. Both methods have their advantages and disadvantages. Invariably, less of the mixture is required in a painting process than in a pouring process.

Thin agar molds are not sufficiently strong by themselves to hold their shape without crumbling or cracking. It has, therefore, become necessary to

Fig. 4.—Making the agar mold of a face. This may be done while the subject is sitting erect. However, a rest for the head should be provided.

A, A small amount of agar is placed on the back of the hand of the subject to test its temperature. If it is too hot, it will not only be uncomfortable, but it must remain on the face longer to allow complete setting.

B, When the temperature is correct, the agar composition is applied from the neck upward. This prevents the agar composition from flowing too rapidly because of the pull of gravity.

C, Care must be taken in working the composition around the nose to allow openings for breathing. In this illustration the composition is allowed to run between the openings of the nostrils.

D, As the work progresses upward, the composition is worked carefully around the openings to the nose. Even if the nostril is covered, normal breathing will cause it to open. The composition will not be sucked into the nose unless it is too fluid.

follow one of two procedures to obtain a good mold. The first is to apply a plaster or a wax-resin shell over the thin agar mold so that it will not warp or break. The other method is to reinforce a thick agar mold with metal supports or with an armature.³ A mask may be made from copper or brass wire or from hollow tubes. This tubular mask is illustrated and described by Kaufman.⁴ The mask made of tubes is superior to the wire one because cold water may be

Fig. 5.—Making the plaster shell to support the agar mold.

A, After the agar mold has completely covered the face, the plaster-water mixture is applied.

B, As the plaster becomes thick during the setting, it is applied with the hand until sufficient thickness is built up.

C, The completed plaster shell. It will be noticed that openings have been left for breathing. Although straws placed in the nostrils could have been used, better results may be obtained if the worker masters the technique of handling both agar and plaster.

D, Agar molds are more easily removed from the face than plaster molds. In fact, the agar mold will generally fall from the face by its own weight when the face is placed parallel with the floor. A separating medium is necessary when making a plaster mold and should be used before the plaster is applied.

³A suitable wire mask is sold by the Warren-Knight Company, Philadelphia.

forced through the tubes and these aid considerably in cooling the agar composition to its setting point. However, both the wire and tubular masks have two disadvantages. Seldom do they fit snugly or closely enough to the skin surface to allow a thin mixture of agar to be applied. If they are anchored to the agar mold with gauze ties previously dipped in agar, their efficacy is reduced and much time is consumed in the process. Less time is required to make a thin plaster shell. Although an agar mold may be reinforced with

Fig. 6.—Making an agar mold of a profile.

A, A cardboard cutout is made to cover the profile of the face. This may be done in one of two methods. A piece of soft solder wire is bent over the face to take the outline of the face and head. This is removed and placed on the cardboard, and its inner surface is traced. The space is then cut out of the cardboard with the scissors. The other method is to place the head against a piece of cardboard. A pencil is then held vertical to the cardboard and an outline of the face is traced. These outlines seldom are absolutely accurate. Open spaces often exist between the face and the cardboard. Pieces of gauze are laid over these openings as the agar is applied. The gauze prevents the agar from running through the opening. As the work progresses from the bottom upward, the gauze is moved adjacent to the face. In cases of very loose hair, as seen in this illustration, it is advisable to give the hair a thin coating of petroleum jelly to prevent the agar from flowing too deeply into the hair. However, this can be dispensed with if the agar composition is applied with a syringe or grease gun having a nozzle which can produce ribbons of agar. Similar devices are used for decorating cakes.

B, The rough outline is cut away after the agar mold is completed. The subject can breathe through the nostril that is not covered with agar. If breathing is difficult through one nostril, an opening is left in the opposite side as the agar mold is applied.

C, The plaster shell is applied after the agar mold is completed.

D, The completed shell covering the agar mold.

gauze dipped in a liquid agar composition, such masks are less effective than the simple application of a thin plaster shell because more of the agar composition is required to make a thick mold, and this takes longer to set. The resulting thick agar mold is seldom as strong as the thin agar mold that is reinforced with a thin plaster shell. Furthermore, when one layer of agar composition is applied over a set layer, the different layers will probably separate and produce a weakened, crumbly mold.

Fig. 7.—The wax cast made from the agar mold seen in Fig. 6 ready for coloring.

A single thin painted layer is generally reinforced by means of a plaster rather than a wax-resin shell or case. It would be logical to reason that this double molding process requires more time to complete. On the contrary, this is not true, for the thin layer of agar composition sets quite rapidly and the plaster may be mixed thick, or its setting time may be accelerated by the addition of sodium chloride or potassium alum. It is practical because detail on the inner surface of the case or shell is not necessary. In this manner both the agar mold and the shell set rapidly, in the same length of time that would be required for a thick agar mold or a detail plaster mold to set.

The thin layer of agar composition obtained in painting shrinks and cracks rapidly. Therefore, the cast must be made soon after the mold is removed from the subject or the mold must be kept in wet towels if considerable time elapses between the making of the mold and the making of the cast. The same rule applies to the making of impressions of the face as well as other surfaces of the body. We have learned from experience that in spite of these drawbacks better results are obtained with the thin agar mold and the reinforcing plaster shell.

Here it may be contended that a plaster mold could have been made in the beginning without the use of agar. This is erroneous for three major reasons: (1) The plaster does not record as much detail as the agar; (2) the mold is more difficult to remove from the subject; and (3) the cast is decidedly more difficult to remove from the mold.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

TISSUE, A New Staining Method for Gram-Positive and Gram-Negative Organisms in Frozen Sections, Krajian, A. A. Arch. Path. 32: S25, 1941.

Method:

1. Prepare frozen sections, 7 to 10 microns thick, in the usual manner.
2. Stain for two minutes in alum-hematoxylin (Harris' method).
3. Wash in tap water until blue, and destain rapidly in acid alcohol, dipping in and out five to seven times.
4. Rinse in tap water and apply copper sulfate-zinc solution for three minutes (7 Gm. of copper sulfate and 4 Gm. of zinc sulfate dissolved in 100 c.c. of distilled water with the aid of heat).
5. Pour off, and apply brilliant green solution for five minutes (0.3 Gm. of brilliant green dissolved in 10 c.c. of copper-zinc sulfate mixture). Rinse in water and fortify for one minute with a 5 per cent aqueous solution of ammonium nitrate.
6. Rinse in tap water and apply carbolfuchsin (Ziehl-Neelsen method) for two minutes.
7. Rinse in tap water, blot, and apply dioxane for two minutes.
8. Pour off, and without washing apply creosote-xylene (equal parts), changing the solution several times and agitating the slide for even differentiation until the background appears to be clear red with no more stain leaving the section. (This step requires about one minute, and it is advisable to control the differentiation under the microscope.)
9. Clear in pure xylene for two minutes.
10. Mount in gum dammar.

With the use of this method, nuclei stain bluish red; gram-positive organisms, bluish green; gram-negative organisms, red; monillias and actinomycetes, green; and Negri bodies, bright red with greenish chromatin bodies.

All the staining solutions are stable, except the brilliant green, which keeps well for about twenty-four hours.

UROBILINOGEN, Determination of, in Feces and Urine. Watson, C. J., and Bilden, E. Arch. Int. Med. 65: 740, 1941.

Direct comparison has been made of the Sparkman and the Watson procedure for estimation of urobilinogen in feces and in urine.

Sparkman's report of higher values obtained with his technique, particularly as applied to urine, has not been confirmed. Opposite result were noted in the present investigation. Reasons for this discrepancy are discussed.

Evidence is presented which indicates the desirability of (a) obtaining an average per diem value for excreted urobilinogen, especially for fecal urobilinogen, over a period of several days, and (b) using a method which permits concentration of small amounts of urobilinogen whenever necessary because of low concentration in the sample.

B. DYSENTERIAE (Flexner). A Tellurite Rosolic Acid Medium Selective for, Wilson, W. J., and Blair, E. M. McV. Brit. M. J. Oct. 11, p. 501, 1941.

To 100 c.c. of melted nutrient agar cooled to 60° C. in a flask are added 0.5 c.c. of 1 per cent rosolic acid dissolved in absolute alcohol, 1 c.c. of a 4 per cent watery solution of iron alum, and finally 3 c.c. of a lactose-tellurite solution. The latter solution is made by boiling 20 Gm. of lactose in 100 c.c. of distilled water, cooling the solution, and then

dissolving in it 0.2 Gm. of potassium tellurite. It is necessary to dissolve the tellurite in a cold temperature, otherwise reduction occurs. This lactose-tellurite solution keeps for weeks, the tellurite being an effective preservative against bacteria, but not against molds. Growth of the latter can be prevented by the addition of 3 per cent of ether and by keeping the bottle tightly stoppered.

When the contents of the flask containing the medium have been thoroughly mixed, they are poured out into Petri dishes and allowed to set with the lids removed. A large loopful of a thick fecal emulsion in peptone water is spread over the surface of the plate and allowed to dry in the air. After incubation at 37° C. for eighteen hours, the pink colonies of Flexner's bacillus are readily distinguished from any yellow colonies of resistant *B. coli* which may have developed. Flexner's bacillus forms alkali, and the colony becomes distinctly pinkish red. In most cases the growth can be tested at once on a slide for agglutination with a polyvalent Flexner agglutinating serum.

PROTHROMBIN DEFICIENCY in Pulmonary Tuberculosis, Sheely, R. F. J. A. M. A. 117: 1603, 1941.

Among 106 cases of active and chronic pulmonary tuberculosis (10.3 per cent of minimal, 20.6 per cent of moderately-advanced, and 69.1 per cent of far-advanced tuberculosis) studied in regard to the concentration of prothrombin in the blood, a significant deficiency of prothrombin was found in 51.

Fifty patients had far-advanced tuberculosis, and 5 of these were receiving treatment with artificial pneumothorax, with resulting unsatisfactory collapse of the diseased lung. Two patients were undergoing re-expansion of the collapsed lung.

Among the patients, 73 per cent with minimal, 60 per cent with moderately-advanced, and 9.6 per cent with far-advanced tuberculosis had a prothrombin concentration within the normal range. (A total of 68.5 per cent of those with far-advanced tuberculosis had a prothrombin concentration below 59 per cent of normal.)

There was no constant relation between the prothrombin concentration and the sedimentation rate. The status as to prothrombin level appeared to coincide with the clinical and roentgenologic status of the majority of the patients.

It is suggested that the prothrombin concentration should be determined in every case of hemoptysis in pulmonary tuberculosis. In 4 cases of frank hemoptysis with associated prothrombin deficiency, the elevation of the blood prothrombin level on the administration of vitamin K, orally and parenterally, was a likely factor in the control of the hemoptysis.

The significance of the prothrombin concentration in surgical procedures on patients with pulmonary tuberculosis must await further study.

The prothrombin concentration in the blood of patients with tuberculosis seems to be related, in some way, to the toxemia resulting from the existing tuberculous infection in the lung.

SULFANILAMIDE, A Simplified Method for the Estimation of Sulfapyridine and, in Biological Fluids, Scott, L. D. Brit. J. Exper. Path. 22: 220, 1941.

1. (a) Stock standard of M & B 693 Dagenan. One hundred milligrams of pure 693 dissolved in 100 c.c. of N/100 sodium hydroxide. A special preparation of 693 is supplied for chemical analysis by May and Baker, Ltd., Dagenham, England.

(b) Stock standard of sulfanilamide, 100 mg. of paraaminobenzene-sulfonamide (B.D.H.) per 100 c.c. of water.

2. Standard solutions of 693 and sulfanilamide. Two standards are prepared of each, 2.5 and 5 c.c. being diluted to 100 c.c. with water. One cubic centimeter equals 0.025 and 0.05 mg. of 693 and sulfanilamide, respectively.

3. Three per cent (by volume) hydrochloric acid.

4. Dilution 1:10 with water of 0.5 per cent aqueous sodium nitrite solution. (The 1:10 dilution is prepared prior to the test or freshly each day.)

5. Fifty per cent aqueous solution of urea.

6. One per cent (by volume) alcoholic solution of dimethyl- α -naphthylamine prepared freshly each month from stock solution (B.D.H.), and stored in an amber ground-glass stoppered bottle.

7. Diluent for colorimetry: 20 c.c. of water, 5 c.c. of 3 per cent hydrochloric acid, and 5 c.c. of absolute alcohol.

8. Normal horse serum and oxalated whole blood (Burroughs Wellcome & Co.).

9. Approximately 0.25 per cent protein solution prepared by a 1:25 dilution of the horse serum with 0.5 per cent sodium chloride. Five to 6 drops of 10 per cent alcoholic thymol solution is added as preservative.

10. Cordite tubes of uniform bore, graduated in 0.1 c.c. and of 5 c.c. capacity (diameter 1 cm., length 12.5 cm.).

Note. Solutions 1, 2, 6, 8, 9 if kept in the refrigerator are stable indefinitely.

Procedure for Cerebrospinal Fluid.—Introduce into two test tubes (graduated at 5 c.c.) in the following order, with thorough mixing after each addition:

<i>Standard</i>	<i>Test Cerebrospinal Fluid</i>
0.5 c.c. of standard (0.05 mg. per c.c.)	1 c.c. of cerebrospinal fluid
0.5 c.c. of 0.25 per cent protein solution	0.5 c.c. of 3 per cent hydrochloric acid
0.5 c.c. of 3 per cent hydrochloric acid	
0.5 c.c. of 1:10 dilution of sodium	0.5 c.c. of 1:10 dilution of sodium nitrite

Stand at room temperature for five minutes.

Add 0.5 c.c. of 50 per cent urea solution to each tube, mix well, and allow standing for three to five minutes longer for the urea to destroy excess of sodium nitrite. (The unused residual nitrous acid otherwise reacts with the dimethyl- α -naphthylamine to form a brownish-orange coloration that makes colorimetric comparison somewhat difficult.)

Add 0.5 c.c. of 1 per cent alcoholic dimethyl- α -naphthylamine to the contents of each tube, and mix very thoroughly. Allow to stand for ten minutes, and then dilute both volumes to the 5 c.c. mark with the special diluent fluid. Mix again, and compare colorimetrically or by dilution colorimetry.

Calculation: $\frac{S}{U} \times 0.025 \text{ mg.} \times 100 = \text{milligrams of sulfonamide}$
per 100 c.c. of cerebrospinal fluid.

Procedure for Blood Serum.—

<i>Standard</i>	<i>Test Serum</i>
0.5 c.c. of normal horse serum	0.5 c.c. of serum
0.5 c.c. of standard (0.025 or 0.05 mg. per c.c.)	0.5 c.c. of water
0.5 c.c. of 3 per cent hydrochloric acid	0.5 c.c. of 3 per cent hydrochloric acid
0.5 c.c. of 1:10 dilution of sodium nitrite	0.5 c.c. of 1:10 dilution of sodium nitrite

Stand at room temperature for five minutes.

Note.—It should be noted that the occurrence of hemolysis renders this technique useless, it being impossible to match the colors of standard and test solution.

Add 0.5 c.c. of 50 per cent urea solution to each tube, stand again for three to five minutes, and then add 0.5 c.c. of dimethyl- α -naphthylamine to the contents of both tubes. Mix and allow to stand for ten minutes, after which the volumes are diluted to 5 c.c. with the dilution fluid. Mix thoroughly and compare in the colorimeter or by colorimetry.

Calculation: $\frac{S}{U} \times 0.0125 \text{ or } 0.025 \text{ mg.} \times 200 = \text{milligrams of sulfonamide per 100 c.c. of serum.}$

Procedure for Whole Blood and Lipemic or Hemolyzed Sera.—

Into a small test tube introduce 2 c.c. of water, and add 1 c.c. of whole blood, serum, or plasma. After mixing well, stand for two to three minutes for plasmolysis to take place. Add 2 c.c. of 15 per cent trichloroacetic acid, drop by drop, with constant shaking. Finally shake the mixture vigorously and filter it through a No. 1 5.5 cm. Whatman paper. Pipette

2.5 c.c. of filtrate into a 5 c.c. graduated test tube, and add 0.5 c.c. of 1:10 dilution of sodium nitrite. Allow the tube to stand for five minutes at room temperature and then add 0.5 c.c. of urea solution, followed by 0.5 c.c. of alcoholic dimethyl- α -naphthylamine.

The standard is prepared at the same time by adding 0.25 c.c. (with a micropipette) of stock sulfonamide solution (100 mg. per 100 c.c.) to 4.75 c.c. of oxalated horse blood or horse serum as the case may be. Mix thoroughly and pipette 1 c.c. into 2 c.c. of water. The above procedure for the test blood is then followed in detail.

After the addition of the coupling reagent to the standard and test solutions, the colors are allowed to develop at room temperature for fifteen minutes, and are then diluted to 5 c.c. with the following diluent: 25 c.c. of water, 10 c.c. of 15 per cent trichloroacetic acid, and 5 c.c. of absolute alcohol. The contents of each tube are mixed well and comparison is made by dilution colorimetry (using the diluent just described), or by colorimetric means.

$$\text{Calculation: } \frac{S}{U} \times 5 = \text{milligrams of sulfonamide per 100 c.c.}$$

Estimation in Urine.—A 1:5 dilution or a 1:10 dilution of urine is made with the 0.25 per cent protein solution, and 0.5 c.c. is taken and compared with a suitable standard.

<i>Standard</i>	<i>Urine</i>
0.5 c.c. of standard (0.025 or 0.050 mg. per c.c.)	0.5 c.c. of 1:5 or 1:10 dilution of test urine with 0.25 per cent protein solution
0.5 c.c. of normal control urine diluted in the same proportion as the test urine with 0.25 per cent protein solution	0.5 c.c. of water

Proceed as for the blood serum method.

$$\text{Calculation: } \frac{S}{U} \times 0.0125 \text{ or } 0.025 \text{ mg.} \times \text{dilution of urine} \times 200 = \text{milligrams of sulfonamide per 100 c.c. of urine.}$$

With other body fluids, such as transudates or exudates, treat exactly as for the blood serum method.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

The Advancing Front of Medicine*

AN EXCELLENT volume dealing with recent advances in all fields of medicine, prepared for the intelligent layman. The various chapters are elaborations of short articles which have recently appeared in *Harper's Magazine* and elsewhere. By virtue of his many years of connection with The Rockefeller Foundation, Dr. Gray has developed a facility in understanding and presenting, in a delightful manner, information in science and in medicine. Physicians will enjoy this book as much as laymen. It is up to the minute and completely authentic.

Stethoscopic Heart Records†

THIS is a book only in the sense that it is a bound volume. The binding covers a series of seven Columbia single-faced records, prepared by Dr. Geckeler for student instruction in cardiac auscultation. The records are played on the phonograph. The auditor sits wearing his stethoscope and the sounds appear to come through the stethoscope, simulating in a remarkable manner what one actually hears at the bedside. There is a running commentary describing what will be heard next.

Normal heart sounds, abnormal heart sounds, murmurs, and arrhythmias are illustrated.

The reviewer was impressed with this excellent idea for student instruction. It will probably also find value among those medical graduates who like to check from time to time on the accuracy of their work. It might be described as a very short refresher course.

One very minor criticism is that at one point the commentator may be misunderstood as implying that one can tell the difference between syphilitic and rheumatic aortic valve diseases by the character of the murmur.

Diseases of the Blood‡

THE book is just what it purports to be, an atlas of hematology. It is beautifully illustrated with many full-page color plates. The text covers not only the pathologic findings but also the diagnosis and treatment of the various blood dyscrasias. An example of the thoroughness of coverage is found in Table XIX, which lists the relative cost to the patient per unit of various brands of liver extract.

Hematology has developed a language of its own, and the first two chapters deal with terminology and definitions of hematologic terms. There follows a discussion of the origin and development of blood cells, and a long section presenting what is known concerning the normal blood and marrow constituents. The major portion of the book is given over to blood diseases.

The volume should be of great value to clinical pathologists and internists.

*The Advancing Front of Medicine. By George W. Gray. Cloth, 425 pages, \$3.00. McGraw-Hill Book Company, Inc., New York and London, 1941.

†Stethoscopic Heart Records. Sounds, Murmurs and Arrhythmias. By George D. Geckeler, M.D., Columbia Records, Set M600, 1941.

‡Diseases of the Blood and Atlas of Hematology. With Clinical and Hematologic Descriptions of the Blood Diseases, including a Section on Technic and Terminology. By Roy R. Kracke, M.D., Professor of Bacteriology, Pathology, and Laboratory Diagnosis, Emory University School of Medicine; Pathologist to the Emory University Hospital; Consultant in Hematology to the Grady Hospital and Eggleston Hospital for Children, Atlanta, Ga. Former ed. 2, thoroughly revised, reset and enlarged. 692 pages, 54 color plates and 46 other illustrations, \$15.00. J. B. Lippincott Company, Philadelphia, London, Montreal, 1941.

Immunology*

ONE is surprised at the paucity of recent books written primarily for discussion of immunology. Most such volumes cover bacteriology and immunology, with major emphasis on the former. Sherwood's book, therefore, stands alone. If there were a profusion of other books, it would still stand alone. This is probably the chief reason why the second edition appeared soon after the first. New chapters have been added, a few changes suggested by reviewers of the first edition have been made, and the subject has been brought up to date.

The Retina†

COVERING much more than its title implies, *The Retina* is a most comprehensive review of anatomy of the retina and the visual pathways and the physiology of vision. The tremendous bibliography illustrates well the thoroughness with which the author has covered his subject in his ten years of investigation. Much of the contents represents original study. There are one hundred full-page plates.

This volume should be of especial interest to ophthalmologists, neurologists, and physiologists. For others it will serve more as a reference volume.

Synopsis of Allergy‡

THE *Synopsis of Allergy* is an excellent addition to the Mosby Synopsis Series. Dr. Alexander has an admirable facility for compressing much knowledge into little space. To accomplish this he has necessarily omitted discussion of pros and cons of moot points. The omission of extensive references to the contributions of others makes for easier reading and saves much space. These references being available in other larger works on allergy, there is no need for their inclusion in a small book the prime function of which is to give meat.

A few sections, especially those on serum allergy, bacterial allergy, and drug allergy could be elaborated upon with no great increase in size of the volume.

A short appendix gives the desired basic information concerning preparation of extracts and methods of diagnostic study in such a way that one who has made no special study of allergy could carry on with the diagnosis and treatment of simple cases. More complicated cases would require reference to more extensive treatises on the subject.

Allergy in Clinical Practice§

ANOTHER addition to the profusion of recent books on allergy; this volume makes no effort to add anything basically new to the subject, and is presented with the same general type of approach that is followed in *Medical Clinics of North America*. It is primarily a series of case reports from the Cleveland Clinic, designed to illustrate the advantage of collaborative work with the allergist on the part of specialists in the several other fields of medicine. The outstanding sections are those on Allergic Dermatoses and Ocular Manifestations of Allergy. References to the literature are rather scant.

CLINICAL AND EXPERIMENTAL

THE ORIGIN AND NATURE OF THE CABOT RING BODIES OF ERYTHROCYTES*

EMIL MARO SCHLEICHER, MINNEAPOLIS, MINN.

INTRODUCTION

CABOT¹ in 1903 enriched the literature with an unique contribution. He described red and blue staining circular and twisted bodies within basophilic, polychromatic, and infrequent orthochromatic erythrocytes, first brought to his attention by one of his associates in a case of lead poisoning and thereafter observed by himself in the anemic blood of patients suffering from pernicious anemia, lead poisoning, and lymphatic leucemia.

The dissertation aroused much interest for a twofold reason: first, no previous mention of such bodies had been made; and second, Cabot's hypothesis that the ring bodies may represent "nuclear remnants" was diametrically opposed to the tinctorial behavior of the structures.

When this paper went to press, the literature contained no feasible explanation for the peculiar affinity of these supposed nuclear derivatives for cytoplasmic stains; no actual proof withstanding critical analysis that the ring bodies are nuclear remnants, and no convincing data to show that they are laboratory creations.

It is the purpose of this communication to show that the Cabot ring bodies are denatured protein configurations, i.e., they are actually laboratory products. The phenomenon occurs in specifically altered cells only, i.e., in erythrocytes and certain erythroblasts that have undergone lysis. This statement is supported by two facts: (a) the creation of numerous Cabot ring bodies at will, in blood samples taken from cases with pernicious anemia in severe relapse, acute lead

*From the Hematological Laboratory, Institute of Anatomy, University of Minnesota.
Received for publication, May 17, 1941.

poisoning, terminal lymphosarcoma, acute malaria, terminal lymphatic leucemia, congenital hemolytic icterus during hemolytic crisis, erythroblastosis fetalis, and a case with generalized Hodgkin's disease; and (b) the production of simulacra in normal, pathologic human erythrocytes, and the creation of analogous structures with egg white by special methods.

For those who are not familiar with the problem at hand the major articles and theories will be presented briefly. Cabot's dictum that divided students of the subject into two groups, those who advocate that the ring bodies are remnants of the nuclear membrane, and those who claim that they are artifacts, is cited first:

"There is no reason to believe them a mark of cellular degeneration . . . they have some connection with the nucleus formerly possessed by the cell that contains them seems to me not unlikely . . . their shapes correspond for the most part very well with those of nuclear figures . . . the best hypothesis, therefore, that I can suggest to account for these appearances is that they represent nuclear remains . . . the significance of their red color with Wright's, a stain which never stains any nucleus red, is not clear to me . . . have these figures any practical significance? Not so far as I know."

Thus Cabot, while very conservative and noncommittal regarding the nature of the bodies, precipitated, by this very approach to the phenomenon, an extensive literature dealing with the mode of origin of the structures bearing his name.

Among the investigators who believe the rings to be identical with the nuclear membrane are Schleip,²⁻³ Pappenheim,⁴⁻⁶ Sluka,⁷ Alder,⁸ Ferrata,^{9,10} Ferrata and Viglioli,¹¹ Juspa,¹² and Jordan, Kindred, and Beams.¹³ Ferrata's hypothesis: "The Cabot ring bodies are the peripheral residue of the nucleus and are produced by vacuolization of the central mass" has become a prevailing view, in spite of his observation that generally the rings stained with pyronin and only an occasional one showed affinity for methyl green, specific for nuclear derivatives. In Ferrata and Viglioli's paper, the concept was enlarged by the authors' statement that "the Cabot ring bodies are morphologically identical with the peripheral part of the nuclear membrane. They are always a sign of a typical pathological maturation of the erythroblasts, the ring bodies occur only in severe anemias." Juspa proposed the following theory: "The ring bodies are not typical nuclear chromatin; they represent nuclear remnants and in all probability are the membrane left behind through pathological endonuclear vacuolization processes and karyolysis." Jordan and co-workers concluded: "Moreover, the genuine Cabot rings seem clearly to represent persistent nuclear membranes."

Among those who proposed that the Cabot rings are artifacts is Demel,¹⁴ who assumed that "the Cabot rings represent the boundary zone between an inner area of more rarefied hemoglobin and an outer more condensed area." Demel was working with normal blood, using a stain (Neo-Giemsa) formulated by Dr. Poletti of Pisa. His theory is refuted, however, by the fact that the rings can be produced after the hemoglobin has been laked.

Russow,¹⁵ commenting on Sluka's paper, pointed out that if the Cabot rings are nuclear remnants, they should be seen in the bone marrow, and their appear-

ance should obviously be more frequent in this organ. He concluded: "the rings are most likely the expression of unusual drying processes of the anemic blood, since the bodies have only been observed in dried peripheral blood preparations."

The neutral side in the controversy is represented by Naegeli,¹⁶ who summarized the literature as follows: "Cabot rings are generally considered nuclear membrane remnants, absent in erythroblasts and the blood forming organs; they are a pathologic phenomenon of nuclear dissolution." Schilling¹⁷ states: "It is not certain that the Cabot-Schleip rings are nuclear remnants." In another publication¹⁸ he records seeing Cabot rings in normal erythroblasts. He further suggests, according to Schröder,¹⁹ that the rings may represent the contour of the "glass body" of the erythrocyte. Isaacs,²⁰ in Downey's *Handbook of Hematology*, informs us that Cabot rings have been found in cells with perfectly intact nuclei and entirely separate from the nuclei. Isamboulas and Malikiosis²¹ present in their article a photomicrograph showing a Cabot ring in the protoplasm of a normal erythroblast obtained by sternal aspiration from a patient with typhus. They come to the conclusion that their observation is "opposed to the prevailing view."

That Cabot rings occur in erythroblasts has been ascertained from the literature cited and from my own observations, but their presence is rare indeed. Over a period of many years I have seen only two specimens. The infrequency is especially brought out by the fact that no clear-cut example was noted by Dr. Hal Downey, in his large collection of preparations in the field of hemopathology. The erythroblast shown in Fig. 14 was found in one of the smears made from the peripheral blood of the case with generalized Hodgkin's disease mentioned above. The only other one was seen in the bone marrow of a patient with severe relapsed pernicious anemia, having about 650,000 red blood cells per c.mm. A probable reason for the scarcity of the presence of Cabot rings in erythroblasts is given elsewhere in this paper.

In over 2,150 bone marrow aspirations,^{22, 23} covering practically all well-known hematologic disorders (mindful of the admixture of sinusoidal blood with the bone marrow specimen), I have in no instance observed a greater number of Cabot rings in the bone marrow preparations than were seen in those made from the peripheral blood. No exception was the case with acute sickle-cell anemia,²⁴ where in the "usable area"²⁵ the erythroblasts numbered eighty-four among one hundred leucocytes, but only four erythrocytes with Cabot rings were observed per 180 micrometer squares.²⁶ The scarcity of Cabot ring bodies seemingly is the rule rather than the exception in severe erythroblastic anemias and toxic anemias associated with erythroblastemia and icterus (leading by their very nature to severe disturbances of the denucleation process), where one would expect Cabot ring bodies to be plentiful in the bone marrow. As already pointed out, this is not the case. Furthermore, dark-field examinations have never revealed that Cabot ring bodies are preformed structures, i.e., nuclear membranes. The hypothesis that the Cabot ring bodies are neither nuclear remnants nor a sign of pathologic denucleation processes, is strengthened by the observations cited in this paragraph.

Structures similar to those described by Cabot have been produced by various investigators.^{27, 28, 38, 45-47} These simulacrum were obtained by exposing erythrocytes to a hemolytic system. It may then be assumed that the creation of the ring bodies depends upon the degree of lysis an erythrocyte or erythroblast has undergone in vivo or in vitro, induced by a specific agent. Thus a plausible reason is advanced for the appearance of these bodies in disorders of the hematopoietic organs associated with severe anemias, and with or without elevated icterus.

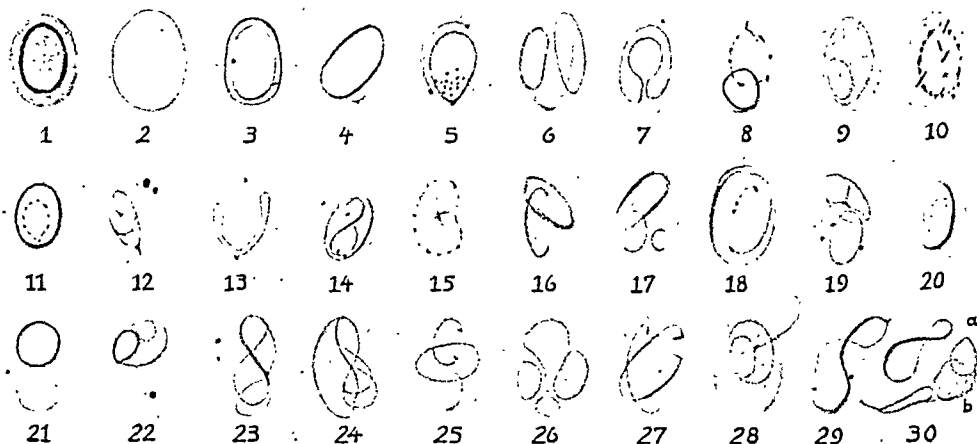

Plate I.

Basophilic and polychromatic erythrocytes showing "denatured protein configurations" (Cabot ring bodies).

THE ORIGIN OF CABOT RING BODIES

A blood smear was presented to me by Dr. R. H. Jaffé* in which he had observed Cabot ring bodies showing an unusually brilliant red hue, as well as width and flatness of the ring bodies. The smear was made from the peripheral blood of a moribund patient with generalized Hodgkin's disease. Figs. 1 and 2a show examples of the bodies seen by Dr. Jaffé. Examination of the preparation revealed that there were only three erythrocytes with Cabot ring bodies per 180 micrometer squares.²⁶ Erythroblasts were numerous in this blood, and many cells showed pathologic denucleation. A severe anemic state was present: red blood cells, 1,020,000, hemoglobin, 3.0 Gm., icterus index, 15 (Wintrobe), and a reticulocytosis of 18.4 per cent; occasionally a reticulocyte with ring bodies, Figs. 2 to 6. As the number of ring bodies was too small to trace their origin, peripheral blood was defibrinated and permitted to sediment in a Wintrobe hematocrit tube. The procedure was designed to gather more specifically altered red cells assuming that hemolyzed cells tend to form the uppermost layer of the blood column. While smears made from the top layer yielded a larger number of ring bodies, I was unable to trace intermediate stages between the nuclear membrane and the Cabot ring bodies.

*Chief pathologist of Cook County Hospital, Chicago, Ill.

An experiment was then set up that conformed to Russow's theory. Peripheral blood was spread on glass slides, placed in a slanting position while drying, allowing the plasma to accumulate near one end of the blood films, and thus delaying the drying process. The control slides were made in the standard manner, rapidly whipping them through the air to accelerate drying. On examination of the preparations, the following observations were made: Many circular and twisted Cabot ring bodies were seen in the area where drying was delayed, whereas the opposite area showed only occasional bodies. The control slides revealed about the same number of ring structures as noted in the rapidly drying area of the slanting preparations. This was definite evidence that the ring bodies were created by delaying the drying process. Plate I shows some of the Cabot ring bodies produced by the slanting method.

Fig. 1.

Fig. 2.

Fig. 1.—Mr. A. K. Generalized Hodgkin's disease, peripheral blood. *a*, Orthochromatic erythrocyte with a typical Cabot ring body. Note that this denatured protein body has a considerable width and appears to be a flat structure within a uniformly stained cell. *b*, Markedly lysed erythrocyte with a fine blue ring.

Fig. 2.—Mr. A. K., peripheral blood. *a*, Erythrocyte with a figure-eight body and a bar at the crossing point. *b*, Erythrocyte with a figure-eight body intersecting at a crossing point. Two globules and an absorption of protein at the cell periphery (at arrow).

The formation of the figure eight may be as follows: two rings form simultaneously in the same plane and flow together, or rings unite from adjacent planes, or a ring retracts rapidly and overlaps.

At no time were the angles great enough to encourage concentrations of red blood cells which might account for the increased number of ring bodies at or near the edge of the blood smear. An estimation of the erythrocyte number with the dry chamber method²⁶ showed an error of from 4.2 to 5.4 per cent for the preparations made by the slanting method, in comparison with the counting chamber number. While in this particular blood the number of ring bodies could be varied at will, this could not be accomplished to the same extent in all blood samples taken from cases with severe anemias, showing one to several ring structures per 180 micrometer squares. In this test series the serum icterus ranged from 2 to 280. When no ring bodies were seen in the routine smears,

their creation by the slanting method frequently met with failure. Fig. 3 shows the development of a Cabot ring body as noted in the areas in which slow drying occurred.

The experiments showed that a severe anemia, high bile pigment concentration, and unusual drying of the blood are not the sole factors responsible for the creation of the phenomenon. The negative results suggested that the formation of ring bodies is dependent upon the presence of a circulating specific hemolysin which alters the relationship of the essential components of the protoplasm while *in vivo*, and that delayed drying, fixing, and staining of the blood are of lesser importance, but are contributory factors. That specific lysis may very likely be a bile derivative "bile acid" that disassociates the chemical components of certain erythroid cells not only *in vivo* but seemingly also *in vitro* is suggested by analytical data presented by Irvin, Johnston, and Sharp* on bile acids and their hemolyzing effect on the red blood cells *in vitro*.

Fig. 3.—Mr. A. K. Peripheral blood showing the development of a Cabot ring body. *a*, Markedly lysed erythrocyte with a reddish corona. Phase I. *b*, Erythrocyte with a pale peripheral area which follows the contour of the cell (for its replica see Plate I, 1). This phenomenon is produced by the retraction of the cytoplasm exposing the transparent envelope. Phase II. *c*, Erythrocyte with retracted peripheral ring. The cell was markedly lysed. The structure had the characteristic red color of Cabot ring bodies. Phase III. *d*, Polychrome with irregular aggregated protein at the periphery. *e*, Group of erythrocytes showing lysis corona suggesting peripheral rings. See Fig. 27 in Cabot's article. *f*, Erythroblast with nuclei approximating the diameter of the ring cell *c*, showing that Cabot's assumption that the bodies may represent nuclear remnants is feasible.

STRUCTURE AND TINCTORIAL BEHAVIOR OF THE CABOT RING BODIES

Experiments were designed to determine the reason for the fluctuation of the dimensions, configurations, and affinity to specific cytoplasmic dyes of the ring bodies.

Preparations were used which were made by the slanting method, showing from 12 to 34 erythrocytes with ring bodies per 180 micrometer squares. The location of all cells chosen for this critical study was determined with the vernier scale of a mechanical stage.

Photographs before and after decolorization revealed that some of the ring bodies were at or near the surface, and seemingly part of the envelope, whereas other rings seemed to belong to a layer or layers distinctly below the erythrocyte

*Annual meeting of the Central Society for Clinical Research, Chicago, Ill., Nov. 1, 1940.

envelope. With the May-Grünwald Giemsa stain these ring bodies were either of a dubious reddish blue, or distinctly red or blue. The ring bodies assumed to be at or near the surface could be made out only with difficulty when decolorization was carried to a point where the nucleus of the leucocytes could still be made out. The deeper lying rings either retained their hue, were a nuance lighter, or became more distinctly red or blue. Some rings which showed irregular staining affinities were invariable composed of irregular thick bars (threads) or of tiny globules. Other ring bodies were composed of not only one, but of two or more thin rings either superimposed on each other or concentrically arranged.

Fig. 4.—Mr. O. H. Pernicious anemia in severe relapse; peripheral blood. *a*, Basophilic megalocyte with a colorless protein ring. The ring, which had a reddish blue tint, could not be restained after the preparation was exposed to room temperature for one week.

Thus it may be assumed that the staining variability depends upon the character and quantity of the substance that makes up a ring, the molecular thickness of such a structure, and the momentary physical state of ring constituents. The latter may supply the answer to the loss of affinity for a dye of a ring body that formerly stained reddish blue. This phenomenon occurred in several basophilic megalocytes from a patient with pernicious anemia in severe relapse when a preparation was decolorized and restained after exposure to room temperature for six days. Fig. 4 shows an example of a colorless ring body in a basophilic megalocyte.

STRUCTURE OF THE MATURE ERYTHROCYTE

It is not within the scope of this article to give an account of the numerous hypotheses that have been advanced concerning the structural make-up of the mature erythrocyte. The literature on this particular subject is more confusing than enlightening. The contributions of Michels,²⁹ Ponder,³⁰ and others^{6, 17, 31-34} give a general picture of this topic.

I have long favored the trend initiated by Ponder to divide the physicochemical structure of the erythrocyte into three components: (a) membrane, i.e., envelope, (b) cytoplasm, and (c) their respective protein-lipoid constituents. This division is not only unreservedly subscribed to by most investigators, but it permits projection of the laboratory experiments presented in this paper into the erythrocytes. All accumulated physicochemical data represent at best only relative values, since the constituents vary with the physiologic state of the subject. The protein component which, as shown elsewhere in this paper, is responsible for the formation of a ring body, constitutes less than 8 per cent of the cell.

Jorpes³⁵ refers to the protein proper as stroma protein and suggests that it has a characteristic composition different from other proteins of the blood. Its chief properties are (a) consistency, (b) elasticity, and (c) contractility.

Bechhold,³⁶ while studying the colloidal structure of the erythrocyte, observed the formation of "globules" in normal mammalian red blood cells during the process known as hemolysis. Salén,^{37, 38} following up Bechhold's work, used human erythrocytes, and noted with the aid of an ultramicroscope the formation of a ring structure within the cell while it was subjected to a hypotonic saline solution and an acid. The ring was formed at or near the periphery of the cell, and as hemolysis progressed, the ring began to retract, finally degenerating into a refractile granule which eventually disappeared.

Fig. 5.—Normal human erythrocytes treated with Salén's method. *a*, Erythrocyte showing peripheral ring. *b*, Erythrocyte with two rings that originated at different planes forming a pseudofigure eight. *c*, Erythrocyte with disintegrating ring. Note the hook formation. *d*, Erythrocyte with bar and two globules. *e*, Erythrocyte with globules. *f*, Lysed erythrocyte (ghost cell).

Fig. 6.—Normal human blood treated with Salén's method. *a*, Free protein rings. *a'*, Ring twisted into a figure eight.

Salén's observations were confirmed. Fig. 5 shows an erythrocyte with a peripheral ring, others with stab bodies, some with granules, and one cell without structures. Fig. 6 shows free rings obtained by mechanically rupturing erythrocytes.

Salén reached the following conclusion: "the ring structure seemingly consists of water-insoluble proteins which are precipitated by potassium ferrocyanide dissolved in dilute acetic acid." He thus furnished tangible evidence that a ring structure is formed when hemolysis sets in, thus associating the phenomenon with degeneration of protein.

After correlating the dye analytical studies with Salén's observations, it could be assumed that Cabot ring bodies might be identical with Salén's ring structures, especially since these bodies showed a selective affinity for cytoplasmic stains.

Thus, aggregated and denatured protein forms the Cabot ring bodies.

Fig. 7.—Protein globules of beaten egg white. *a*, Globule with two rings. The peripheral ring had a reddish blue color, the inner ring was tinted blue. The cross bar stained light red. See arrow. *b*, Ruptured globule. The broken top ring, which is partially extruded, had a deep blue color and was seemingly superimposed on another ring, also broken, that was reddish blue in hue. The two other rings and the cross bar (at arrow) had the same tint as the latter ring.

THE NATURE OF CABOT RING BODIES.

The following experiments prove that the ring bodies are protein derivatives of the envelope and cytoplasm; and that the variability of affinity for acid and basic dyes is determined by the molecular thickness and momentary physico-chemical state of the protein mass.

Experiments With Egg White.—Experiment 1. The white of a raw egg was carefully separated from the yolk and beaten (or shaken in a test tube) until it was stiff. With the aid of a wire loop a small amount of the substance was transferred to a clean glass slide and spread to a thin film with a suitable spreader, cover slip, etc. The film was permitted to dry, then covered with Wright's blood stain for one minute, after which the stain was diluted with an equal amount of distilled water. The diluted stain was allowed to act for two to three minutes. The preparation was then rinsed in distilled water and permitted to air dry. Such preparations not only showed numerous single globules, but the globules varied also in size and thickness, and thus in some respects resembled normal and pathologic protein quantities of an erythrocyte, i.e., the globules are analogous to the erythrocyte envelope. The majority of the globules showed one or two, and less frequently three or more, reddish-blue rings, either concentrically arranged, or superimposed upon each other. Fig. 7 shows two representatives of the globules; the globule to the right, ruptured either during the drying process or during the staining procedure, shows a striking difference in thickness of the rings; a replica of Cabot rings in every respect.

Experiment 2. A thin film of unbeaten egg white was made on a microslide, and the substance was exposed to room temperature for at least one hour and then stained with Wright's stain in the usual way. In such a preparation there are areas in which many various-sized round to oval structures may be seen that show generally one concentric complete ring, and variable types of incomplete structures. A typical example is shown in Fig. 8, a replica in every respect of Fig. 1. When two thin films are superimposed upon each other, the formation of a figure eight is frequently encountered. Fig. 9 shows the manner in which such a configuration is produced. These protein structures are broader and flatter than those produced with beaten egg white.

Fig. 8.

Fig. 8.—Protein ring bodies of unbeaten egg white. *a*, Spherical body with deep blue flat ring. Note the uniformity of staining of the outer and inner area of the mass. A striking simulacrum of Fig. 1*a*.

Fig. 9.

Fig. 9.—Protein configurations of two thin films of unbeaten egg white. Incomplete figure eight. Note that two spherical bodies at different planes are involved in its formation.

Thus variability of dimensions, i.e., thickness of Cabot ring bodies, depends upon the availability of protein within the envelope or cytoplasm of a given erythrocyte.

The experiments showed that protein, regardless of its source, forms predominantly circular structures. The following hypothesis is offered for the presence of more than one ring body in an erythrocyte:

It is assumed that the human red blood cell envelope is not homogeneous, but consists of a series of concentric lipoprotein layers which under certain conditions may separate, in contrast to the cytoplasm which is a homogeneous mass, and thus merely retracts, behaving the same way as a thin layer of unbeaten egg white. Thus it is not at all difficult to account for the occurrence of more than one Cabot ring body at the same or at different planes within an erythrocyte, as well as for the thickness and configuration of the protein structures, as shown in Plate I.

DIFFUSE AND PUNCTATE BASOPHILIA

It is a well-known fact that Cabot ring bodies may appear in an erythrocyte showing either diffuse or punctate basophilia. Pappenheim³⁹ believed that polychromatophilia, punctate basophilia, and reticulation represent diffuse or aggre-

gate states of the spongioplasm. Many investigators, among them Key, Daum, and Cooke, have shown that Pappenheim's hypothesis was based on sound observations. Key⁴⁰ proved by appropriate methods that a basic substance retained by certain erythrocytes may be made to appear either as polychromatophilia, reticulation, or punctate basophilia, the latter representing an aggregation of the basophilic substance in the cell due to a pathologic process. Daum⁴¹ showed that punctate basophilia may be created in vitro by permitting normal defibrinated blood to stand at room temperature for twenty-four to thirty-six hours. She observed that as autolysis progressed, diffused polychromatophilia changed to stippling, and as time went on, the punctate basophilia became more and more coarse, apparently in direct proportion to the autolysis. Daum came to the conclusion that the basophilic substance is most likely a colloid that is denatured and coagulated by heat, alcohol, or any other agent. Pappenheim thought the substance to be a lipid, as opposed to others who assumed the basic substance to be albuminous. Cooke,⁴² using the blood smear method, employed a benzidine-alcohol-hydrogen peroxide mixture for the demonstration of punctate basophilia and reticulation in normal mature erythrocytes. He reached the following conclusion: "When obtained by the usual staining methods, this would point to increased permeability or a defect in the lipid envelope of the erythrocyte. There may be, and probably is, a close relationship between punctate basophilia, diffuse polychromatophilia, diffuse polychromasia, and reticulation and maturity." Cooke's conclusion supports the observation of Falconer,⁴³ of the occurrence of basophilic stippling in mature erythrocytes in the blood of normal healthy persons. On analysis of the evidence derived from the literature, it may be assumed that basophilia, polychromatophilia, reticulation, and punctate basophilia (stippling) are nothing more than the morphologic expression of denatured and coagulated colloid substances, i.e., lipoproteid colloids.

THE PRODUCTION OF DIFFUSE AND PUNCTATE BASOPHILIA WITH EGG YOLK

The experiments with egg white did not produce the phenomenon known as diffuse and punctate basophilia, and thus Pappenheim's assumption that lipoids may be responsible, was apparently supported. The following experiments were designed to obtain information concerning the role played by lipoids.

Experiment I. A thin layer of unbeaten egg yolk was made on a microslide, air dried, and stained with Wright's blood stain. The preparation revealed a homogeneous layer of a more or less reddish-purple hue.

Experiment II. A thin film of unbeaten egg white was made on a microslide and permitted to dry at room temperature. A thin layer of unbeaten egg yolk was superimposed and permitted to dry. The preparation was tinted with Wright's blood stain, air dried, and mounted in Clarite. Numerous round and oval bodies were seen that showed the well-known tinctorial characteristics of diffuse and punctate basophilia. The experiment showed that the presence of a protein layer enhances aggregation of lipoids. Fig. 10 shows several of these bodies. Thus the following opinion may be expressed: 1. The various tinctorial shades of diffuse basophilia are apparently the expression of a more or less

homogeneous state of protein and lipoids. 2. Punctate basophilia may be interpreted as the result of disassociation of these substances, or the independent reaction of the laminated lipid component.

Thus it is understandable why a ring body can appear in an erythrocyte exhibiting either diffuse or punctate basophilia. Fig. 11 shows a polychromatic red blood cell with a faintly stained ring body and punctate basophilia superimposed.

Fig. 10.

EXPERIMENTS WITH NORMAL HUMAN ERYTHROCYTES

As previously pointed out, the prerequisite for the formation of Cabot ring bodies is a physicochemical imbalance of the protein-lipoid components of the cell, permitting disintegrating agents to permeate and to precipitate the stroma protein. While these constituents are properly balanced, they form a definite structural unity. The process which supposedly modifies the envelope of the red blood cell is called "hemolysis," assumed to be a reaction between a lysin and the protein. It is obvious that the production of a simulacrum of the Cabot ring bodies in normal erythrocytes is possible only if the erythrocyte is exposed to a hemolysin that modifies the permeability of the envelope. If colloidal proteid is the substance that through denaturation forms a ring structure, then the problem at hand is to set up experiments that first assured hemolytic action, i.e., conditioning of the envelope in such a manner that denaturation of the protein is assured, followed by the penetration of a dye which would stain the protein.

The oldest and most effective means of altering envelope permeability is heat. This thermal factor, while a weak hemolysin, is responsible for many artifacts in cytology, but under controlled conditions is a valuable agent, especially when combined with strong alcohols and weak acids. The investigations carried out by Foà⁴⁴ on mammalian and human blood, and by Dehler⁴⁵ on domestic fowl, brought out the fact that the entrance of dissolved substances, such as dyes, into

the envelope and cytoplasm, is more rapid at high temperatures than at low temperatures. This knowledge has been utilized in devising an experiment for the creation and staining of replicas of "synthetic" Cabot ring bodies. While studying the variability of the envelope resistance, I consulted the papers by Weidenreich⁴⁶ and Sakai.⁴⁷ The latter, as already pointed out, produced ring bodies, but failed to suggest their similarity to Cabot rings. The striking replicas obtained by Sakai made his method the one of choice for preliminary work. The method, however, had to be modified for the use of human erythrocytes. Below is Sakai's method as I modified it:

I. Solutions

1. Ethyl alcohol, absolute.
2. Phenol (crystals C.P.) 2 per cent aqueous solution.
3. Phenol-gentian violet solution. (Add 5 Gm. of gentian violet to 100 c.c. of pure acetone-free methyl alcohol.)
Take 40 c.c. of solution (2) and 10 c.c. of solution (3), mix well, and let stand at room temperature for 24 hours. Filter and transfer to a staining jar. The dye is good for only 24 to 36 hours.

II. Method

1. Make a thin blood smear and let air-dry for 5 hours.
2. Place into ethyl alcohol for 5 minutes.
3. Place into phenol solution 2 per cent for 30 seconds.
4. Place into phenol-gentian violet for 2 minutes.
5. Rinse in distilled water for 15 seconds.
6. If counterstain is desired, cover preparation with diluted Giemsa solution for 5 minutes.
7. Rinse in distilled water and let air-dry.
8. Mount with dammar or Clarite.

In a blood smear subjected to the foregoing treatment, the erythrocytes have a bluish tint, and their contour is sharply defined and not distorted. At the periphery a narrow, somewhat lighter area follows the shape of the cell. This phenomenon is apparently a sequela of the formation of a ring body; it can be seen in Fig. 3, cell *b*. A well-defined flat and dark-stained blue ring structure, at some distance from the periphery, is present in every mature erythrocyte, a striking replica of a Cabot ring body (Plate I, 1). The ring structure seems to be derived from a layer or layers at or near the surface, or adjacent to the envelope. Frequently two ring structures may be seen. Cell degeneration is thus seemingly expressed as complete or incomplete rings, or a ring is suggested by a ringlike arrangement of beads or rods. Cell immaturity can be recognized by the decreasing definition of the ring structure, which eventually is replaced by more or less fine granules which may fuse and form coarse clumps. The percentage of the latter types corresponds to that of the reticulocytes, Fig. 12, cells *c*, *e*, *f*. The amount of basophilic spongioplasm within the cell apparently determines the respective pattern. These standard patterns are thus the expression of the physicochemical status of an erythrocyte. In normal basophilic erythroblasts the spongioplasm is diffuse and deeply staining. Fig. 12 shows a characteristic pattern obtained with the method. Fig. 13 shows an erythroblast in mitosis, late in telephase stage. The lipoproteid colloids may well be in a transition stage, i.e., the respective quantities are as yet not properly assimilated. If this is the case, then the question of why Cabot ring bodies are so rarely seen

in erythroblasts is answered. However, bizarre patterns may be observed in severe anemic bloods, especially when cytolysis of erythroblasts is pronounced. When such blood is exposed to the phenol-gentian violet solution, the erythroblasts may occasionally show incomplete rings, but generally, fine or coarse granules, rods, spotted or diffuse spongioplasm, or combinations of the enumerated patterns may be seen. When in a routinely stained blood smear an erythroblast with a Cabot ring body is observed, the cell is most likely abnormal, as shown in Fig. 14.

The experiment revealed that replicas of Cabot ring bodies may be produced in normal mature erythrocytes but not in normal erythroblasts. The creation of the bodies depends upon the physicochemical state of the lipoprotein colloids at the various maturation stages. Further, an explanation is furnished for the rare occurrence of Cabot ring bodies in erythroblasts. There is no doubt in my mind of the identity of the simulacrums created by the afore-mentioned method and the Cabot ring bodies. Both structures are the expression of denatured protein.

GLACIAL ACETIC ACID METHOD FOR THE CREATION OF DENATURED PROTEIN CONFIGURATIONS (CABOT RING BODIES) IN NORMAL MATURE ERYTHROCYTES

This method was based upon the well-known facts that weak acids and strong alcohols are hemolysins which in turn denature protein. The method has the advantage of reducing the room temperature exposure time. Heating the stain was found to facilitate rapid penetration.

I. Solutions

1. Wright's blood stain.
2. Glacial acetic acid 0.02 per cent.
3. Clarite or dammar.

II. Method

1. Permit the blood smear to air-dry at room temperature for one hour.
2. Place 20 drops of Wright's blood stain in a test tube, and heat over a flame to 50° C. Pour the dye quickly over the blood film, starting at the thick end.
3. Dilute the dye with 60 drops of glacial acetic acid 0.02 per cent. Mix well with an eye dropper by drawing in and expelling the dye.
4. Direct a flame under the glass slide and heat the dye solution to 50° C. This temperature is generally reached when the solution begins to steam.
5. Permit the hot dye to react for one minute. Rinse in distilled water for a few seconds and then let the preparation air-dry.
6. Mount with dammar or Clarite.

With the method described above patterns resulted identical to those created with the phenol-gentian procedure. When, however, the stain and acetic acid are heated together and permitted to act about one minute, many interesting patterns are obtained. Fig. 15 shows an example pattern that is produced with this modified procedure when blood samples of severe toxic and chronic anemias are used. The incomplete removal of the hemoglobin is responsible for the bizarre patterns. There is no erythroblast in the field.

DISCUSSION

While Cabot suggested that the ring bodies he described may represent nuclear remnants, it seemingly remained for Ferrata, Viglioli, and others to show

Fig. 12.—Mrs. B. W. Pernicious anemia in severe relapse. Peripheral blood treated with the author's acetic acid method. *a*, Normal mature erythrocyte with a characteristic protein ring. Note the striking resemblance to Fig. 1*a* and Fig. 8*a*. *b*, Mature erythrocyte with a ring body and a globule. *c*, Macro-erythrocyte with two ring bodies. The peripheral ring was light red, the other one was partially red and blue. Note the cross bars connecting the rings. A replica of the bars is seen in Fig. 7*a* and *b*. *d*, Macro-erythrocyte with incomplete light red rings and two blue globules. *e*, Megalocyte with retracted away from the periphery, leaving a light zone. *f*, Megalocyte (reticulocyte stage) more immature than cell *e*. The cytoplasm has retracted away from the periphery, leaving a light zone. *g*, Erythrocyte with the envelope ruptured. *h*, Thrombocytes.

Fig. 13.

Fig. 14.

Fig. 13.—Mr. F. M. Normal bone marrow treated with the acetic acid method. *a*, Erythroblast, late telophase. Note the basophilic spongioplasm, sharply defined nuclear membrane, and blotches in the cytoplasm. The constituents of the envelope and cytoplasm are seemingly not properly assimilated, and this may account for the absence of rings in erythroblasts. In the few exceptions cited, it is assumed that protoplasmic maturation was further advanced and that this led to the production of ring bodies.

Fig. 14.—Mr. A. K. Generalized Hodgkin's disease; peripheral blood. *a*, Pathologic polychromatic erythroblast with two twisted protein rings. The darker structure had a deep red color; the lighter one, lying at a lower plane, had a blue hue. *b*, Markedly lysed polychromatic erythrocyte with a red protein ring. *c*, Ruptured erythrocyte with the cytoplasm flowing around cell *b*. The ring had a reddish blue tint and appeared to belong to the envelope.

that the structures are identical with the nuclear membrane. This prevailing view, however, is based on misinterpretation of artifacts so commonly encountered in cytology. The literature dealing with the subject is extensive, and contains many diametrically opposed theories regarding the origin and nature of the Cabot ring bodies. None of the investigators has furnished convincing proof that the structures are either nuclear derivatives or artifacts, and thus laboratory creations. I have attempted to show that the Cabot ring bodies are actually the expression of denatured protein, i.e., colloid protein, and thus that the bodies have no immediate relation to the nuclear membrane. The ring bodies created at will in the laboratory, by slanting the glass slide while making the blood smear, and thereby delaying the drying process in a certain area, are in every respect identical with the genuine structures.

Fig. 15.—Mr. G. E. Chronic toxic anemia (carcinoma of the cecum), treated with the acetic acid method (modified). The variability of the erythrocyte envelope to lytic agents is well demonstrated. In some cells which have been partially hemolyzed the hemoglobin simulates nuclear dissolution (Ferrata). Other cells conform to Demel's theory. There is no erythroblast in the field.

The replicas were produced in the anemic blood of patients with pernicious anemia, acute lead poisoning, terminal lymphosarcoma, acute malaria, terminal lymphatic leucemia, congenital hemolytic icterus during hemolytic crisis, erythroblastosis fetalis, and terminal malignant Hodgkin's disease. According to the literature, these toxic and hemolytic anemias furnished, for the most part, the material for Cabot ring bodies in routine blood smears, and thus there can be little doubt that hemolysis plays an important role as a preconditioning factor for the production of the structures.

It has been shown that Cabot ring bodies can occur only in cells in which the permeability of the envelope has been altered by a specific lysis. The reason for the preponderance of flat circular bodies lies in the assumed geometry

of the erythrocyte and the tendency of protein to aggregate into a ring structure. The rarity of Cabot ring bodies in erythroblasts is assumed to be due to either a peculiar quantitative or a qualitative state of the lipoproteid colloids, or these constituents at this particular developmental stage have not yet assumed their mature relationships. An explanation has been offered for the presence of both a ring body and punctate basophilia in the same erythrocyte by showing that ring structures are aggregations of protein and punctate basophilia is identified with lipoids. Simulacrums of both phenomena were reproduced with egg white and egg yolk, and by special methods in normal mature erythrocytes.

The formation of a Cabot ring body is seemingly as follows: a specific hemolytic agent (bile acid) affects a certain erythrocyte whether basophilic, polychromatic, or orthochromatic; the lysis is injurious to the envelope, i.e., it produces changes either qualitative or quantitative, or both, in the lipoprotein constituents of the surface layer which not only influences the permeability but also may lead to microscopic tears in the envelope. This physicochemical change encourages disassociation of the lipoproteid layers, leading to a separation of the normally fused layers into individual ones, or to the separation of a mass of fused layers. This irregular splitting produces the variability of flatness and thickness of the ring bodies. This segregation of protein layers occurs during the drying process, leading either to the formation of the protein configurations known as Cabot ring bodies, or to such structures as globules or bars, as shown in Plate I, 5 and 10. The answer to Cabot's query "why," the reddish blue, red, or blue color of the ring bodies lies in the very nature of the structures.

CONCLUSION

The origin and nature of the Cabot ring bodies of erythrocytes have been discussed and demonstrated by special methods. Cabot ring bodies are neither nuclear remnants nor are they identical with the nuclear membrane; they are laboratory creations, the expression of cellular degeneration induced by hemolytic agents, i.e., they are the expression of aggregated and denatured colloid protein.

I wish to thank Dr. Hal Downey, who offered numerous helpful suggestions, and who was kind enough to edit the manuscript; Dr. R. A. Gortner, Head of the Department of Agricultural Biochemistry, University of Minnesota, for his aid in connection with the chemical aspect of the problem; F. N. Ruslander, medical photographer, Detroit, Mich., for the care exercised in preparing the photomicrographs. I am also grateful for the personal communications of the late Dr. R. H. Jaffé, whose genuine interest in the problem stimulated the investigation.

THE TREATMENT OF GONORRHEAL URETHRITIS IN THE MALE WITH SULFONAMIDE DERIVATIVES*

A STUDY OF 199 CASES

LEROY W. LA TOWSKY, M.D., M.Sc., FRANK KNIGHT, M.D.,
CHARLES A. W. UHLE, M.D., AND RICHARD B. BAKER, M.D.
PHILADELPHIA, PA.

IT IS AN established fact that the use of sulfanilamide in gonococcic infections is not indicated since the later sulfonamides have been introduced. Pelouze¹ states that this substance was effective in only 25 to 40 per cent of over 900 cases treated by the Cooperating Clinics of the United States Public Health Service. Excluding sulfanilamide from the therapeutic armamentarium, there are three sulfonamide derivatives whose value has been established in the treatment of gonorrheal urethritis in the male. These substances are sulfapyridine, sulfathiazole, and sulfadiazine.

The authors have previously reported their experiences with these three substances in the treatment of gonorrhea in the male.²⁻⁵ Though the number of cases we treated is not large, we believe that we are able to make some comparison of the therapeutic efficiency and action of these three sulfonamide derivatives. The basis for this report is the study of 199 patients with gonorrhea, who presented themselves for treatment, at the Genito-urinary Clinic of the Philadelphia General Hospital during the years 1939 to 1941.

Of the 199 cases of gonorrheal urethritis studied in the male, 167 were followed to the final step of either apparent cure or failure, while 32 patients defaulted. The average age of the 199 patients was 25 years, but their ages ranged from 11 to 54 years. One hundred and seventy-two of the patients were black, 26 were white, and one was Chinese. One hundred and forty-three had no treatment of any kind before coming to our clinic, while 56 had some type of treatment. Twenty-six had purchased sulfanilamide from druggists. One hundred previously had a gonorrheal infection, while 99 never had gonorrhea.

The classification of gonorrhea in the male, which was used in this study, is that of Eisendrath and Rolnick. They classify gonorrheal infection as follows⁶:

- Acute urethritis (up to 3 months)
 - Anterior
 - Posterior
- Subacute urethritis (3 to 6 months)
 - Anterior
 - Posterior
- Chronic urethritis (6 months or more)
 - Anterior
 - Posterior

*From the Genito-urinary Clinic, the Philadelphia General Hospital, Philadelphia.
Received for publication, May 24, 1941.

Of the 199 patients who presented themselves to our clinic for treatment, there were 130 with acute anterior urethritis, 59 with acute posterior urethritis, 3 with subacute anterior urethritis, 6 with subacute posterior urethritis, and one with chronic posterior urethritis. Of the 156 patients who were eventually cured by these sulfonamide derivatives, 18 had epididymitis, 4 had gonorrheal arthritis, 4 had balanoposthitis, one had a periurethral abscess, and one had inguinal adenitis before therapy was begun.

The diagnosis of gonorrheal urethritis was based on the history, clinical symptoms and signs, and positive bacteriologic studies. These bacteriologic studies consisted of a smear and culture of the urethral exudate in every case. *All stains were done by the Gram technique. The cultural technique used to identify the gonococcus was as follows**:

The urethral exudate or prostatic fluid is collected on a cotton swab. This swab is previously moistened with sterile physiologic saline. The swab is streaked on chocolate blood agar plates,† which are then incubated‡ at a temperature of 37.5° C. for twenty-four to forty-eight hours. At the end of this period typical colonies are isolated and placed on chocolate blood agar slants. These slants are incubated at the same temperature for twenty-four to forty-eight hours. The culture on the slant is tested for purity by the Gram stain technique, and sugar tubes, containing dextrose, maltose, and levulose with a broth base, are incubated at the same temperature for twenty-four to forty-eight hours at 37.5° C. Gonococci ferment only dextrose with the production of acid and no gas; they do not ferment the other sugars. From the chocolate blood agar slants the organisms are also tested by the Alkali Solubility Test.§

The patients were seen twice a week during the early stages of treatment, and later at intervals of one or two weeks. At each visit the customary urologic examinations were made, including bacteriologic work at appropriate time intervals. Complete studies of the cellular elements of the blood were made in 55 cases before and after treatment with the drugs. Electrocardiographic tracings were taken before and after treatment in 51 cases. Blood levels of the sulfonamide were made on almost every patient. The technique of Bratton and Marshall was used in these analyses.¶

In the beginning of the study it was decided to keep the dosage as uniform as possible, yet to individualize the dose to fit the patient's disease. The drugs were continued for a few days after the patient was free of discharge or the urine had become clear in both glasses.

All cases received the drug in divided doses, usually two, three, or four times a day. With sulfapyridine the average dose to effect a cure was 23.5 Gm. given

*This technical aspect of the study was done by Drs. H. A. Shelanski and L. Shelanski, of the Department of Zoology, the University of Pennsylvania.

†The composition of chocolate blood agar is as follows: Difco proteose No. 3 agar. Add 0.3 per cent whole defibrinated horse blood. Add blood when agar is 70° to 75° C. to get chocolate agar.

‡All cultures are placed in an atmosphere of 10 per cent carbon dioxide and an excess of moisture when they are incubated.

§The procedure of the alkali solubility test is as follows: 0.1 N sodium hydroxide is added to a suspension of bacteria. If the bacteria are gonococci, there will be complete lysis of the organisms. This does not occur if the organisms are meningococci or *N. catarrhalis*.

over a period of eight days. The range of dosage was 14 to 111 Gm. given over a period of from seven to thirty-seven days. With sulfathiazole the average dose to effect a cure was 28 Gm., given over a period of eight days. The range of dosage was 12 to 48 Gm., given over a period of four to twenty-eight days. With sulfadiazine the average dose to effect a cure was 17.5 Gm., given over a period of eight days. The range of dosage was from 4 to 58 Gm., given over a period of from four to twenty-one days (see Table I).

TABLE I
CHEMOTHERAPY IN GONORRHEAL URETHRITIS IN THE MALE
SUMMARY OF ESSENTIAL DATA

	SULFAPYRIDINE 57 CURED CASES	SULFATHIAZOLE 48 CURED CASES	SULFADIAZINE 51 CURED CASES
Dosage to effect a cure	Average: 23.5 Gm. in 8 days Range: 14 to 111 Gm. in 7 to 37 days	Average: 28 Gm. in 8 days Range: 12 to 48 Gm. in 4 to 28 days	Average: 17.5 Gm. in 8 days Range: 4 to 58 Gm. in 4 to 21 days
Duration of discharge	Average: 3 days Range: 2 to 8 days	Average: 3 days Range: 1 to 7 days	Average: 4 days Range: 1 to 30 days
Time elapsing from beginning treatment until appearance of first negative prostatic culture	Average: 51 days Range: 14 to 162 days	Average: 28 days Range: 7 to 88 days	Average: 13 days Range: 3 to 43 days
Time elapsing from cessation of symptoms until last positive culture of the prostatic fluid (the carrier state)	Average: 17 days Range: 2 to 50 days	Average: 17 days Range: 3 to 53 days	Average: 3 days Range: 0 to 18 days

The provocative tests were begun when clinical symptoms had ceased, and the urine had remained clear for three or four days. These tests were begun early because of the type of patients with which we were dealing. Most of the patients had a tendency to default when they began to feel that they were improving. The following consecutive tests were required of a patient before he could be discharged as cured: (1) Prostatic massage, smear and culture of fluid; (2) alcoholic indulgence; (3) passage of a sound into the urethra; (4) examination of a condom specimen; (5) repeated prostatic massages, both smear and culture of the prostatic fluid to be negative for gonococci on two or more occasions.

The results of treatment of gonorrheal urethritis in the male with the three sulfonamide derivatives are summarized in Table II. Of the 199 patients studied, 32 (16.2 per cent) defaulted and 167 (83.8 per cent) were followed to the completion of the cure, or failure. Of the 167 patients followed, 156 (93.5 per cent) were apparently cured, as evidenced by satisfying all criteria of cure, and 11 cases (6.5 per cent) were failures. Most of the patients treated had anterior urethritis, but all forms of acute and subacute urethritis were represented in this study.

Of 62 cases treated with sulfapyridine and followed, 92 per cent were apparently cured. Of 50 cases treated with sulfathiazole and followed, 96 per cent

were apparently cured, and of 55 cases treated with sulfadiazine and followed, 93 per cent were apparently cured. There is no significant statistical difference between these cure rates.

TABLE II

TREATMENT WITH SULFONAMIDE DERIVATIVES OF GONORRHEAL URETHRITIS IN THE MALE
AN ANALYSIS OF 199 CASES

Philadelphia General Hospital, 1939-1941

	TOTAL CASES	CASES FOL- LOWED	CURED CASES		FAILURES		DEFAULTERS	
			NO.	%	NO.	%	NO.	%
Sulfapyridine	87	62	57	92	5	8	25	28.8
Sulfathiazole	55	50	48	96	2	4	5	9
Sulfadiazine	57	55	51	93	4	7	2	3.5
Total cases	199	167	156	93.5	11	6.5	32	16.2

The results of treatment were uniformly good, no matter what the existing pathologic condition was at the time of beginning treatment. There were no complications in any cases during the period of treatment.

Analysis of the cured cases showed the average number of visits to the clinic before cure was complete to be eight for sulfapyridine, six for sulfathiazole, and eight for sulfadiazine.

In the entire series 11 cases were treatment failures. With sulfapyridine there were 5 failures. Failure in 2 cases was due to sensitivity to the drug that resulted in exfoliative dermatitis. The other 3 failures with sulfapyridine were patients who failed to cooperate during the period of treatment. They had coitus and alcoholic debauches during the early stage of treatment. With sulfathiazole there were 2 failures. These 2 patients failed to cooperate during the treatment period. With sulfadiazine 4 cases were treatment failures. It is interesting to note that 2 of these cases were syphilitic and were receiving mapharsen 0.06 Gm. per week at the same time that they were receiving sulfadiazine. The poor results in these two cases would bring up the question as to whether or not mapharsen has an inhibiting effect on the action of sulfadiazine. One of the failures had previously been a therapeutic failure with sulfanilamide and sulfathiazole. At the time that he began treatment with sulfadiazine he had a subacute anterior-posterior urethritis and prostatitis refractory to the two sulfonamides mentioned. The other failure did not cooperate.

The incidence of those who defaulted with sulfapyridine was 28.8 per cent, with sulfathiazole 9 per cent, and with sulfadiazine 3.5 per cent. The differences in default rate may be related to differences in the toxicity of the three drugs.

Toxic reactions were more commonly observed with sulfapyridine than with any of the other drugs. Seventy-five per cent of the patients treated with sulfapyridine complained of symptoms of toxicity, 11.5 per cent with sulfathiazole, and only 8.8 per cent with sulfadiazine. Three cases treated with sulfapyridine developed severe exfoliative dermatitis requiring hospitalization. These three cases were previously reported in detail.⁸ Headache was the most common complaint with all three drugs. Complaints were severe among those receiving sulfapyridine, but minor among those taking sulfathiazole and sulfadiazine.

In the cured cases the time elapsing between the beginning of specific therapy and the cessation of discharge for sulfapyridine averaged three days, and ranged from two to eight days; for sulfathiazole, it averaged three days, and ranged from one to seven days; and for sulfadiazine it averaged four days and ranged from one to three days (see Table I).

The time that elapsed between the beginning of specific therapy and the first culture of the prostatic fluid which was negative for the gonococcus showed interesting differences among the three drugs. This period of time for sulfapyridine averaged fifty-one days, and ranged from fourteen to one hundred and sixty-two days; for sulfathiazole it averaged 28 days, and ranged from seven to eighty-eight days; and for sulfadiazine it averaged thirteen days, and ranged from three to forty-three days (see Table I).

The time elapsing from the disappearance of the symptoms of gonorrheal urethritis to the last culture of the prostatic fluid positive for the gonococcus is the period of time known as the so-called "carrier state." This period for sulfapyridine averaged seventeen days, and ranged from two to fifty days; for sulfathiazole it averaged seventeen days, and ranged from three to fifty-three days; and for sulfadiazine it averaged three days, and ranged from zero to eighteen days (see Table I).

Blood levels of the drugs, appearing with the dosages stated previously, were as follows: sulfapyridine, total, 1.6 to 9 mg. per 100 c.c.; sulfathiazole, free, 0.4 to 8.7 mg. per 100 c.c.; and total, 1 to 11 mg. per 100 c.c.; sulfadiazine, free, 1.5 to 10.4 mg. per 100 c.c.; and total, 2.1 to 11.5 mg. per 100 c.c. We did not find the blood levels of any prognostic value in regard to predicting toxic reactions or in determining the rapidity of cure.

The effect of the various sulfonamide derivatives studied on erythrocyte count, hemoglobin, leucocyte count, and differential count, was observed in 55 patients. In general, there were no significant changes.

Electrocardiographic studies were made on 51 patients before and after treatment with the drugs. There were no significant changes.

SUMMARY

A total of 199 patients were studied. Of this number 167 were followed to the completion of the study. Ninety-three and one-half per cent of these cases were cured. The rate of cure was 92 per cent for sulfapyridine, 96 per cent for sulfathiazole, and 93 per cent for sulfadiazine.* There is no significant statistical difference in these cure rates.

To effect a cure, the average dose required was for sulfapyridine 23.5 Gm. in eight days, for sulfathiazole 28 Gm. in eight days, and for sulfadiazine 17.5 Gm. in eight days.

*Five months' follow-up on the cases apparently cured by sulfadiazine revealed that of the 51 cases originally discharged as apparently cured, 8 had returned with reinfection. Each of these 8 cases had been observed for from twenty-eight to seventy-six days and had three to eight smears and cultures of the prostatic fluid negative for the gonococcus before being discharged as apparently cured. It is difficult to say definitely whether the reappearance of infection was due to recurrence of the old infection or to reinfection from a new contact of gonorrhea. Several cases gave a history of exposure. If we are to count the 8 cases of reinfection as treatment failures our percentage of apparent cures with sulfadiazine would be 78 per cent instead of 93 per cent originally reported.

Toxic reactions from the drugs occurred in 75 per cent of the cases treated with sulfapyridine, 11.5 per cent with sulfathiazole, and 8.8 per cent with sulfadiazine.

The average time for the discharge to cease in patients treated was three days with sulfapyridine, three days with sulfathiazole, and four days with sulfadiazine.

The average time for a bacteriologic cure, based on the appearance of the first negative culture of the prostatic fluid, was fifty-one days for sulfapyridine, twenty-eight days for sulfathiazole, and thirteen days for sulfadiazine.

The "carrier state" so-called (the period from the disappearance of symptoms to the last culture of the prostatic fluid known to contain living gonococci) averaged seventeen days for sulfapyridine, seventeen days for sulfathiazole, and three days for sulfadiazine.

The criteria of cure in this study were strict and included as the final provocative test two or more negative smears and cultures of the prostatic fluid.

CONCLUSIONS

From our studies it would seem that sulfadiazine is a valuable drug in the treatment of gonorrheal urethritis in the male because it has a high cure rate and a low incidence of toxicity; it causes the prostatic fluid to become free of living gonococci sooner than any of the other sulfonamides we used.

Sulfathiazole is very effective therapeutically and causes few toxic reactions.

Sulfapyridine would better not be used in the treatment of gonorrhea in the ambulatory patient. It is very effective therapeutically, but it gives rise to many and severe toxic reactions.

We wish to acknowledge the cooperation of Dr. Jefferson Clark, chief of the laboratories; Dr. Walter Crocker, chief of the division of clinical pathology; Dr. John Reinhold, chief of the division of biochemistry; and Dr. Thomas McMillan, chief of the division of cardiology of the Philadelphia General Hospital.

Sulfapyridine was furnished to us by Merck & Co., Rahway, N. J.

Sulfathiazole was furnished by the Maltbie Chemical Co., Newark, N. J.

Sulfadiazine was furnished through the courtesy of the Pneumonia Control Committee of the Philadelphia General Hospital, and the Nepera Chemical Co., Yonkers, N. Y.

The retinae exhibited tortuosity of the retinal vessels, several small exudates, crossing phenomenon, and a vein-artery ratio of 2 to 1. A rough, low-pitched systolic murmur was heard loudest at the upper end of the sternum and the aortic region. The blood pressure was 220/110. There was slight edema of the lower extremities.

On admission the urine contained 0.521 per cent albumen, one granular cast per high-power field, and ten to twelve pus cells; blood counts were essentially normal. Eight hours following admission, the membranes ruptured spontaneously, and uterine contractions promptly ensued. Approximately ten minutes later no fetal heart sounds were heard. No abnormalities were found on vaginal examination. Labor was terminated at the end of twelve hours by the delivery of a full-term stillborn male infant. There was evidence of compression of the umbilical cord due to the peculiar manner in which the cord was wrapped about the infant's abdomen and both thighs. Ten hours' post partum the patient was seized by a severe pain in the right chest which markedly impaired respiratory movements. Examination revealed a friction rub in the area of pain, and a blood pressure reading of 165/100. Symptomatic treatment was instituted consisting of morphine and nasal oxygen. Four hours later a similar episode occurred, involving the lower portion of the left chest. Her pulse was of poor quality and her temperature was 100° F. rectally. A bedside flat plate of the chest was obtained, which showed only a haziness in the lower lung fields. The following day her condition appeared to be slightly improved; orally, her temperature was 102° F. On the third post-partum day her temperature rose to 104° F., and she had a chill. Her complaints then were referable to the pain in the chest, and no new physical findings were obtained. Another flat plate of the chest showed a clearing of the previously reported congested areas. From the fourth to the ninth days post partum, inclusive, she maintained a low-grade temperature elevation. On the tenth post-partum day the temperature which rose to 104.8° F. was accompanied by a chill and increased pain along the right costal border. On the eleventh post-partum day the temperature rose to 103.4° F. There were many clumps of pus cells and 1+ albumen in catheterized specimens of urine obtained these two days. A tentative diagnosis of pyelitis was made. A blood culture was obtained which yielded a gram-negative bacillus, which had typical cultural characteristics of the paradysentery bacillus and was agglutinated by Hiss-Strong anti-serum to a dilution of 1:160.

The patient was given sulfanilamide therapy by mouth, following which there was general improvement in her condition. Examination of the fundi on the twelfth post-partum day revealed the presence of a recent flame-shaped hemorrhage in the right fundus. From the fourteenth to the twenty-eighth post-partum days the low-grade temperature elevation persisted, following which her temperature returned to normal and remained so thereafter for a period of twenty-two days. Her blood pressure stabilized at 140 systolic and 100 diastolic. Urea clearance was 51 per cent. X-ray studies made of the chest, urinary tract, gastrointestinal tract, and biliary tract failed to add any information to this case. A diagnosis of toxemia of pregnancy upon a vasculorenal basis, pulmonary embolism, septicemia due to a paradysentery bacillus, and post-partum pyelitis was made.

A gram-negative bacillus identical with that obtained from the blood was obtained in pure culture from the urine on July 19, 1940, and was isolated from the stool on July 23, 1940. A second stool specimen on July 26, 1940, yielded the same organism. Blood cultures made on July 19, August 3, August 4, and August 6, 1940, were all negative.

Blood drawn from the patient on July 23, 1940, agglutinated *S. paradysenteriae* Strong at 1:160 dilution and *S. paradysenteriae* Hiss at 1:40 dilution. It agglutinated the organisms obtained from the blood, the urine, and the stool cultures at a dilution of 1:5,120. On August 20, 1940, the patient's blood serum agglutinated both Hiss and Strong dysentery bacilli at 1:160, and the organism isolated from the patient at 1:2,560 dilution.

Gram-negative bacilli, which seemed to be rough variants of the paradysentery bacillus, were isolated from the urine and stool on August 20, 1940. These bacilli gave typical fermentation reactions in the test substances used, but in spite of repeated efforts, smooth strains, which would be suitable for agglutination tests, were not obtained from the cultures.

It seems possible that this patient was a carrier of the paradysentery bacillus and, since her resistance was reduced, an acute infection with the organism developed. The probable persistence of the organisms in the rough form after the acute symptoms had disappeared is of interest in this connection. Neter⁵ concluded from his study of urinary tract infections caused by paradysentery bacilli, that these infections may occur during or following an attack of intestinal dysentery or in patients without clinical evidence or history of dysentery. It seems possible that the organism may persist in the genitourinary or intestinal tract after mild attacks of dysentery that the patient does not remember.

CONCLUSION

A case of septicemia and urinary tract infection due to *Shigella paradysenteriae* complicating the post-partum course of a patient has been reported. So far as we have been able to determine this is the first case to be reported of a paradysentery bacillus infection of the urinary tract with a positive blood culture.

SYNDROME SIMULATING DIABETES INSIPIDUS IN DOGS INDUCED BY DESOXYCORTICOSTERONE ACETATE*

CLINICAL OBSERVATION OF SYNDROME WITH ADDITION OF TETANY

ROBERT C. MOEHLIG, M.D., AND LOUIS JAFFE, M.D., DETROIT, MICH.

RECENTLY Ragan and associates¹ reported that with daily 25 mg. doses of desoxycorticosterone acetate injected into dogs for a period of six weeks, they were able to induce a syndrome of polydipsia and polyuria. Pitressin did not influence the syndrome, thus differing from true diabetes insipidus. We obtained similar results in dogs, using smaller doses in varying concentrations (5 and 10 mg.) over a period of four months. Some of the material used was dissolved in propylene glycol.†

Two of 5 dogs used developed the syndrome of polydipsia and polyuria, and one of these died.

Muscular weakness and lack of coordination were prominent features in all 5 dogs. Ragan and associates observed this in their dogs, and stated that it had previously been observed by Kuhlmann and others.

*From the Department of Internal Medicine, Harper Hospital, Detroit.

†The material was kindly furnished by Dr. Max Gilbert, of the Schering Corporation. Received for publication, May 31, 1941.

The specific gravity of the urine in our polyuric dogs showed a gradual decrease toward 1.000. The intake of fluids was not accurately measured but all the experimental animals showed a marked increase in fluid intake.

Two dogs had outstanding symptoms of polydipsia and polyuria, being constantly thirsty and drinking large quantities of water. These two dogs died, while the others showed disappearance of the syndrome when the dosage was reduced to 5 mg. per day.

Soon after the syndrome was noted in the dogs, a male patient suffering from myasthenia gravis and in a relapse had a total pellet implantation of 1,300 mg. of desoxycorticosterone acetate. One pellet of 150 mg. was purposely crushed. Within two weeks he developed a very marked polydipsia and polyuria. There was an increase of blood pressure from systolic 110 and diastolic 68 to systolic 138 and diastolic 92.

Coincident with the polydipsia and polyuria, there developed symptoms of tetany—a positive Chvostek sign and Trousseau's phenomenon was easily brought out during the reading of the blood pressure. He had spontaneous tetany of his hands several times during the day. Paresthesia of the extremities was also present. The serum calcium was 8 mg., and phosphorus was 3.93 mg. per 100 c.c. of blood. The electrocardiogram showed a prolonged RT-interval of 0.32 like that seen in hypoparathyroidism.

It is of interest that soon after the implantation the patient had a return of muscular strength, but when the polydipsia, polyuria, and tetany set in, symptoms of muscular weakness became marked. This was in distinct contrast to the striking improvement following the first implantation of the pellets. This muscular weakness differed from the original myasthenia gravis symptoms in that there was no recovery with rest; nor was there any speech difficulty. Further details of this will be given elsewhere. We know from our experimental data, as well as that of Ragan and associates, that this muscular weakness was in all likelihood due to overdosage of the drug.

The symptoms mentioned continued for two months, and for the last three months the patient states that he has never felt as well since the onset of his illness in October, 1939. A mild degree of polydipsia and polyuria are still present, but the tetany and paresthesia have disappeared. To our knowledge, this is the first instance in which the syndrome of polydipsia, polyuria, and tetany with paresthesia has been produced in a human being by overdosage with desoxycorticosterone acetate.

The patient has repeatedly emphasized that the injections of the drug, while seemingly holding the disease stationary, do not compare with the relief obtained by implantation of the pellets. This is also the observation of Thorn.²

Our experiments confirm the findings of Ragan and his associates. They made careful electrolytic studies of their dogs in which they induced polydipsia and polyuria by giving daily injections of 25 mg. of desoxycorticosterone acetate. While the symptoms were similar to diabetes insipidus, they noted that pituitrin was relatively ineffective, and fluid restriction did not cause dehydration in the animals. The converse is true in diabetes insipidus. They are of the opinion, therefore, that the condition which they described is primarily a thirst, and only secondarily a polyuria. Why this should be is not known, although speculative possibilities naturally present themselves.

Sections of various organs, such as the thyroid, adrenal, testes, ovaries, kidney, spleen, and muscle were all normal, except in one dog which showed deglycogenation of the liver. Separate sections of the hypothalamic area were made of the two dogs showing the polydipsic and polyuric syndrome. Unfortunately, the pituitary was lost during preparation for sectioning. The remainder of the pathologic report follows:

"In sections of one of the blocks there is a region in which the leptomeninges are infiltrated with plasma cells and in this region an adventitial infiltration of the intracerebral vessels is also seen. The infiltrating cells consist almost exclusively of plasma cells forming large coats around the lumen of the vessels. There seems to be an increase of blood vessels. However, this picture could be due to a more pronounced marking of pre-existing vessels because of adventitial infiltration. There is no visible adventitial endothelial proliferation. The region in which this definite pathologic finding was seen belongs to some part of the hypothalamus. It could not be determined which hypothalamic nucleus particularly is involved. The pituitary was not included in the blocks."

Summary: "The finding represents a localized encephalitic reaction showing a plasmacellular infiltration of the leptomeninges and the adjacent intracerebral blood vessels. Whether or not this encephalitic reaction is a part of a more generalized process cannot be determined because of lack of material."*

These findings suggest certain correlations with the clinical picture of hypertension, polydipsia, and polyuria. This is based on the known physiology of the hypothalamus in its influence on blood pressure and water balance. Further studies along these lines are suggested by these data.

One of the dogs was pregnant and received the desoxycorticosterone acetate injections daily for six weeks and bore a litter of seven, only two of which were viable. One of the latter died within a week. One may conclude from this that the drug was probably responsible for the fetal deaths. We are not prepared to say as to the mechanism by which this was produced.

Selye's³ work is of interest in this connection. He concluded that his experimental evidence indicated that both in the mouse and in the rat desoxycorticosterone acetate causes marked involution of the adrenal cortex. He stated that the atrophy of an endocrine gland caused by the administration of an excess of the hormone or hormones which it produces is regarded as the exact antithesis of the compensatory hypertrophy elicited by the hormone deficiency occasioned by partial extirpation of such a gland. For this mechanism of readjustment, Selye suggests the term "compensatory atrophy."

He is of the opinion that this is of clinical importance and says that, for example, the use of desoxycorticosterone acetate (a substance which is practically devoid of androgenic activity) in cases of adrenogenital syndrome in which there is an excess production of androgen in the adrenal may prove useful in inhibiting the faulty endocrine secretion of the cortex.

This would not be without its dangers, however, since in this syndrome hypertension is already present, and the known hypertensive effects of the desoxycorticosterone acetate would add fuel to the fire. Certainly the danger of

*We wish to thank Dr. Gabriel Steiner from the Department of Pathology, Wayne University, for the pathologic report.

vascular cerebral, and cardiac accidents, is to be considered, and this might occur before "compensatory atrophy" had set in.

The drug, no doubt, is a very useful one but must be used with caution, since it may give rise to dangerous, toxic symptoms.

SUMMARY

A syndrome of polydipsia and polyuria was induced in two dogs by comparatively large doses of desoxycorticosterone acetate. Profound muscular weakness was noted in the dogs so that they were unable to co-ordinate their muscles.

A pregnant dog which had received the drug for a period of six weeks gave birth to a litter of 7, 5 of which died, one lived for a week, and the remaining one survived.

Sections of the hypothalamus showed a localized encephalitic reaction with a plasmacellular infiltration of the leptomeninges and adjacent intracerebral blood vessels. Whether or not this encephalitic reaction is a part of a more generalized process cannot be determined because of lack of material. The suggestion was made that the clinical picture of polydipsia, polyuria, and hypertension might be understood by changes occurring in the hypothalamus.

A patient with myasthenia gravis, who had an overdosage of the drug by implantation of the pellets of this material and the crushing of one pellet, showed the syndrome of polydipsia and polyuria. Muscular weakness, such as was noted in the experimental animals, was also present. In addition, he had signs and symptoms of tetany, which we believe is a new symptom of overdosage.

THE EFFECT OF PITRESSIN ON RENAL CIRCULATION AND URINE SECRETION*

KHALIL G. WAKIM, M.D., J. F. HERRICK, PH.D., EDWARD J. BALDES, PH.D., AND
FRANK C. MANN, M.D., ROCHESTER, MINN.

CONSIDERABLE work on human subjects and on various species of animals has been done in an effort to determine the action of pitressin on the circulation of blood in the kidney as well as on urine formation, and to explain the mechanism of antidiuresis. Diverse methods have been employed, and pituitary extracts containing various amounts of impurities have been administered. Consequently, considerable data have accumulated which manifest equivocal interpretations and contradictory conclusions. This paper is a presentation of an attempt to demonstrate the alterations in the glomerular tuft of capillaries and other vessels in the frog kidney, as seen under the microscope, and the changes in renal blood flow in the dog kidney under the influence of pitressin when administered through the various possible routes under similar conditions. The only preparation used for the work reported in this paper was pitressin in ampoules (1 c.c. = 20 units).

A. EFFECT OF PITRESSIN ON THE GLOMERULAR CIRCULATION IN THE FROG KIDNEY

Adolph^{1, 2} employed pituitrin (solution of posterior pituitary) as one of the methods of decreasing urine formation in the frog kidney. He observed that all the methods that diminished the production of urine decreased the circulation of the blood either locally or generally. He, therefore, suggested that these effects on the circulation account for the decrease in urine formation. By subcutaneous injection of pituitary extract into the frog (*Leptodactylus ocellatus*), Biasotti³ found that in twenty-four hours the normal frogs had an average increase of 15.6 per cent in weight, and those with ligated ureters had an average increase of 26 per cent. He stated that Brunn⁴ did not consider the effect to be produced by the kidney, because even in nephrectomized frogs the administration of pituitary extract causes a greater increase in weight than in the controls. Rey⁵ injected posterior pituitary extract (Pituilobine Byla A or B) into the abdominal lymph sac of frogs (*Rana temporaria*), and observed a great diminution of urine formation for two or three hours after injection. He suggested that the posterior lobe extract modifies the three factors that take part in the regulation of water exchange in the body: namely, (1) the excretion by the kidney, (2) the retention by the tissues, and (3) the absorption by the skin.

On the other hand, the work of Collin and Drouet⁶ casts doubt on the water retention action of the posterior pituitary extract. They injected the extract

*From the Mayo Foundation, the Mayo Clinic, Rochester.
Received for publication June 9, 1941.

(Choay No. 2 and No. 4) into frogs and compared their weight changes, for forty-eight hours after injection, with those of controls under the same environmental conditions. Their findings indicated weight changes in those injected with extracts of the posterior pituitary lobe similar to the changes in the controls. Burgess, Harvey, and Marshall⁷ accumulated evidence which enabled them to conclude that pitressin and pituitrin exert no antidiuretic action in the frog, but that in mammals the antidiuretic action of these substances is "due to a stimulation of water reabsorption by the thin segment of the loop of Henle." From his work on water interchange in frogs and their weight increases under the influence of pitressin, Steggerda⁸ suggested the probability that pitressin causes an increase in skin permeability, possibly by acting directly on the circulatory system or by some change in the melanophores. He expressed the opinion that the antidiuretic effects of pitressin do not play a major role in the weight increases of the frogs. Richards and Schmidt⁹ observed that small amounts of pituitrin administered intravenously increased the number of active glomeruli, and also the number of active capillaries in the tuft of a single glomerulus in the frog kidney; but both were decreased under the influence of large doses.

Method.—For our observations on the circulation in the frog kidney we modified the method of illumination described by Knisely.^{10, 11} The experiments were made on anesthetized male frogs (*Rana pipiens*) whose weights ranged from 25 to 45 Gm. Anesthesia was produced by injecting into the dorsal lymph sac 0.1 c.c. of a 25 per cent solution of urethane per 10 Gm. of body weight. The abdomen of the frog was opened by a paramedian incision, carefully avoiding the big vessels, and the edges of the incision were gently cauterized to prevent loss of blood. The animal was laid on a block of cork with frog-Ringer's solution gently flowing over the exposed viscera to prevent drying. Water was kept trickling around the intact body of the frog to dilute the Ringer's solution in contact with the skin and to prevent dehydration. The kidney was protected from the heating effect of the light, transmitted through the quartz tubing, by a constant stream of Ringer's solution flowing through the bore in the delivery tip introduced retroperitoneally, dorsad to the kidney. Such a preparation could be kept functioning normally, without any signs of hemorrhage or other disturbances, for at least nine hours. Healthy frogs were used, and the normal kidney circulation in several microscope fields was carefully studied before any observations on the effects of pitressin were made. Amounts of pitressin ranging from 0.01 to 0.1 c.c. were injected either into the lymph sacs or intravenously into the anterior abdominal vein, or were applied directly through a very fine needle to the microscope field under observation. A stop watch was used to record the time when the drug was administered, when any effect was observed, and when the affected parts returned to their original condition previous to the administration of the drug.

Results.—When pitressin was administered by direct application of 1 or 2 drops over the microscope field under observation, it was found that in three to ten seconds undiluted pitressin produced cessation of activity in all glomeruli in the field. In some glomeruli the afferent arterioles contracted to disappearance during the maximal effect, and whatever blood cells were in the glomerular tuft of capillaries remained motionless until renewed activity gradually took

place. Such renewed activity would occur in a period ranging from two to ten minutes. However, not all the glomeruli ceased functioning at once, nor did they become active again at the same time. The afferent arterioles of some glomeruli contracted enough to prevent passage of blood cells while plasma still passed and gradually forced the corpuscles out of the glomeruli, thus leaving the glomerular tuft of capillaries free of blood cells until renewed activity took place. The blood flow in the other vessels of the kidney area under observation became so slow after application of pitressin that for a period of several minutes no axial or peripheral streams could be demonstrated, and the cells, white and red, could be easily identified in the slow stream throughout the lumina of the vessels. Dilutions of pitressin up to 1:100, when directly applied in 2 drops over the area under observation, gave the same changes but for much shorter duration. Higher dilutions gave no detectable change.

Injection of undiluted pitressin in amounts ranging from 0.05 to 0.1 c.c. into the lymph sac produced within two minutes a noticeable slowing of blood flow throughout the kidney areas under observation. Changes similar to those described under direct application of the drug were noticed, except that the glomeruli, instead of showing complete cessation of blood flow, showed very sluggish flow through their capillary tufts. This lasted for at least twenty minutes, and often for more than half an hour. Dilutions up to 1:200, when given in amounts of 0.1 c.c. into the lymph sac, produced a slowing of the blood stream in the various vessels of the kidney area, which was much less marked and shorter in duration than that produced by the undiluted dose.

The injection of 0.05 c.c. to 0.1 c.c. of undiluted pitressin into the abdominal vein of the frog produced, within twenty seconds, complete cessation of activity of all the glomeruli under observation. Some glomeruli became completely blanched and had no blood cells in their tuft of capillaries whatsoever, while other glomeruli had their capillaries packed with motionless red and white blood cells. This cessation of activity lasted for periods varying from two to eight minutes, after which recovery began to take place in the glomeruli at different times. The other vessels in the area showed marked slowing of the blood stream to such an extent that the flow became jerky, and in some vessels it wavered back and forth without much forward progress. The slowing of the blood stream in the kidney tissue under observation lasted from twenty to forty-five minutes. Dilutions up to 1:500 gave such effects as already described, but the duration generally varied inversely with the dilution. Dilutions higher than 1:500 produced no detectable changes. No matter what route was used for administration, undiluted pitressin produced various degrees of anemia of the area under observation as a result of vascular constriction.

B. EFFECT OF PITRESSIN ON RENAL BLOOD FLOW AND URINE SECRETION IN THE DOG

In a clinical investigation on human subjects, Stead, Kunkel, and Weiss¹² found that the intramuscular administration of pitressin produced a greatly reduced blood flow in the hands as well as abdominal cramps and ashen pallor. In their study on the trained dog, Geiling and co-workers¹³ reported a marked and prolonged decrease of blood flow in the femoral and carotid vessels (arteries

and veins) following the intravenous administration of pitressin. However, in a few observations on the renal artery they observed a transient decrease followed by a prolonged and marked increase. Grindlay and two of us (Herrick and Mann¹⁴) reported a marked decrease in the blood flow of the spleen following the intravenous injection of 0.05 c.c. of pitressin into dogs. Essex and his co-workers¹⁵ reported that the intravenous administration of pitressin into trained dogs produced a decrease from 64 to 84 per cent in the coronary blood flow and reduced the heart rate.

Handovsky and Samaan,¹⁶ using the Rein thermostromuhr on both anesthetized and unanesthetized dogs, observed an initial reduction followed by a prolonged increase in renal blood flow under the influence of large doses of posterior pituitary extract administered intravenously. They used various commercial preparations of posterior pituitary extracts. Janssen and Rein¹⁷ determined the renal blood flow of decerebrate dogs under the influence of fresh posterior pituitary extract. They concluded that the process of antidiuresis was not accompanied by any alterations in the renal blood flow. Walker and co-workers¹⁸ injected pituitrin subcutaneously into unanesthetized rabbits and dogs, and determined the renal blood flow during the development of the antidiuresis. They observed very slight decrease in renal blood flow in some experiments, and an apparent marked increase in three of ten experiments. They stated that decrease in renal blood flow does not play any part in the antidiuresis in either dog or rabbit. Unpublished observations by A. E. Livingston and one of them, reported in a footnote, indicate a decrease in the size of the dog's kidney observed roentgenographically during pituitrin antidiuresis. They attributed this decrease to changes in tubule volume rather than to a decrease in the size of the vascular bed. Their observations on creatinine clearances indicated no consistent reduction under the effect of pituitrin, and they concluded that changes in the glomerular filtrate are not the mechanism of the antidiuresis.

In their work on dogs, Underhill and Pack¹⁹ found that intravenous administration of pituitrin caused marked dilution of the blood, and that exclusion of the kidneys by mass ligature at the hilus previous to the injection of pituitrin did not modify the hydremia produced by the pituitrin. They considered the hydremia and the antidiuretic action to be due to some unknown action on capillary permeability. From his work on the isolated, perfused kidney of the dog, Verney²⁰ concluded that the pituitrin-like secretion picked up by the blood passing through the head inhibited the polyuria of the isolated kidney and decreased the renal blood flow. Richards and Plant²¹ determined renal blood flow by the method of Barcroft and Brodie²² in dogs, rabbits, and cats under urethane anesthesia after intravenous administration of small doses of pituitrin. They obtained a decrease in renal blood flow in dogs and rabbits but not in cats.

Method.—The observations on the renal blood flow were made by the thermostromuhr method of Rein, which was modified by Essex and two of us (Baltes and Herrick^{23, 24}). Direct current thermostromuhr units were carefully calibrated before and after application. The calibrations were made and checked in such a way that the deflections of a sensitive moving coil galvanometer could be translated into cubic centimeters of blood flow per minute.

Fig. 1.—Effect of pitressin on the renal blood flow in the trained dog. *A* demonstrates the sudden and marked decrease of blood flow in the renal vein under the influence of intravenously administered pitressin. More than eighteen minutes elapsed before the blood flow returned to the preinjection level. *B* demonstrates the effect of a small dose of pitressin given intravenously on the blood flow in the renal artery. This was markedly decreased, but within five minutes the flow increased beyond the preinjection level.

Fig. 2.—Effect of various doses of pitressin on the carotid blood pressure and on the blood flow in the right and left renal veins of the anesthetized animal (pentobarbital sodium).

Three groups of healthy dogs were used for investigating this phase of the problem. The anesthetic used on the first group was pentobarbital sodium, which was slowly administered intravenously in amounts of 25 mg. per kilogram of body weight. The kidney was well exposed through a midline incision of the abdomen, and the renal artery or vein was gently dissected and carefully cleaned, avoiding injury to any of the nerves in the hilus. A calibrated unit was snugly fitted around the renal vessel and conveniently anchored to avoid any interference or turbulence in the blood flow of the vessel used. The same technique was used in applying another unit on the vessel of the second kidney. In some experiments a unit was placed on the common iliac artery or vein instead of one of the kidney vessels in order to permit simultaneous recording of the effect of pitressin on the blood flow of the kidney as well as of the lower extremity.

TABLE I

PITRESSIN: A COMPARISON OF SUBCUTANEOUS, INTRAMUSCULAR, AND INTRAVENOUS INJECTIONS

DOG NO.	WEIGHT (KG.)	OBSERVATIONS MADE	DOSE (UNITS PER KG.)	MODE OF INJECTION	PERCENTAGE DECREASE IN RENAL BLOOD FLOW FOLLOWING INJECTION
1	13.3	During pentobarbital sodium anesthesia	0.6	Intravenous	66
			0.6	Intramuscular	6
			0.6	Intramuscular	8
			0.6	Subcutaneous	8
			0.6	Subcutaneous	8
			0.6	Intravenous	75
2	19.3	During chloralosan anesthesia	0.6	Intravenous	48
			0.6	Intramuscular	3
			0.6	Subcutaneous	1
			0.6	Subcutaneous	9
			0.6	Intramuscular	7
			0.6	Intravenous	7
3 Trained dog	17	Second day after operation	0.3	Subcutaneous	7
			0.075	Intravenous	38
			0.3	Intramuscular	10 (increase)*
			0.15	Intravenous	47
		Third day after operation	0.15	Intravenous	55
			0.45	Intramuscular	11 (increase)*
			0.30	Intravenous	51
4 Trained dog	21.7	Second day after operation	0.15	Intravenous	96
			0.15	Intravenous	96
		Third day after operation	0.075	Intravenous	96
			0.3	Intramuscular	30
			0.3	Subcutaneous	21

*In two instances the flow was increased slightly by intramuscular injections in Dog 3.

NOTE: Intravenously administered, pitressin produces consistently a decrease in renal blood flow; intramuscularly, it gives variable results; subcutaneously, it usually has no effect on the renal blood flow.

Both ureters were isolated and cannulated at their entrance into the bladder. Y-shaped glass tubing was connected to the ureteral cannulas to lead the urine into a common exit for recording the rate of urine flow. The femoral vein was exposed for intravenous administration, and the carotid artery was cannulated for recording blood pressure. Heparin was used as anticoagulant in the system for optical recording of the carotid blood pressure. The abdomen was closed, leaving between the sutures the tubing of the ureteral cannulas and the flexible, rubber-insulated lead wires of the units. The two galvanometer deflections translating the blood flows in the two kidneys and the optical record of

the blood pressure were all photographed on slowly moving photosensitive paper, thus furnishing permanent records of control values, and of any changes during and after the administration of pitressin for any length of time desired.

The same technical procedures and observations mentioned in the preceding paragraph were made on another group of dogs which were anesthetized by slow intravenous administration of chloralosan—100 mg. per kilogram of body weight, dissolved in warm Ringer's solution.

Fig. 3.—Effect of pitressin under different anesthetics: *A*, chloralosan; *B*, pentobarbital sodium. Under chloralosan, the injection of pitressin, in spite of the much larger dose, gave a much smaller decrease in renal blood flow than did pentobarbital sodium.

For the purpose of avoiding the influence of anesthesia, another series of experiments were performed on dogs that had been trained to lie quietly on the table. On a day prior to the experiment, the dogs were etherized and, with the usual aseptic technique, the renal vessel was exposed and a calibrated unit was applied as previously described. The lead wires of the unit were exteriorized, and the abdominal incision was carefully sutured according to surgical principles. Observations on renal blood flow were made after the dog had recovered from the operation. After a few days of blood flow studies, the femoral artery was exposed under local anesthesia, and the blood pressure was optically recorded simultaneously with the renal blood flow on the same chart.

TABLE II

EFFECT OF SUCCESSIVE DOSES OF PITRESSIN (GIVEN INTRAVENOUSLY) ON BLOOD FLOW IN RENAL VEINS (WEIGHT OF DOG, 13.2 KG.)

DOSE (UNITS PER KG.)	PERCENTAGE DECREASE IN BLOOD FLOW	
	LEFT RENAL VEIN	RIGHT RENAL VEIN
0.15	67	70
0.15	66	58
0.15	75	72
0.15	63	65
0.075	50	49
0.075	54	57

TABLE III

EFFECT OF PITRESSIN ON URINE FORMATION IN ANESTHETIZED DOGS

DOG NO.	WEIGHT (KG.)	DOSE (UNITS PER KG.)	MODE OF INJECTION	URINE, DROPS PER MINUTE		DURATION OF EFFECT (MINUTES)
				BEFORE INJECTION	AFTER INJECTION	
1	13.3	0.6	Intravenous	6	3	6
		0.6	Intramuscular	4	4	No effect
		0.6	Subcutaneous	6	6	No effect
2	19.3	0.6	Intravenous	6	1	9
		0.6	Intramuscular	13	9	30
		0.6	Subcutaneous	12	12	No effect
5	13.8	0.4	Intravenous	3	1	8
		0.4	Intramuscular	2	2	No effect
		0.4	Subcutaneous	1	1	No effect
		0.4	Subcutaneous	1	1	No effect
6	12.0	0.5	Intravenous	5	1	8
		0.5	Intramuscular	3	2	60
7	18.8	0.3	Intravenous	4	1	7
		0.5	Intramuscular	11	10	60
8	22.0	0.65	Intravenous	4	1	8
		0.65	Intramuscular	3	3	No effect
9	15.4	0.5	Intravenous	5	1	10
		0.5	Intramuscular	3	3	No effect

NOTE: Intravenous administration of pitressin immediately causes anuria followed by oliguria for about six to ten minutes. Intramuscularly it produces slight oliguria, but subcutaneously it does not have any effect on the urine formation in the anesthetized animal.

Results.—When given intravenously, pitressin has a pronounced effect on the renal blood flow in the trained dog, that is, a marked decrease (Fig. 1). This effect depends on the amount of the drug injected (Fig. 2). The decrease in flow is less pronounced when the dog is anesthetized and seems to vary with the kind of anesthetic used (Fig. 3).

When pitressin is given either intramuscularly or subcutaneously, its effect is less marked. In contrast to the intravenous injection, the subcutaneous injection produces no significant change in either the renal blood flow or in the systemic blood pressure. Intramuscular injections produce slight but variable changes in renal flow (Table I).

Some investigators have expressed the opinion that subsequent injections of pitressin do not have as marked an effect as the first injection. We have not been able to confirm this. Successive injections were never made, however, until the renal blood flow had returned to the preinjection value. Under these circumstances successive injections caused a decrease similar to that of the first (Table II).

Concerning the effect of pitressin on blood pressure, we wish to call attention to the fall in blood pressure following the immediate transient rise (Figs. 2C and 3B) which sometimes takes place previous to the prolonged moderate increase.

The decrease in renal blood flow is not maintained over as long a period as that in the femoral or carotid arteries. Another distinguishing characteristic is that the initial decrease in renal flow is followed sometimes by a prolonged and marked increase in the trained dog (Fig. 1B).

The well-known decrease in urine flow occurred following intravenous injections of pitressin (Table III).

SUMMARY

By means of transillumination, direct observations were made on the effect of pitressin on the glomerular tuft of capillaries and other vessels in the frog kidney. Various dilutions of pitressin were applied directly to the illuminated area of the kidney, or were injected into the lymph sac or into the abdominal vein of the frog under urethane anesthesia. Depending on the amount and dilution used, pitressin produced cessation of the circulation in the glomerular tuft of capillaries for a fraction of a minute to several minutes, and slowed the circulation in the other vessels to such an extent that no axial stream was observed, and the white and red corpuseles could be easily distinguished in the slowly moving stream within the lumen of the vessel.

Simultaneous records of urine and renal blood flows and optical records of blood pressure were made on a group of dogs under pentobarbital sodium anesthesia and on another group under chloralosan anesthesia. It was observed that pitressin, subcutaneously administered, caused no changes in urine or renal blood flows or in the blood pressure. Intramuscular injections produced variable but slight changes; but, when given intravenously, pitressin always produced transient anuria followed by oliguria for several minutes and a marked decrease in renal blood flow, from which recovery usually was not complete in half an hour, and sometimes not even in one hour. Intravenous injections of pitressin produced a sudden but transient rise in blood pressure, followed occasionally by a transient fall, and then by a gradual prolonged but moderate rise which lasted for approximately a quarter hour.

A series of observations on renal blood flow was performed on a group of trained dogs. The results under influence of pitressin injected subcutaneously, intramuscularly, or intravenously were practically the same as in the anesthetized groups. However, it was observed that the decrease in renal blood flow after intravenous administration of pitressin was more marked and usually lasted longer in trained dogs than in anesthetized dogs.

CONCLUSIONS

The data presented justify the conclusion that the same preparation of pitressin administered under identical conditions into the same animal produces different effects on the renal blood flow, depending primarily on the route of administration. Subcutaneously administered, it produces very slight, if any, change in the blood flow. Intramuscular injections give variable results, pos-

sibly dependent on the vascularity and activity of the area involved and its influence on the rate of absorption. Intravenously administered pitressin invariably decreases the blood flow, and caution regarding its intravenous use may aid in the prevention of untoward effects.

SILICON IN NONSILICOTIC LUNGS: ITS RELATION TO APICAL SCARS AND TO NODULES*

GEORGE J. McHEFFEY, M.D., ROCHESTER, MINN.

IT HAS been accepted generally that the fibrotic scarring observed at the apices of lungs is of tuberculous origin. This view has been held until recently, when it was suggested that carbon pigment plays a part in the development of such scars. Still more recently, work has been done to demonstrate the relationship between the accumulation of silicious dust in the lungs and the presence of scars showing no evidence of healed tuberculosis.

ETIOLOGIC CONCEPTION OF APICAL SCARS

Tuberculosis.—In 1900 Naegeli¹ reported a study of the incidence of tuberculosis in 500 cases in which necropsy was performed. Apical scars were present in the lungs in 90 per cent of the cases in which the patients had lived in cities and had died of causes other than tuberculosis. He, therefore, suggested that the scars were of tuberculous origin. His view has been supported by many other workers. Aschoff,² in particular, stated that 90 per cent of adults have apical scars and affirmed that all of these are of tuberculous origin. Few investigators have put forth a satisfactory explanation as to why this scarring occurs. Opie³ expressed the opinion that the lesion is a secondary type of infection derived from an exogenous source. He found apical scars in one of five or six adults in the later decades of life. He also found that many lesions were active and that the primary complex was calcified. Consequently, he expressed the opinion that this lesion is a secondary type of infection. Van Zwaluwenburg and Grabfield⁴ in 1921 were convinced that this lesion is closely associated with a previous tuberculous infection of the tonsils or cervical lymph nodes. Grober⁵ injected India ink into the pharynx of dogs. The dogs were killed and the lymphatics of the neck and apical regions were dissected to determine the dissemination of the ink. He found that the ink had been carried down the cervical lymphatics directly into the pleurae of the apices of the lungs. He concluded that apical scarring is brought about in this manner and that this is possibly the route of infection in many cases of pulmonary tuberculosis. Baldwin, and co-workers⁶ of the Trudeau Foundation, expressed the opinion that the infection reaches the apex through the blood stream by way of the pulmonary artery. They subscribed to the hypothesis that the hilus node in the active stages of the primary infection is unable to hold all the organisms of tuberculosis that lodge there, and consequently the organisms are thrown off into the thoracic duct and thus into the pulmonary artery.

Abstract of thesis submitted to the faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Pathology.

Received for publication, June 9, 1911.

Dust.—While relatively little work has been done concerning the possibility of inhaled dusts as an etiologic agent for apical scars, what has been done seems to indicate a silicotic or dust origin for these scars contrary to the view of others that they are invariably of tuberculous origin. The work does not rule out, however, other inflammatory processes. Histologic examination of the lungs often shows an excess of anthracotic deposits associated with various degrees of fibrosis; and since apical scars are frequently associated with heavy anthracotic deposits, some workers have suggested that carbon pigment may play a part in the development of the scars, although at the same time they feel that the lesions are tuberculous in origin. This view has been expressed by Sato.⁷ Davson and Susman⁸ in 1937, studying micro-incinerated sections, concluded that the development of apical scars is secondary to the accumulation of silicious matter at the apex of the lungs. Also they showed that there is a definite relationship between silicious dust accumulating in the upper part of the lung and the scars that did not show evidence of tuberculosis.

MATERIAL AND METHODS

Micro-incineration.—Without going into the details of the technique of micro-incineration, let it suffice to say that it is a histologic method to demonstrate the presence and distribution of some of the various mineral components in tissues. The method is based upon the principle that, when a section of tissue is subjected to a temperature of 600° C., all organic material is destroyed, leaving the inorganic ashes. In these ashes are found the heat-resistant minerals, and in particular in the case of lung tissues, the deposits of the silicon compounds. The method is of value in determining the relative quantity of silicious matter in a given section of lung tissue and is of particular value in differentiating the silicotic nodule from the tuberculous nodule, as shown by Policard and Doubrow,⁹ and Irwin¹⁰ (Figs. 1, 2, 3, and 4). In the silicotic nodule the silicious ash is distributed rather uniformly throughout the entire nodule, while in the tuberculous nodule the silicious material is limited to the periphery of the nodule in the region corresponding to the capsule. Irwin inferred that if the ash pattern of silicosis is found, it represents a silicotic nodule, even if the corresponding area in the stained section has degenerated beyond recognition; and if such an area does not contain any particles of ash or only a few scattered ones, it is an area of nonsilicious fibrosis.

Method of Procedure for This Study.—The lungs in 200 patients in whom necropsy was performed at the Mayo Clinic from Sept. 1, 1938, to Dec. 31, 1938, inclusive, were examined. On gross inspection, the degree of anthracosis and the grade of apical scarring were noted. Both findings were recorded on a basis of 1 to 4. In addition, the presence or absence of evidence of healed tuberculosis in the lung or hilus lymph nodes was observed. The lungs that did not show evidence of healed tuberculosis were examined roentgenographically by Squire¹¹ for calcium deposits which were later recovered by him. Cases in which calcium deposits were found in the lungs were added to those cases of healed tuberculosis already ascertained by visual inspection. Finally, the age, sex, occupation, and residence of the deceased were recorded. The great majority of these 200 persons were adults more than 20 years of age,

while the minority consisted of younger persons, including a few children. Also, the lungs and portions of lungs in several known cases of silicosis were examined. A similar examination was made of the lungs of a few newborn infants. The latter two sets of lungs, those from persons who had had silicosis

Fig. 1.—Silicotic nodule in a known case of silicotuberculosis (hematoxylin and eosin, $\times 42$).

Fig. 2.—Consecutive section to Fig. 1, incinerated, showing ash pattern of a silicotic nodule (dark field, $\times 42$).

and those from infants, were examined for the purpose of comparison and control, but neither of these sets was included in the 200 afore-mentioned cases, none of which revealed any evidence of clinical silicosis during life.

The lungs were sectioned longitudinally at intervals of $\frac{1}{2}$ inch (1.3 cm.) to determine whether or not there was any gross evidence of silicosis, such as the presence of a nodule in the lung or hilus nodes, the presence of "egg shell"

Fig. 3.—Tuberculous nodule situated near the silicotic nodule shown in Fig. 1 (hematoxylin and eosin, $\times 34$).

calcification in the hilus nodes, or the presence of suspicious regions of fibrosis. If any such lesions were discovered, blocks of tissue were made of the region involved and were placed in a fixative of 10 per cent formalin. Then routinely one block of tissue was cut from the apical scar or from the apex in those lungs

not revealing a scar, one block from the upper lobe near the scar but not including it, one block from the lower lobe, and one of a hilus lymph node that did not contain calcareous material. These blocks, after fixing, were embedded in paraffin in the usual manner, and serial sections were cut of a thickness of 5 microns. Three sections were cut, one for staining with hematoxylin and eosin, and two unstained sections for micro-incineration. After incineration the sections were treated with concentrated hydrochloric acid so as to remove the inorganic ash, and then were examined with dark-field illumination. By comparison with the consecutive stained sections, an exact localization of any deposits of silicious ash was obtained. Furthermore, since all sections were of equal thickness, the amount of silicious ash was compared by visual estimation.

For the purpose of estimation of the amount of silica in any given section, four grades were recognized: grade 1, slight amount of ash deposits about the blood vessels or bronchioles; grade 2, moderate amount of ash deposits about the blood vessels or bronchioles associated with a slight amount of diffuse scatterings of ash throughout the parenchyma; grade 3, large collections of ash deposits about vessels and bronchioles associated with a uniform scattering of ash throughout the parenchyma; and grade 4, large collections of local deposits associated with large deposits throughout the parenchyma. In the case of silica grade 4, the amount corresponded to that found in sections from the fibrotic portions of silicotic lungs.

RESULTS

The apical scar lesion occurred at the apex of either one or both lungs and was characterized by a firm, grayish-white, opaque, "scarred" region with variable degrees of puckering of the visceral pleura. In some cases the scarring was more extensive and formed a cap. A few of these caps felt on palpation as if they were constructed of cartilage. Sections of the region had in some cases a dark anthracotic fibrosis in the subjacent lung substance without any evidence of caseation or calcification. A few scars revealed gross evidence of calcification. In some cases the parenchyma of the lung directly beneath the scar contained an emphysematous cavity or multiple smaller ones.

By histologic examination there was fibrous thickening of varying depth, and the subjacent lung parenchyma revealed a greater or lesser degree of fibrosis. The fibrous tissue when stained with hematoxylin and eosin usually exhibited a bluish pink to pink color of the connective tissue fibers. In many cases the connective tissue had become hyalinized. The extent of the fibrotic regions varied; in younger people the lesions were smaller, while in the older age groups the more massive lesions usually occurred. There was considerable proliferation of collagen fibers throughout the fibrotic regions in some of the lesions, some of which could be traced into the parenchyma of the adjacent lung and merged with it. The fibrotic regions contained varying amounts of carbon pigment scattered diffusely throughout the scar. In some cases numerous alveoli containing clumps of phagocytes laden with carbon occurred within the fibrotic regions. In four scars giant cells were seen.

Micro-incineration of the apical scars showed that the deposits of silica were always present with the carbon and in corresponding amounts, except for

a few cases in which the silicious matter was greater than the corresponding carbon and vice versa (Figs. 5, 6, 7, and 8). Also as far as the lungs were concerned, the silicious material was found to be more or less uniform throughout, although there was a moderate increase in the silica grade in the upper

Fig. 5.—“Nonspecific” apical scar (hematoxylin and eosin, $\times 42$).

Fig. 6.—Consecutive section to Fig. 5, incinerated, showing diffuse and local collections of silicious deposits in precisely the same locations as the carbon deposits (dark field, $\times 42$).

lobes. In a few apical scars and in many lungs and hilus lymph nodes the intensity of silica was quite comparable to that seen in microscopic sections from silicotic lungs. In these cases there were seen in the stained section areas of fibrosis characterized by circumscribed hyalinized areas which appeared to

be identical with silicotic nodules. They contained the finely distributed carbon sprinkling commonly seen in silicotic nodules. Incineration of these lesions revealed that they contained the silica ash pattern appearing very similar to those found in known silicotic nodules. In some of the better incinerated

Fig. 7.—“Specific silicotic” or dust “apical scar.” Note silicotic nodule in the apical scar (hematoxylin and eosin, $\times 48$).

Fig. 8.—Consecutive incinerated section to Fig. 7 (dark field, $\times 48$).

sections of apical scars there was noted the ash pattern of the scar, and in the background appeared a faint ash network which somewhat resembled the architecture of lung tissue and which merged with the ash pattern of the normal adjacent lung. This ash pattern seen in the background of the fibrotic

areas was no doubt the lung that previously had occupied the area and which was replaced by collagenous connective tissue.

The findings of this study are given in seven different tables. Table I summarizes the number of cases of apical scars in both sexes and their relation to the age of the patients and to the amount of anthracosis in their lungs. There was no anthracosis in the first decade of life; anthracosis grade 1 began in the second decade, with a maximal number of cases in the seventh decade; anthracosis grade 2 began in the third decade, with a maximum in the sixth decade; anthracosis grade 3 began in the fifth decade, with a maximum in the seventh decade; and anthracosis grade 4 occurred only in the seventh decade. Of the 133 cases of apical scars (66.5 per cent) the least number occurred in the third and ninth decades, and the greatest number in the seventh decade. Cases of apical scarring did not occur during the first two decades. Finally, it is noted that the degree of anthracosis increased with the age and the number of cases of apical scars increased with age as the grade of anthracosis increased, this being true up to the higher decades of life, at which point the number decreased.

TABLE I

GRADE OF ANTHRACOSIS AND OCCURRENCE OF APICAL SCARS BY AGE OF PATIENTS, BOTH SEXES

AGE (YR.)	CASES	GRADE OF ANTHRACOSIS					APICAL SCARS	
		0	1	2	3	4	CASES	PER CENT
0-9	2	2	0	0	0	0	0	0.0
10-19	10	3	7	0	0	0	0	0.0
20-29	10	0	9	1	0	0	6	60.0
30-39	14	0	13	1	0	0	8	57.0
40-49	28	0	20	7	1	0	18	64.0
50-59	46	0	30	14	2	0	35	76.0
60-69	54	0	40	8	4	2	39	72.0

80 and more	11	0	7	3	1	0	6	54.0
Total	200	5	141	42	10	2	133	66.5

TABLE II

AVERAGE AGE OF PATIENTS AND OCCURENCE OF APICAL SCARS BY GRADE OF ANTHRACOSIS

GRADE OF ANTHRACOSIS	SEX		TOTAL CASES	AVERAGE AGE (YR.)	APICAL SCARS	
	MALE	FEMALE			CASES	PER CENT
0	2	3	5	8.6	0	00.0
1	81	60	141	54.5	89	63.1
2	35	7	42	58.5	34	81.0
3	10	0	10	65.0	8	80.0
4	2	0	2	66.5	2	100.0
Total	130	70	200		133	66.5

While Table I reveals the relationship of apical scars and anthracosis to the various age groups, a much better relation is obtained by studying Table II, which shows the relationship of anthracosis and apical scars to the average age. Here it is noted that the majority of cases are anthracosis grade 1, and that the number of cases decreases as the grade of anthracosis increases beyond grade 1, but that the average age of the patients increases. The percentage of apical scars increases with the average age and with the grade of anthracosis.

Thus far, the discussion has been concerned mostly with anthracosis. The reason for this will be obvious when Table III is studied. This table, con-

structed exactly like Table II, shows the relationship of apical scars to the average age and to the total deposits of silica in the lungs, as estimated by micro-incineration. Here it is noted that of the 200 cases studied, 157 reveal silica grade 1 in the lungs, while a decreasing number of cases reveal silica, grades 2, 3, and 4, respectively. Ten cases reveal no silica at all, and the average age of this group is 24 years. Of the cases of silica grade 1, the average age is 54.3 years. Of the grades of silica higher than 1, the average age increases for each silica grade group, except grade 4, while the total number of cases for each silica grade decreases beyond the peak of silica grade 1. As concerns the apical scars, here again it is noted that the percentage of apical scars increases with age as the total content of silica of the lungs increases. After studying Tables II and III, one is struck by the close parallelism of the gross anthracotic grade with the microscopic total silica grade with respect to the total number of cases, the average age, and the percentage of apical scars. Thus far, the study seems to verify the findings of previous workers, namely, that silica deposits occur in conjunction with anthracotic deposits, and in roughly corresponding amounts. In addition, the findings suggest that the amount of anthracosis determined by gross examination of the lungs is a fairly good index to the total amount of silicious material present in the same lungs.

TABLE III

AVERAGE AGE OF PATIENTS AND OCCURRENCE OF APICAL SCARS BY GRADE OF TOTAL SILICA IN LUNGS AS ESTIMATED BY MICRO-INCINERATION

GRADE OF TOTAL SILICA	SEX		TOTAL CASES	AVERAGE AGE (YR.)	APICAL SCARS	
	MALE	FEMALE			CASES	PER CENT
0	6	4	10	24.0	2	20.0
1	95	62	157	54.3	104	66.2
2	25	4	29	64.3	23	79.3
3	3	0	3	69.6	3	100.0
4	1	0	1	68.0	1	100.0
Total	130	70	200		133	66.5

What has been said concerns the apical scar and its relation to the silica deposits in the lungs. Now what about the relation of this lesion to the silica deposits in the scar itself, and the relation of the latter to the silica deposits in the respective lungs and hilus lymph nodes? It is noted in Table IV that as the thickness of the apical scar increases, the total content of silica in the apical scars and their respective lungs and hilus nodes tends to increase. This is much more evident in the male sex.

Of the 133 cases of apical scars, it was of interest to note that in only four cases (3.0 per cent) and possibly in only 3 cases, was there no evidence of tuberculosis in the lungs or hilus lymph nodes. In other words, in 129 cases of apical scars (97.0 per cent) there were signs of tuberculosis in either the lung or the hilus lymph nodes. Of the 4 nontuberculous patients, 2 were men and 2 were women. One patient was a 73-year-old man with a very thick apical scar and a correspondingly high silica content in the scar, lung, and hilus nodes, while the other 3 cases were in young persons (ages 24, 30, and 32 years) with correspondingly low silica determinations. While it is possible for an old man not to have evidence of healed pulmonary tuberculosis, it must be stated that this was the only case in which roentgenologic examination of the lungs for calcium deposits

was not made. Hence the previous statement that possibly in only 3 cases was there no evidence of tuberculosis in the lungs or hilus nodes is probably correct.

TABLE IV
APICAL SCARS WITH RELATION TO THEIR SILICA CONTENT

SEX	GRADE OF SCAR	CASES	TOTAL SILICA, AVERAGE GRADE ON BASIS OF 1 TO 4		
			SCAR	LUNG	HILUS NODE
Male	1	47	1.4	1.3	2.2
	2	26	1.7	1.3	2.4
	3	10	2.1	1.9	2.6
	4	5	2.0	1.2	2.2
Female	1	28	1.1	0.9	2.3
	2	12	1.6	1.3	2.3
	3	4	1.6	1.2	2.3
	4	1	1.0	0.7	2.0
Total		133			

Of the 67 cases without apical scars, there was evidence of tuberculosis in the lungs or hilus nodes in 48 (72 per cent) (Table V). The average total content of silica in the lungs and hilus nodes of the men without apical scars, but with evidence of tuberculosis, is found to be somewhat less than for the men with apical scars. As to the female sex, the corresponding silica determinations are considerably less than for those females having apical scars.

TABLE V
PATIENTS WITH NO APICAL SCARS WITH TUBERCULOSIS PRESENT IN LUNGS OR HILUS NODES

SEX	CASES	AGE, YEARS			TOTAL SILICA, AVERAGE GRADE	
		MEAN	YOUNGEST	OLDEST	LUNG	HILUS NODE
Male	36	54.5	20	97	1.2	2.2
Female	12	48.3	11	83	0.8	1.8

Table VI summarizes the remaining 19 cases, in which there were no apical scars and no evidence of tuberculosis in the lungs or hilus nodes. In general, the patients without evidence of tuberculosis were those in the lower average age groups, and the average total silica was also correspondingly low. On the other hand, the patients that did reveal tuberculosis were in the higher average age groups, and the total content of silica was higher. In nearly all instances the silica content of male patients was somewhat higher than that of female patients.

TABLE VI
PATIENTS WITH NO APICAL SCARS WITH NO TUBERCULOSIS PRESENT IN LUNGS OR HILUS NODES

SEX	CASES	AGE, YEARS			TOTAL SILICA, AVERAGE GRADE	
		MEAN	YOUNGEST	OLDEST	LUNG	HILUS NODE
Male	7	34.1	11	68	0.6	1.2
Female	12	40.8	2	76	0.7	1.1

In passing, a word might be mentioned concerning the general incidence of healed tuberculosis in the 200 cases studied. In 96 cases evidences of healed tuberculosis were found in the lungs by gross dissection. Squire,¹¹ by post-mortem roentgenologic examination of the lungs, found 28 more cases. Two

cases were found by microscopic examination. This makes a total of 126 cases in which evidences of healed tuberculosis were found in the lungs. In the hilus nodes 127 cases were found by gross dissection. Squire found 38 more cases by roentgenologic examination, making a total of 165 cases in which evidences of healed tuberculosis were found in the hilus nodes. Thus, according to this survey of 200 cases, the incidence of healed tuberculosis is 177 cases, or 88.5 per cent.

"Silicotic" or "Dust" Nodules in Apical Scars.—It was previously stated that lesions were found in the lungs or hilus nodes that resembled silicotic nodules and which, upon micro-incineration, revealed the ash patterns of silicotic nodules. In 7 of 133 cases of apical scars, there was an ash pattern comparable to that of known silicotic nodules (Figs. 7 and 8). Thus, the incidence of apical scars that can be said to be "specific silicotic" or "dust scars" is 5.3 per cent. Table VII summarizes these cases. It is noted that in 5 cases the patients were men and in 2 cases they were women, the average age for all being 69 years. The average grade of the apical scars is 2+, and the total silica grade in each scar and hilus node is high, while the silica content of the lung varies. However, note that there is a fairly close correlation between the silica content of the apical scars and the silica content of the hilus nodes.

TABLE VII
PATIENTS WITH SILICOTIC NODULES IN APICAL SCARS

SEX	AGE (YR.)	OCCUPATION	GRADE OF APICAL SCAR	TOTAL SILICA, GRADE		
				SCAR	LUNG	NODE
M	67	Street car conductor	3	4.0	3.0	4.0
M	55	Civil engineer	2+	2.0	1.0	3.0
M	77	Farmer	4	3.0	3.0	4.0
M	71	Auto trimmer	1	3.0	2.0	3.0
M	73	Miller	2	3.0	1.5	3.0
F	55	Housewife	2	3.0	1.0	4.0
F	85	Housewife	2	3.0	1.5	4.0
Average	69		2+	3.0	1.9	3.6

"Specific Tuberculous" Apical Scars.—In 4 of the 133 cases of apical scars, there were giant cells, in one case there were tubercles, and in 12 cases there were calcium deposits in the scars themselves. This makes a total of 17 cases of "tuberculous" apical scars (12.8 per cent). In these 17 cases the average age of the patients was 60 years, and the average apical scarring was grade 2+. However, the average silica content of the scar, lung, and hilus node was 1.5, 1.2, and 2.3, respectively, an amount considerably lower than the corresponding average silica content in the "specific silicotic" apical scars.

Since 5.3 per cent of the apical scars are "silicotic" and 12.8 per cent are "tuberculous," the total number of "specific apical scars" is 18.1 per cent. What of the apical scars making up the remaining 81.9 per cent? These apical scars are the "nonspecific scars," characterized by a more or less hyalinized fibrosis of variable thickness, all of which contain some silicious deposits, and all of which, with the exception of 3 or possibly 4 cases, are associated with healed tuberculosis, either in the lungs or hilus lymph nodes or both.

Incidence of the Silicotic Nodule in the Nonsilicotic Lung.—By microincineration the ash pattern of the silicotic nodule was found to be present in 21 cases.

Seventeen patients were male and 4 were female with an average age of 68.4 years. The silicotic ash pattern was found in 7 apical scars, in 5 lungs, and in 17 hilus nodes. The finding of the lesion in both the apical scar and the hilus node in the same subject occurred in 2 cases, while the presence of the lesion in the apical scar, in the lung, and in the hilus node in the same subject occurred in 3 cases. The local silica value for all these lesions was high, while the total silica content was relatively high in the respective lungs and hilus nodes. Even the average silica content for all 21 cases was seen to be higher than that found in the great majority of the 200 cases studied. Therefore, on the basis of this study of 200 cases, the incidence of the silicotic nodule in the nonsilicotic lung is 10.5 per cent. In general, the nodules were considerably smaller than the silicotic nodules seen in advanced cases of silicosis. Of all the cases studied, there were none in which the occupation of the patient was predisposed to silicosis; yet there were 21 cases in all of which one or more silicotic nodules were observed. There was little difficulty in distinguishing between healed tuberculous nodules and the nodules due to silica deposits when the method of microincineration was employed. In a few lungs not included in the series of 21 cases, early stages of formation of silicotic nodules were seen in the fibrous capsule of healed tuberculous nodules. It is known that carbon tends to collect around the fibrous walls of such lesions, and in these cases enough silicious material was present, as shown by micro-incineration, to produce the early stages of formation of silicotic nodules.

Considering all cases examined, this study demonstrates that silica deposits are present in normal lungs along with carbon deposits and are coextensive with them. Moreover, the deposits occur in localized regions in quantities comparable with those obtained in cases of diffuse silicosis. Therefore, all persons are exposed to a common source of dust particles. According to Policard and Doubrow, the source might be the smoke from domestic and industrial furnaces, since a high percentage of coal ash is silica. Jephcott¹² quoted figures published by the Chicago Board of Health in 1931, estimating that 134 tons of silicious matter fall per month per square mile. This suggests that all city dwellers during their lifetime inhale appreciable amounts of silica. It is also noteworthy that Campbell¹³ found 44 per cent of silica in the dust from tarred roads.

COMMENT

By comparing the silica content of the upper lobes with that of the lower lobes it was found that in nearly every case the intensity of carbon and silica accumulations was less in the lower than in the upper lobes. This tendency might be explained by the relative immobility of the apex, as compared with the greater mobility of the lower lobe, so that particles once inhaled tend to lodge in the apical region, while the better ventilation of the rest of the lung tends to favor the removal either by the bronchi or by the lymphatic drainage. Thus, since silicious material tends to collect in the apical region, it is probable that the tendency for scars to occur at the apex is linked to some degree with such dust deposits. This is stated with reserve, because it is quite well known that accumulations of silica occur in regions of fibrosis, regardless of cause. Although the average total silica determined in all the "specific tuberculous" apical scars

is lower than that of the "specific silicotic" scars, there are individual instances in which the silica value is comparable to the dust accumulations found in other apical scars.

CONCLUSIONS

1. Anthracotic and silicious dust deposits in the lung tissue increase with age, and the grade of anthracosis in a given lung is a rough index to the relative amount of silica deposits present in the same lung, since silica deposits occur in conjunction with anthracotic deposits and in corresponding amounts.

2. The average total content of silica in the lungs of the male is higher than that of the female.

3. The percentage of cases of apical scars increases with age and with the grade of the total silica content of the lung.

4. Of the cases of apical scars 97.0 per cent reveal evidence of healed tuberculosis elsewhere in the lung or hilus lymph nodes.

5. The average total content of silica in lungs possessing apical scars is higher than in those lungs that do not have apical scars.

6. On the basis of 200 cases the incidence of healed tuberculosis in the lungs is 88.5 per cent.

7. On the basis of 133 cases of apical scars the incidence of "specific silicotic" apical scars is 5.3 per cent, and the silica content in these specific cases is relatively high.

8. On the same basis the incidence of the "specific tuberculous" apical scars is 12.8 per cent, and the average silica content in these cases is considerably lower as compared to the "specific silicotic" scars.

9. The incidence of the silicotic nodule in the nonsilicotic lung is 10.5 per cent.

FOOD REMNANTS AS A CAUSE OF CONFUSION IN THE DIAGNOSIS OF INTESTINAL PARASITES*

NADENE DENISON, M.S., NEW ORLEANS, LA.

INTRODUCTION

ONE of the everyday problems of the diagnostician in the clinical parasitology laboratory is the differentiation of helminth eggs and protozoan cysts of pathogenic parasites of the intestine, not only from nonpathogenic species and free living organisms, but from various remnants of foods present in feces. The latter, due to their size and general appearance, are often confused with parasites. The object of this study was to find out experimentally what foods are responsible for some of the remains so frequently confused with intestinal parasites.

As early as 1717 van Leeuwenhoek, in examining human exudates, was able to demonstrate that the remains of foods eaten could be recognized in fecal material. The studies initiated by the idea that diseases could be diagnosed by crystals in excreta and the interest aroused in the physiology of digestion in the late nineteenth century led to several works on the composition of the feces. An early worker in this field, Rawitz (1845), classified the residual particles in feces as animal residue, plant residue, single cells, and foreign bodies, but his meaning, particularly in regard to the identity of the "single cells" and "foreign bodies," is not clear. Chiefly concerned with the normal and faulty digestion of foods, much of the work since 1899 has been based upon an extensive monograph by H. L. Q. van Ledden Hülsebosch, who discussed the macroscopic and microscopic structures of numerous plant foods. An excellent summary of the knowledge of fecal constituents was given in 1914 by Cammidge, who recognized the difficulties of gross parasitologic diagnosis, especially of the smaller nematodes and tapeworm proglottids, with which numerous fibers are easily confused upon macroscopic examination. Some anomalies found in microscopic fecal examinations were reported by Faust from China in 1924. Structures which he listed as confusing to the parasitologist were physical artifacts, contaminations, partially digested animal and plant cells, animals introduced by accident, harmless coprozoites, and body cells or tissues produced by noninfective agencies.

EXPERIMENTAL DATA

In order to secure a point of departure for the study of the origin of some of the confusing remains, it was deemed advisable to find out which of the more common foods were most likely to leave particulate remains resembling

Received for publication, June 16, 1941.

intestinal parasites in human feces. These undigested or partially undigested food remnants found in feces are difficult, if not at times almost impossible, of identification. However, by becoming acquainted with the structural elements of any given food before it was eaten, it was possible to determine its more characteristic residues. To do this a basic nonresidue diet was used, and for the checking of each individual food studied, a controlled diet was taken. For the remainder of the work hospital patients were used; these patients were on identical diets and their digestion was for all purposes apparently normal.

The basic diet consisted of strained vegetable and fruit juices, ground cooked meat, mashed Irish potatoes, milk, coffee, and white bread. Since cellular structure was absent in the liquids, was destroyed by cooking the bread and potatoes, or was easily recognized, as in the case of the meat, this diet served the purpose well. A small quantity of each food to be studied was obtained in the form in which it was to be served, and was teased apart in saline to separate the various structural elements. Drawings were made of these cells at an average magnification of $\times 540$. Stools passed twelve to fifteen hours after the food was eaten were examined for remains of fibers and other structures. These remains were studied, and sketches were made of their characteristic appearance. In both cases the material was studied unstained as well as stained with D'Antoni's iodine.

Animal Foods.—Such animal products as milk, cheese, custards, gelatin, and cooked eggs may be classified as nonresidue foods, except when eaten in excessively large amounts, such as milk in the dietary of infants. Of the animal tissues studied, as liver and muscle, only the muscle retained a close resemblance to its original structure, and fecal remnants of muscle fibers could be recognized as such without difficulty. Of the sea foods, crab meat maintained the characteristic structure of arthropod muscle fibers, but oysters and most fish left little residue.

Plant Foods.—Undigested plant foods in the form of single cells left the most confusing residues and those most likely to be mistaken for the eggs or cysts of parasites. A variety of common vegetable foods was studied, including representative grains eaten as cereals or in breads, fruits both fresh and dried, leafy vegetables, roots, and some leguminous seeds.

Fragments of whole vegetable tissues were not difficult to recognize as such, for their characteristic cellular arrangements obviate confusion with animal parasites. Bits of the husk of oats and whole corn were often observed to be almost undigested, as well as large pieces of leaf or epidermal tissues and aggregates of fibers from fibrovascular bundles.

Single epidermal cells separated from their tissue did, in a few cases, resemble eggs or cysts, but their heavy cellulose walls and complete lack of internal organization were diagnostic of their plant origin. More confusing were epidermal gland cells or epidermal hairs which, separated from the remainder of the tissue, respectively, resembled tapeworm eggs and small nematode larvae. Palisade cells, particularly from beans or peas, serve as diagnostic landmarks not only for the type of vegetable but also for the particular kinds of legumes, since they are characteristic for each plant, but they are easily differentiated from parasites on the basis of their thick walls and lack of internal structure.

Plate I.—Plates I, II and III represent the characteristic structures of each prepared food, together with their remnants commonly found in feces. The whole foods are figured upward and to the right, remnants are below and to the left of each figure number. 1, Beef; 2, corned beef muscle; 3, pork muscle; 4, crab meat; 5, oyster; 6, fish muscle; 7, wheat; 8, oats; 9, whole kernel corn.

A, Muscle fibers; B, elastic fibers; C, parenchyma cells; D, starch; E, fragments of husk; F, aleurone grains; G, epidermal cells; H, stone cells; I, tube cells; J, bast fibers; K, fibro-vascular bundles; L, "skin" of seed; M, epidermis with gland cell (g) and stomata (s, s); N, palisade cells.

Plate II.—10, Apple; 11, raisin; 12, prune; 13, peach; 14, banana; 15, orange; 16, lettuce; 17, mustard greens; 18, spinach. (See Plate I legend for explanation of letters.)

Plate III.—19, Cabbage; 20, celery; 21, onion; 22, beet; 23, carrot; 24, sweet potato; 25, pea; 26, lima bean; 27, string bean. (See Plate I legend for explanation of letters.)

The smaller particles from fibrovascular bundles are the characteristic lignated spirals and tubes, even fragments of which could be rarely ever confused with animal cells. Bast fibers, on the other hand, elongate lignated elements of the fibrovascular bundles, frequently simulate nematode larvae, the criterion of differentiation here again being the very thick walls and lack of internal structure in the plant cell. Stone cells, particularly of fruits, appeared frequently in feces; their shape and size at times closely resembled the eggs and cysts of parasites. Parenchyma cells were the most common of all cell types found singly, and, because of their shape and the presence of cytoplasm, might easily be confused with parasites. Because of the protection from digestion afforded by their cellulose walls, the remaining abundant cytoplasm allows the parenchyma cells of leafy vegetables, roots, and legumes to resemble helminth eggs, except for the lack of cellular organization or embryonic membranes. Parenchyma cells of bananas which frequently remain attached end-to-end have the appearance of minute tapeworm segments, but they lack internal organization or cuticular structures.

Starch granules observed in this study were for the most part destroyed by cooking; hence they were infrequently characteristic either in their staining reaction to iodine or in their structural appearance. Aleurone granules from grains often appeared much like minute protozoan cysts and might be very confusing unless closely studied.

Plates I, II, and III portray the characteristic appearance of the individual food elements studied both before and after digestion.

DISCUSSION

Foods ready to be served and the remnants occurring in feces have been studied from individuals whose digestive processes were apparently normal. Animal foods left no detritus that might cause any confusion in parasitologic diagnosis, but vegetables present a wide variety of remains, especially single-celled elements which closely simulate parasitic cysts or eggs. Fairly large, heavy-walled cells with shrunken cytoplasm, occurring as fecal remains and simulating helminth eggs, are usually derived from potatoes, leguminous seeds, such as peas and beans, or occasionally from various greens. Smaller cells and aleurone granules may simulate minute protozoan cysts.

It is not particularly difficult to determine into which general groups of plant foods fecal remnants may be classified, for as a rule some tissue fragments as well as single cells will occur, and a tentative diagnosis can be made from a consideration of the collective residues as to the foods eaten. Since such tissue fragments, because of their group organization, are not confusing, it is the undigested cells found in feces that are difficult to diagnose. However, their structure or their lack of structural organization should obviate errors in parasitic diagnosis, for, unlike protozoan cysts or helminth eggs, these cells are irregular in shape and size, their cytoplasm is shrunken, they rarely have nuclei, and they lack the internal order common in animals. Thus, even though a number of foods after apparently normal digestion have residues which might be confused with parasites, sufficient structures are left to prevent diagnostic mistakes.

SUMMARY

1. An experimental study was conducted to ascertain which of the more common foods leave remnants in the feces which might be confused with intestinal parasites or their products.

2. A controlled nonresidue diet was used, to which various foods were added one at a time to allow study of the characteristic remnants of each food.

3. Foods which had no residue of any importance at all were animal products, such as milk, cheese, and eggs, and sea foods, such as oysters.

4. Animal foods which had residues were muscular fibers and liver, but their residues occurring in feces have no structures which could possibly be confused with parasites.

5. Remnants from plant foods included pieces of plant tissue, which should not lead to confusion, and single undigested cells, which might cause confusion. Of these, single parenchyma cells of leafy vegetables, roots, and legumes, epidermal gland cells, epidermal hairs, bast fibers, and aleurone granules are the most common elements likely to be mistaken for parasites.

6. Though many foods have confusing residues in the feces, there are sufficient differences in structure, including their inconstancy of size and shape, their irregular walls, their lack of nuclei and internal organization, to provide differential diagnosis.

I wish to acknowledge with gratitude the kindly council and guidance of Professor Ernest Carroll Faust.

THE PATHOLOGIC TISSUE CHANGES PRODUCED BY SULFATHIAZOLE AND SULFATHIAZOLINE IN RABBITS*

JOHN A. KOLMER, M.D., PHILADELPHIA, PA.

WITH THE TECHNICAL ASSISTANCE OF ANNA M. RULE AND LORAINÉ GROSCHIN

AS SHOWN by Rake, Van Dyke and Corwin,¹ the toxicity of sulfathiazole and sulfapyridine, including the pathologic tissue changes produced by oral administration, varies in mice, rats, and monkeys. Thus sulfathiazole was found more toxic for mice than sulfapyridine with the production of more pronounced tissue changes in the spleen and kidneys. In rats, however, sulfapyridine was found more toxic than sulfathiazole, with the production of more marked lesions in the kidneys. The most pronounced pathologic tissue changes produced by both compounds were observed in the kidneys due to the deposition of crystals in the collecting tubules with the production of uroliths resulting in obstruction associated in some instances with necrosis of the tubular epithelium. The spleen probably ranked next in histologic injury, largely confined to the germinal centers of the Malpighian corpuscles with hyperplastic changes sometimes associated with pyknosis of the surrounding lymphoblastic cells and their ultimate disappearance. The liver was less frequently involved, with the production of cloudy swelling sometimes associated with fatty infiltration and hyaline necrosis, while the lungs, brain, and meninges have uniformly shown no gross or microscopic evidences of injury.

In view of the importance of including gross and microscopic examinations of the organs in connection with studies bearing upon the toxicity of chemotherapeutic compounds, we have thought it advisable to determine the chemopathologic effects of sulfathiazole in rabbits by oral administration of the compounds; also of 2-sulfanilyl-3-5 dihydrothiazole (sulfathiazoline), a new thiazole compound synthesized by Raiziss and Clemence,² and reported by Raiziss, Severac, and Moetsch³ as being of low toxicity for mice, rabbits, and dogs with therapeutic effects about the same as sulfathiazole in the treatment of experimental types II and III pneumococcal infections of mice and superior to sulfathiazole in the treatment of experimental staphylococcal infections of mice.

EXPERIMENTAL

Normal adult rabbits were employed. In order to insure accurate dosage each compound was administered orally in capsules twice daily (10:00 A.M. and 3:00 P.M.) in doses of 0.050, 0.100, and 0.200 Gm. per kilogram of weight,

*From the Research Institute of Cutaneous Medicine, Philadelphia.
Received for publication, July 3, 1941.

for ten days in succession (20 doses), four animals being used for each dose. These amounts totaled 0.1, 0.2, and 0.4 Gm. per kilogram daily, equivalent to 7 to 28 Gm. per 70 kg. of weight daily over a period of ten days.

TABLE I

PATHOLOGIC TISSUE CHANGES PRODUCED IN RABBITS BY THE ORAL ADMINISTRATION OF SULFATHIAZOLE

11	1,700	0.200	Survival	++	+	++	-
12	1,700	*	*	+	-	-	-

*Orally in capsules twice daily for ten days (20 doses).

† = No gross or microscopic changes from the normal.

‡ = Dilatation of the convoluted tubules with crystals; ++ = dilatation of the convoluted and collecting tubules with some necrosis of the tubular epithelium and the formation of cellular casts; congestion with blood in Bowman's capsules.

§ = Slight cloudy swelling; ++ = cloudy swelling and some fatty infiltration associated with slight peripheral necrosis.

¶ = Slight hyperplastic changes in the germinal centers of the Malpighian corpuscles; ++ = same with pyknosis of the surrounding lymphoblastic cells.

As shown in Tables I and II, all animals survived in the case of both compounds. There was no diarrhea or other clinical evidence of toxicity, except

some loss of weight in the case of the 8 animals receiving the largest doses of both compounds.

One week after the last dose all animals were sacrificed with macroscopic examination of the kidneys, liver, spleen, brain, spinal cord, and meninges. Sections were also prepared of these organs and subjected to microscopic examination.

RESULTS

The results are summarized in Tables I and II. It will be observed that neither compound in dose of 0.05 Gm. per kilogram twice daily showed any gross or microscopic evidences of injury of the organs studied. Both, however, have shown evidences of injury of the kidneys, liver, and spleen in dose of 0.1 Gm. per kilogram twice daily in the case of some animals which were more frequent, and sometimes more pronounced in those given 0.2 Gm. per kilogram twice daily. No gross or microscopic evidences of injury were found in the meninges, brain, and spinal cords of any of the animals, including those receiving the largest amounts of both compounds.

The usual changes in the kidneys consisted of slight enlargement with hyperemia due to dilatation of the convoluted or collecting tubules sometimes associated with tubular necrosis, cellular casts, and occasionally blood in the capsules of Bowman. The latter changes were found only in rabbits receiving the largest doses of both compounds.

The spleen was next in the frequency of tissue injury, and especially in the case of those animals receiving the largest amounts of both compounds. When involved, it was slightly enlarged and hyperemic, usually showing upon microscopic examination some hyperplasia of the germinal centers of the Malpighian corpuseles occasionally associated with congestion and with pyknosis of the surrounding lymphoblastic cells.

Both compounds in dose of 0.1 Gm. per kilogram twice daily showed only occasionally a slight cloudy swelling of the lobules of the liver. In the case of animals given 0.2 Gm. per kilogram twice daily, however, the degree of cloudy swelling was more pronounced, sometimes associated with fatty infiltration and slight necrosis of the peripheral cells of the lobules. There were no evidences, however, of injury or obstruction of the biliary ducts.

Like sulfapyridine, it would appear, therefore, that the main injury from sulfathiazole and sulfathiazoline is to be found in the kidneys, mainly due to obstruction of the tubules by crystals of the acetylated compounds. This may result in hydronephrosis, with enlargement of the organs which may progress in some instances to tubular necrosis.

Insofar as comparative results of the two compounds are concerned, it would appear that both are of extremely low toxicity for rabbits by oral administration and of about equal toxicity insofar as injury of the kidneys, liver, and spleen are concerned. As previously stated, neither compound showed any clinical, macroscopic, or microscopic evidences of injury of the central nervous system.

SUMMARY

1. Both sulfathiazole and sulfathiazoline are of low toxicity for rabbits by oral administration. Doses of 0.05, 0.1, and 0.2 Gm. per kilogram twice daily for ten days in succession (20 doses) were well borne with no fatalities.

2. Neither compound showed any macroscopic or microscopic evidences of injury of the meninges, brain, or spinal cord.

3. In dose of 0.05 Gm. per kilogram twice daily for 20 doses neither compound showed any gross or microscopic injuries of the kidneys, liver, or spleen.

4. Both compounds in dose of 0.1 and 0.2 Gm. per kilogram twice daily for 20 doses showed injury of the kidneys largely due to obstruction of the tubules by crystals of acetylated compounds, sometimes associated with tubular necrosis. These were the most frequent lesions observed. Both compounds were about the same in their production.

5. Both compounds in dose of 0.1 and 0.2 Gm. per kilogram twice daily for 20 doses were about equal in the production of injury of the liver, usually expressed as cloudy swelling sometimes associated with slight fatty degeneration and necrosis of the peripheral cells of the lobules.

6. Both compounds in dose of 0.1 and 0.2 Gm. per kilogram twice daily for 20 doses were about equal in the production of injury of the spleen, usually expressed by slightly hyperplastic changes in the germinal centers of the Malpighian corpuscles.

SULFANILAMIDE FOR THE TREATMENT OF GONORRHEA OF THE ANAL CANAL

ROBERT TURELL, M.D., NEW YORK, N. Y.

WITH THE TECHNICAL ASSISTANCE OF MIRIAM GREEN

IN A previous report¹ I emphasized that sulfanilamide administered orally is effective in the treatment of anal gonorrhea in the absence of localized suppurations or poorly draining sinuses. The plan of treatment consisted of the administration of 1 Gm. of sulfanilamide every four hours for 24 to 30 doses, which resulted in a concentration of from 6 to 11 mg. of free sulfanilamide in each 100 c.c. of blood. Thereafter, the drug was reduced to from 3 to 4 Gm. daily and was continued for a period of from four to five weeks. Berek,² using smaller amounts of sulfanilamide, has also noted good results in the treatment of this lesion.

The following case histories are illustrative of the effectiveness of sulfanilamide* therapy for gonorrhea of the anal canal.

Received for publication, July 8, 1941.

*Sulfathiazole or sulfadiazine is now preferred.

CASE 1.—A 34-year-old white woman was seen on March 22, 1938, with intermittent discomfort of the anus and occasional sharp pain on defecation. About three years before, she had received intensive treatment for genital gonorrhea. Proctologic examination now revealed a superficial fissure with a deep, reddened, infected, and edematous crypt of Morgagni on the posterior arc of the anal canal. Material obtained from the interior of the involved crypt with the aid of a bent platinum wire loop (which was inserted through small anal speculum) revealed numerous leucocytes and gram-negative intracellular diplococci resembling gonococci. The sedimentation time was above normal. Six grams of sulfanilamide were given daily by mouth for five days; 4 Gm. daily for the succeeding eleven days, and thereafter 3.3 Gm. daily for a period of over five weeks. Instrumental examination was avoided for a period of seventeen days. At the end of that time, as well as during subsequent re-examinations, no gram-negative intracellular diplococci were observed. The patient remained cured when last seen on May 12, 1939.

CASE 2.—A 30-year-old white woman had received an undetermined amount of sulfanilamide by mouth (the exact amount of the drug taken could not be ascertained) and azosulfamide solution parenterally in June, 1937, for the treatment of genital gonorrhea. On Dec. 16, 1938, she had complained of sharp shooting pains in the muscles of the thighs and in various joints. The physical examination was normal, except for reddening, injection, and tenderness of the anal canal and lower rectum. Thin mucopurulent material obtained from an anteriorly situated inflamed crypt of Morgagni showed gram-negative intracellular diplococci. On Sept. 29, 1939, tenderness in the region of the right Bartholin gland was observed, which was relieved by external heat. On Jan. 15, 1940, the patient again complained of pain in the muscles of the left thigh; this persisted intermittently in spite of conservative therapy (hot hip baths, salicylates). Reexamination on May 1, 1940, showed injection of the anal canal. A Gram stain of the material obtained from the interior of an anteriorly situated crypt of Morgagni again revealed gram-negative intracellular diplococci and many leucocytes. Sulfanilamide therapy was begun on May 25, giving 4.5 Gm. daily for the first four days, and 2 to 4 Gm. daily thereafter until a total of 50 Gm. of sulfanilamide had been taken. Re-examination of the anal canal on June 14, and again on July 22, showed a few leucocytes per field; no gram-negative intracellular diplococci were found. The patient has remained symptom-free to date.

COMMENT

These results show that sulfanilamide appears to be effective in the treatment of uncomplicated gonorrhea of the anal canal. The plan of sulfanilamide therapy employed has been found safe for the patient who is under daily medical supervision.

Gonorrheal proctitis is "a disease one sees only if one looks for it" (Jullien-Martin). It is realized that gonococci may remain alive and virulent for years in the anal structures,³ and that reinfection of the genital tract may occur from the anal focus.⁴⁻⁷ Except for cases of pederasty, contamination in girls and women is believed to take place during the act of defecation, when a simultaneous expulsion of gonococci-laden discharge from the vagina and a normal eversion of the anal mucous membrane occur. Suitable biologic conditions for the inception and maintenance of gonorrheal infection are furnished by the transitional epithelium of the intermediate zone of the anal canal,⁶ the anal ducts, and the crypts of Morgagni.⁸ The infection may spread to the deeper perianal and perirectal structures through the anal ducts which lead to racemose multiglandular structures located in the perianal tissues, and penetrate the sphincter muscles, especially the internal sphincter,⁹⁻¹¹ producing suppurations and subsequent fistulas.

SUMMARY

Sulfanilamide has been successfully employed in the treatment of uncomplicated gonorrhea of the anal canal.

876 PARK AVENUE

BACTERIUM COLI ANAEROGENES SEPTICEMIA*

REPORT OF A CASE WITH RECOVERY

H. JACOB FLAX, M.D., AND FREDERICK W. SHAW, M.D.
RICHMOND, VA.

THE incidence of infection with *Bacterium coli anaerogenes* is very small, and only a few cases of septicemia produced by this organism have been reported. Lembke¹ in 1896 originally described this organism which he recovered from dog dejecta and named it *B. coli anaerogenes*. In 1900 Migula,² in his *System of Bacteriology*, called it *Bacterium lembkei*. Apparently, the same organism was reported by Castellani³ in 1907 as *Bacillus ceylonensis*; he recovered it in four cases of a febrile disease in Ceylon. In two of these cases he obtained the organism by blood culture. Wilson⁴ the next year isolated such an organism in six cases of cystitis. Houston⁵ in 1906, and Swan⁶ in 1909, found similar bacteria in the stools of healthy persons. In 1906 Dudgeon⁷ isolated a pathogenic bacillus of this type from the secretion of an enlarged prostate gland. Also in this year similar organisms were found by Cathcart⁸ among the flora of "blown" tins of preserved food. Nabarro⁹ in 1923 isolated from cases of epidemic and other forms of diarrhea, which occurred mainly in children, a group of bacteria which he called *B. coli anaerogenes*. However, some of these strains were later shown by Kerrin¹⁰ in 1928

*From the Stuart Circle Hospital and the Department of Bacteriology and Parasitology, Medical College of Virginia, Richmond.

Received for publication, July 16, 1941.

to be identical culturally and serologically with the *B. dysenteriae* Sonne. Bamforth¹¹ in 1923 concluded in his studies that it was serologically related to some other members of the coli-dysentery group, but not to the Sonne organism. In 1939 Savino and co-workers¹² demonstrated the presence of bacteria of the *Coli anaerogenes* group in gray rats caught in Buenos Aires.

The organism under discussion is known by several other names:¹³⁻¹⁴ *Bacterium anaerogenes chester*, *Bacillus belfastiensis*, *Castellanus coli anaerogenes*, *Escherichia anaerogenes*, and *Eberthella belfastiensis*. *Bacterium coli anaerogenes*, according to Bergey,¹³ is a small, nonmotile, gram-negative rod. On agar the growth is slow, producing circular, grayish-white, smooth colonies on plates, and a grayish-white streak on the slant. There is no liquefaction in the gelatin stab; litmus milk is turned acid and coagulates; broth is made turbid; a brown growth is produced on potato, and indol is formed. Acid, but no gas, is observed in dextrose, levulose, arabinose, lactose, maltose, sucrose, raffinose, mannitol, sorbitol, and isosorbitol; no acid from inulin, salicin, dulcitol, glycerol, or adonitol. It is a facultative anaerobic, growing best at 37° C., and is found in the intestinal tract of man where it may produce symptoms that resemble those of typhoid fever. Ford¹⁴ stated that *B. coli anaerogenes* is virulent to guinea pigs: one cubic centimeter of a twenty-four-hour broth culture will produce enteritis, peritonitis, congestion of the liver and lungs, and cloudy swelling of the kidneys.

REPORT OF CASE

A white woman, aged 47 years, was admitted to Stuart Circle Hospital with menstrual bleeding of three months' duration. Pelvic examination revealed a large tumor, which filled the right side of the pelvis. A diagnosis of multiple fibroids of the uterus was substantiated at operation two days following admission, but there was also found a large intraligamentous ovarian cyst of the multilocular type which filled the pelvis. The left ovary appeared normal. Both tubes were in a state of hydrosalpinx. The surgery undertaken consisted of a right oophorectomy, supravaginal hysterectomy, bilateral salpingectomy and a prophylactic appendectomy; the abdomen was closed without drainage. The patient left the operating room in good condition.

The postoperative course was marked by considerable nausea and vomiting for which the patient received parenterally solutions of dextrose and normal saline. Abdominal distention was relieved by a continuous suction apparatus attached to an inlying duodenal tube and by the low gravity method of colonic irrigation. During the first postoperative day (beginning twenty-four hours after operation) the temperature rose to 100° F. and on the second day it became suddenly elevated to 105.4° F. A severe chill was experienced, and the pulse rate reached 120 per minute. That night, and the following day, the temperature gradually came down to 100° F. On this, the third postoperative day, a transfusion of 500 c.c. of blood was given by the direct method. Blood was taken for a culture, and this was repeated the following morning. From both of these there was recovered a small, nonmotile, gram-negative rod, which could not be readily identified. During the next two days the patient had repeated chills at which times the temperature went as high as 104° F.

Sulfanilamide, 15 grains every four hours, was started on the fifth postoperative day. The night of the sixth day the patient was suddenly stricken with an attack of dyspnea, chills, and a temperature of 105° F. She appeared cyanotic; the heart action was accelerated, and the blood pressure increased from systolic 150 to 200 mm. Hg in less than an hour. The heart and lungs were found to be clear to auscultation and percussion. Since a pulmonary embolus was suspected, the patient was placed in an oxygen tent. Her dyspnea was benefited and her color returned to normal under oxygen therapy and was maintained for two

days. However, the chills and fever (maximum 105° F.) continued despite all therapy. A pelvis pyelophlebitis was next considered as a possible cause of these symptoms. Sulfathiazole was then given orally instead of sulfanilamide, but this was also discontinued in thirty-six hours, after 120 grains were ingested without any demonstrable relief. Although some pneumonitis was seriously suspected, no definite lung findings could be detected, except for a few hypostatic râles in both bases. A roentgenogram of the chest was not taken. On the eighth day a second transfusion of 500 c.c. of whole blood was given without any apparent improvement in the patient's condition. The next day a widespread herpes labialis became evident, and this caused the patient much discomfort. The chills and fever (maximum 103.5° F.) continued with varying intensity until the thirteenth postoperative day. On the fourteenth day the stitches were removed, revealing a well-healed wound free of infection. The patient improved gradually under symptomatic treatment and was discharged as cured on the thirty-second day following her operation.

Throughout the period of infection the leucocyte count remained relatively low, between 8,000 and 10,000 cells per cubic millimeter, and reached 14,700 cells per cubic millimeter only once—on the tenth day. The hemoglobin on admission was 67 per cent (Newcomer), and during the postoperative period it dropped to 45 per cent; it finally reached 58 per cent before the patient left the hospital. The sedimentation index on the ninth postoperative day was 24 mm. in sixty minutes. The urine contained albumin in varying amounts, from a faint trace to four plus on the eighth postoperative day; it finally became negative on the fifteenth day. Five days following the patient's discharge, a report was received from the Virginia State Board of Health, which stated that the organism isolated from the blood culture was classified as belonging to the para-colon group, culturally resembling *Bacterium coli anaerogenes* in that it failed to produce gas in certain carbohydrates. A similar report was received through the Virginia State Board of Health from the New York State Board of Health and was verified by one of us (F. W. S.). Two months following her discharge, the patient returned to the hospital for a physical examination, at which time blood for agglutinations was taken. A positive titer of 1:1,500 dilution against *Bacterium coli anaerogenes* was discovered.

COMMENT

The focus of infection in this case was not determined. Since the *Bacterium coli anaerogenes* is an inhabitant of the intestinal tract in some people, it would seem logical to assume that the primary focus of infection was in the lymphatic vessels leading from the intestinal canal. From here, because of lowered resistance following the operation and the initial anemia which was still further lowered owing to the loss of blood during the operation, the bacteria might readily have spread through the lymphatic channels into the blood stream where a secondary focus could have been set up in the congested pelvic veins resulting in pyelophlebitis, and finally a septicemia. The patient was so overwhelmingly toxic throughout her febrile course that she was not expected to live on several occasions. Neither the blood transfusions nor the sulfonamide preparations (sulfanilamide, 90 grains, and sulfathiazole, 120 grains) seemed to have any therapeutic effect in shortening the course of the infection.

THE ANTAGONISM BETWEEN ANESTHETIC STEROID HORMONES AND PENTAMETHYLENETETRAZOL (METRAZOL)*

HANS SELYE, M.D., PH.D., F.R.S.C., MONTREAL, CANADA

IT IS well known that analeptic, convulsive drugs, such as picrotoxin or pentamethylenetetrazol (metrazol), counteract the narcotic effect of certain anesthetics, especially the barbiturates and tribromethanol (avertin). Since the relevant literature has recently been reviewed in detail by Beecher,¹ it will not be necessary to discuss it here. It has also been found that some steroid compounds, especially those endowed with hormone action, act as anesthetics if given intraperitoneally or intravenously, that is to say, if administered in a manner which permits the rapid establishment of a high steroid concentration in the blood.²⁻⁷ This type of anesthesia produced by naturally occurring hormonal substances proved very satisfactory for use in laboratory animals, since the safety margin between the anesthetic and lethal dose is comparatively great, and the anesthesia is accompanied by very pronounced muscular relaxation. Steroid anesthesia is especially suitable when long-lasting narcosis is required, but it cannot be used satisfactorily in cases in which a deep anesthesia of short duration is needed because a dose sufficient to produce deep anesthesia, at any one time in the course of its action, usually maintains the state of narcosis for several hours. It appeared of interest, therefore, to establish whether pentamethylenetetrazol could arouse animals from the hormone anesthesia whenever desired.

EXPERIMENTAL

In our first experiment young male albino rats were divided into three equal groups. In the first two groups deep anesthesia was produced by the intraperitoneal administration of desoxycorticosterone acetate (D.C.A.) in peanut oil solution. Thirty minutes after the injection of this hormone, when all animals were in complete narcosis, one of the groups pretreated with desoxycortico-

This investigation was supported by a grant from the Committee on Research in Endocrinology, National Research Council.

Received for publication, July 13, 1941.

sterone acetate and a group of controls not pretreated received a subcutaneous injection of pentamethylenetetrazol in aqueous solution. Table I summarizes the results of this experiment.

TABLE I

ANTAGONISM BETWEEN DESOXYCORTICOSTERONE ACETATE AND PENTAMETHYLENETETRAZOL

TREATMENT	NO. OF ANIMALS	AVERAGE BODY WEIGHT IN GM.	AVERAGE DEGREE OF ANESTHESIA	CONVULSIONS	DEATHS
Desoxycorticosterone acetate 4 mg. per 0.2 ml.	7	35	+++	0	0
Pentamethylenetetrazol 5 mg. per 0.2 ml. and Desoxycorticosterone acetate 4 mg. per 0.2 ml.	7	36	Trace	0	1
Pentamethylenetetrazol 5 mg. per 0.2 ml.	7	36	0	+++	7

Our data clearly indicate that pentamethylenetetrazol antagonizes the anesthetic action of desoxycorticosterone acetate. It should be stated that this is not merely a prevention but an actual interruption of the anesthesia, since the animals in the group in which desoxycorticosterone acetate was administered before the pentamethylenetetrazol, were deeply anesthetized at the time the latter drug was administered, yet five minutes later they were on their feet again and showed only slight traces of a narcosis, such as uncertainty of their movements and unwillingness to run about. It is even more interesting to note that in the condition of hormone anesthesia, otherwise lethal doses of pentamethylenetetrazol did not kill a single animal and indeed prevented even the appearance of convulsions. The animals not pretreated, which died from pentamethylenetetrazol overdosage, developed very pronounced lung edema. This was also prevented by desoxycorticosterone acetate. Thus we can see that the antagonism between desoxycorticosterone acetate and pentamethylenetetrazol is mutual.

TABLE II

ANTAGONISM BETWEEN PROGESTERONE AND PENTAMETHYLENETETRAZOL

TREATMENT	NO. OF ANIMALS	AVERAGE BODY WEIGHT IN GM.	AVERAGE DEGREE OF ANESTHESIA	CONVULSIONS	DEATHS
Progesterone 5 mg. per 0.2 ml.	10	45	+++	0	0
Pentamethylenetetrazol 3 mg. per 0.2 ml. twice and progesterone 5 mg. per 0.2 ml.	12	47	0	0	0
Pentamethylenetetrazol 3 mg. per 0.2 ml. twice	10	46	0	+++	10

A second series of experiments was performed under very similar conditions in order to establish whether progesterone, which is also a potent anesthetic when given by the intraperitoneal route, would likewise prove to be an antagonist of pentamethylenetetrazol. The results of this experiment are summarized in Table II.

In this experiment pentamethylenetetrazol was administered in two injections. The first dose of 3 mg. aroused the animals from progesterone anesthesia

for a period of about fifteen minutes, after which they began to relapse into narcosis. Permanent awakening was produced, however, by a second dose of 3 mg. The controls not pretreated showed marked convulsions even under the influence of the first injection of pentamethylenetetrazol, and one animal died from lung edema. The second injection produced fatal lung edema in all the remaining controls.

DISCUSSION

Our experiments indicate that pentamethylenetetrazol can interrupt steroid anesthesia so that in this respect the narcosis produced by progesterone and desoxycorticosterone acetate resembles that elicited by barbiturates or tribromethanol. It is also evident that the convulsions and the fatal lung edema usually produced by lethal doses of pentamethylenetetrazol are very effectively prevented by steroid anesthetics. In this respect the steroids again resemble the barbiturates which, according to Maloney⁸ likewise raise resistance to convulsive drugs. The anesthetic steroids and pentamethylenetetrazol may be regarded as potent mutual antagonists of each other's pharmacologic actions.

SUMMARY

Experiments on young albino rats indicate that the anesthesia produced by the intraperitoneal administration of steroid hormones (progesterone or desoxycorticosterone acetate) can be interrupted at will by pentamethylenetetrazol (metrazol). Conversely, fatal doses of pentamethylenetetrazol are readily tolerated without causing either convulsions or lung edema by rats receiving suitable doses of anesthetic steroid hormones.

I am indebted to Doctors Gregory Stragnell and Erwin Schwenk, of the Schering Corporation, New Jersey, for the progesterone and desoxycorticosterone acetate, and to Dr. Fred B. Western, of the Bilhuber-Knoll Corporation, Orange, N. J., for the metrazol used in these experiments.

CLINICAL CHEMISTRY

PLASMA PROTEINS IN THERAPEUTIC FEVER*

ISRAEL KOPP, M.D., BOSTON, MASS.

CHANGES in the plasma proteins have been observed in various infections and have consisted in the main of a reduction in the albumin and increases in the globulin and fibrinogen.¹⁻⁵ A study of the factors responsible for the edema occasionally resulting during the course of therapeutic malaria has revealed also rather marked changes in the plasma protein fractions.⁶

The present communication is concerned with the changes in the plasma proteins of nine patients to whom malaria, artificial fever, and typhoid vaccine fever were administered for treatment of syphilis of the central nervous system.

Material.—Nine male patients, ranging from 40 to 51 years of age, were hospitalized for fever therapy of general paresis. Physical and laboratory procedures revealed no other complicating diseases.

Methods.—Six patients were given tertian malaria only; one patient, artificial fever and malaria; one patient, tertian and quartan malaria and typhoid vaccine fever; and one patient, typhoid vaccine fever.

Malarial therapy was administered by the intravenous injection of 3 to 4 c.c. of malarial blood. The incubation period ranged from one to seven days. True tertian or quartan fever was not encountered, the fever being of the mixed or quotidian type. Malaria was terminated in seven patients after 10 to 13 paroxysms by the daily administration of 30 grains of quinine sulfate for one week. One patient experienced only four paroxysms of fever above 104° R. after two inoculations with tertian malaria and one with quartan malaria.

Typhoid vaccine fever was induced by the intravenous injection of increasing doses of mixed typhoid vaccine (*Bacillus typhosus*, paratyphoid A and B), administered usually three times a week. One patient was given eleven bouts of fever, and a second, sixteen bouts of fever.

Artificial fever was induced by means of the inductotherm and humidified air cabinet. Body temperature was raised to level of 105° to 106° R., and prolonged for two hours at each treatment. A total of fourteen treatments was given to one patient over a thirty-eight-day period.

The daily hospital diet consisted roughly of the following: protein 80 Gm., carbohydrate 315 Gm., and fats 85 Gm. When malarial fever was present and food intake diminished, the daily diet was reinforced by the addition of at least one quart of milk and two eggs (protein 42 Gm., carbohydrate 50 Gm., and fat 52 Gm.). After termination of the malarial fever the patient was given a high vitamin and high caloric diet and 20 grains of ferrous sulfate daily.

*From the Boston Psychopathic Hospital, Dr. Harry C. Solomon, Chief of Therapeutic Research.

Received for publication, January 26, 1942.

Sodium chloride was administered to seven patients during fever therapy as a result of the observations of Judd,⁷ who felt that patients were better able to tolerate malarial therapy when 10 grains of this salt were given on those days when body temperature rose above 103° R. Larger doses, ranging from 3 to 6 Gm. daily, were given to our patients. The sodium chloride was omitted when therapeutic fever was terminated with the exception of one patient, who continued to receive 6 Gm. daily for one week.

Studies were made of the plasma proteins, hematocrit, red blood cell, white blood cell, and hemoglobin (Sahli) levels on venous blood samples in the resting state. The total protein was obtained by the determination of the total nitrogen by a modified micro-Kjeldahl.⁸ The nonprotein nitrogen was determined by the method of Folin and Wu,⁹ and the difference between the total nitrogen and the nonprotein nitrogen was multiplied by the factor 6.25 to give the total protein. The albumin and globulin were determined by the sodium sulfate method of Howe.¹⁰ The fibrinogen was determined by precipitation as fibrin by the method of Cullen and Van Slyke,¹¹ and the nitrogen was determined by the difference between the total nitrogen and the nitrogen in the fibrinogen-free filtrate. In the last series of studies the fibrinogen was precipitated as above, and the nitrogen content of the fibrin was determined directly. Potassium oxalate in the concentration of 2 mg. per cubic centimeter was used as the anticoagulant.

RESULTS

Malaria.—Intravenous malarial inoculation was followed in seven of eight patients by a slight or a marked and rapid fall in albumin during the incubation period and before any fever occurred. One patient experienced no fever for thirteen days following his first inoculation with tertian malaria. Albumin fell from 4.82 to 4.01 Gm. during this period. A second patient showed a reduction in albumin from 5.1 to 4.3 Gm. three days after inoculation with tertian malaria and one day before any fever resulted. Only one patient showed an increase in albumin, from 4.37 to 4.70 Gm. Globulin and fibrinogen showed fluctuating changes during the incubation period; the changes in globulin ranging from a reduction of 25 per cent to an increase of 45 per cent, and those of fibrinogen from a fall of 50 per cent to an increase of 300 per cent.

The onset and recurrence of the malarial fever were accompanied by a rapid, progressive, and marked reduction in albumin (Chart 1). The reductions in albumin ranged from 30 to 40 per cent, falling from prefebrile values of 3.67 to 5.1 Gm. (average 4.53 Gm.) to levels of 2.23 to 3.25 Gm. (average 2.89 Gm.). Globulin fluctuated considerably during malarial fever but showed no consistent trend. Increases of 11 to 65 per cent occurred in seven patients. In the eighth patient globulin values throughout malaria remained below the original level of 3.03 Gm., with a maximum reduction of about 32 per cent. Fibrinogen also showed no consistent trend during active malaria. Of the eight patients, one showed significant reductions as much as 50 per cent below prefebrile values; two, an increase and then a progressive fall below initial levels; two, fluctuations above and below original levels; and three, similar values or an increase.

The fall in albumin ceased immediately or within a few days after the administration of quinine and the cessation of malarial fever (Chart 1). Albumin values then rose rapidly, reaching prefebrile levels in six patients in fourteen to twenty-four days. In one patient the prefebrile value was reached only after seventy days. The malarial fever of the eighth patient ceased spontaneously, and no quinine was administered. Sixteen days after the last febrile reaction albumin differed only little from the lowest level obtained during

Chart 1.—Plasma proteins in therapeutic malaria.

malarial fever, namely, 3.6 and 3.23 Gm. Globulin remained increased for only a short period after malarial fever was terminated, and then fell slowly to reach prefebrile values in ten to eighteen days. The fibrinogen values returned to original levels fairly rapidly, in about seven days. Fibrinogen and globulin values of the patient who received no quinine therapy remained elevated even after two weeks' time.

Typhoid Vaccine Fever.—Only slight fluctuations in albumin, ranging from a fall of 9 per cent to an increase of 13 per cent, occurred in two patients to whom 11 and 16 bouts of typhoid vaccine fever were administered over periods of twenty-four and thirty-nine days, respectively (Chart 2). This is in marked contrast to the severe reductions of 30 to 40 per cent which were found during malaria. Globulin also showed fluctuations in both directions but of a smaller magnitude than in malaria. Both albumin and globulin values when treatment was terminated approximated those present before therapy. Fibrinogen in-

Chart 2.—Plasma proteins in fever induced by typhoid vaccine.

Chart 3.—Plasma proteins in fever induced by artificial means (inductotherm).

creased in both patients as a result of typhoid vaccine fever, in one 33 per cent and in the second 40 per cent. In the former fibrinogen returned to its original level within seven days after treatment ceased, but in the latter fibrinogen remained increased, more than 200 per cent, as late as thirty-one days thereafter.

Artificial Fever.—Repeated administration of artificial fever resulted in only a slight reduction of the albumin, the maximum fall being 13 per cent below the prefebrile level (Chart 3). The final value, however, after a course of 14 treatments, over a thirty-eight-day period, differed only little from that before treatment. The changes in globulin fluctuated equally, about 12 per cent, in both directions. Fibrinogen values during therapy tended to fall as much as 30 per cent below prefebrile levels but remained within normal limits. Three weeks after therapy was terminated the patient was inoculated with tertian malaria and experienced a 30 per cent reduction in albumin as a result of malarial fever (Chart 1).

DISCUSSION

The changes in the plasma protein fractions as a result of therapeutic malaria consist of a marked reduction in albumin, fluctuating changes in the globulin, and generally increased fibrinogen. Similar changes have been found in hookworm disease accompanied by severe anemia,¹² less marked changes in tuberculosis,¹³ and other infections.⁴ Lloyd and Paul,¹ by refractometric methods, found marked reductions in albumin and slight falls in the total globulin in patients with malignant and benign tertian malaria. The degree of albumin reduction seemed to parallel the intensity of the infection, greater reductions occurring in patients with high temperatures than in those with subfebrile infections. Similar changes were found by these authors in patients with typhoid fever. The rise in albumin to normal was said to be more rapid following malaria than typhoid fever, and was attributed to the presence of a specific drug, quinine, for the treatment of the former. It is possible that the absence of quinine therapy in one of our patients may be responsible for the only slight rise of albumin from its lowest level of 3.23 Gm. during malaria to 3.6 Gm. sixteen days after fever spontaneously ceased, and for its failure to rise to the original level of 4.82 Gm. during this period. Lloyd and Paul¹ observed several untreated patients with malaria in whom parasites were present in the peripheral blood stream but no fever was present. All showed the characteristic protein changes, a reduction in albumin, and variable changes in globulin.

The changes in the serum protein fractions as a result of malaria were much more pronounced than those found in fever produced either by mixed typhoid vaccine or by artificial means. This may be due to (a) the rapid recurrence and greater amount of fever; (b) the presence of blood destruction; and (c) the presence of an infectious process in malaria. Active malarial fever required from ten to seventeen days in contrast to thirty-eight days for artificial fever, and twenty-four and thirty-nine days for typhoid vaccine fever. The paroxysms of malaria were usually of daily occurrence, whereas treatment in the other types of fever was given two or three times each week. The total amount of fever above 100° R. was also greater in malaria, an average of one

hundred twelve hours, in contrast to eighty-seven hours and fifty-five hours for typhoid vaccine fever and artificial fever, respectively. On the other hand, the plasma protein changes of the eight patients given malarial therapy differed only little, regardless of the number and frequency of the paroxysms, the maximum temperature experienced, the total amount of fever above 100° R., or the total duration of malarial therapy. The number of malarial paroxysms (temperature 103° R., and above) ranged from four to thirteen, the total amount of fever above 100° R. from seventy-one to one hundred fifty-four hours, the duration of malaria from fourteen to twenty-two days from the time of inoculation, and that of actual malarial fever from ten to seventeen days. Despite these wide variations the percentage reduction in albumin in the eight patients was nearly the same, namely, from 30 to 40 per cent. One patient after three malarial inoculations experienced only four paroxysms and a total of one hundred ten hours of fever above 100° R. over a twenty-nine-day period, whereas a second patient after one inoculation experienced nine paroxysms and a total of seventy-one hours of fever above 100° R. over a ten-day period. Notwithstanding such differences the reduction in albumin in the former was 34 per cent and in the latter only 41 per cent. Tareev and Gontaewa,¹⁴ however, contrary to our own findings, observed that the reduction in albumin in malarial infections paralleled the clinical severity. They observed more marked reductions in induced malaria than in the naturally acquired form; these were attributed to the more rapid recurrence of fever in the former type.

The rapidly induced anemia is a prominent feature of malaria, and one questions whether this factor plays any part in the low serum albumin levels obtained. Low serum albumin values have been found in anemias, both primary and secondary, but have been attributed to the accompanying malnutrition.⁴ These anemias, however, are of a chronic type. The fall in albumin during malaria cannot be attributed to red cell destruction, since both Láng¹⁵ and Bodansky and co-workers¹⁶ found no change in the serum albumin of dogs in which anemia was produced by the administration of phenylhydrazine and acetyl phenylhydrazine, respectively.

The liver has been considered by some as the main source of albumin and the source of much of the globulin.¹⁷ It is the sole source of fibrinogen. It has been shown that infections impair the manufacture of plasma proteins in the liver, despite the fact that protein intake may be maintained.¹⁸ This may well explain the marked reductions in serum albumin (37 and 39 per cent) in two patients who exhibited a "ravenous appetite" throughout malaria yet showed as marked a reduction in albumin as a third patient whose food intake was poorer and whose weight loss was greater (10 pounds in contrast to 4.5 and 2.5 pounds). It does not explain the increases in globulin which were obtained at these times unless one predicates as Loeb² has that albumin and globulin are formed by different cells in the liver. Experimental observations reveal that only a small portion of protein is stored in the liver as preformed plasma protein.¹⁷ Thus, not only is the liver unable to synthesize new plasma protein from exogenous material, i.e., food, because of an infection, but it is also unable to convert its stored protein into plasma protein because of a disturbance in the plasma protein-forming mechanism of the liver. The rapid rise in albumin practically immediately after the malaria was terminated, and at a

time when food intake remained essentially unchanged, would tend to verify the importance of infection in impairing serum protein production in the liver. The absence of an infectious process in fever induced by typhoid vaccine and artificial methods may well explain the slight and insignificant fluctuations in albumin which occurred during these types of therapy. In support of this is the finding of a marked reduction in albumin in typhoid fever,¹ though the very limited food intake at this time is an important factor not to be overlooked.

The low serum albumin values of severe infections have been attributed by some to the accompanying malnutrition,⁴ i.e., insufficient protein intake. Continuous wasting due to malnutrition causes a steady fall in albumin.¹⁹ It is difficult to evaluate true weight loss in patients undergoing malarial therapy, since subclinical fluid retention may well have occurred during its course because of low albumin values.⁶ The weight losses obtained ranged from 1 to 10 pounds and, though they may indicate insufficient total caloric intake, they do not imply an inadequate protein intake. One patient showed a weight gain of 2.5 pounds during malarial therapy at a time when albumin had been reduced 34 per cent, from 4.82 Gm. to 3.23 Gm. No clinical evidence of edema was seen. It is possible that the protein intake of our patients, adequate for the patient when in normal health, was insufficient during malarial fever to supply the increased protein demands when fever was present. It does not appear logical to attribute the rapidly falling albumin during malaria to malnutrition, since the fall in albumin appeared early and even before the malarial fever occurred. This is well shown by the progressive fall in albumin from 4.82 to 4.01 Gm. in one patient over a thirteen-day afebrile incubation period, and the rapid fall in albumin from 5.1 to 4.3 Gm. in a second patient three days after malaria inoculation and one day before fever occurred. Sufficient protein storage in the liver and muscles should be present and readily available at this time to supply the body's needs,¹⁷ especially since the dietary intake of each patient prior to and during the incubation period of malaria had been adequate. The albumin values of the eight patients were within normal limits prior to the induction of the malaria, with the exception of that of one patient who showed a low, unexplained level of 3.67 Gm. Little or no loss of serum albumin occurred in our patients by way of the kidney, since urine examinations infrequently revealed more than a very slight trace of albumin, and kidney function is relatively normal in uncomplicated malaria.²⁰

The increases in globulin as a result of therapeutic fever were most marked during malaria, less marked during typhoid vaccine fever, and least marked during artificial fever. An increase in globulin occurs frequently as a result of infections, and is said to parallel the severity of the infection.⁵ The increase in globulin during infections has been considered as mainly responsible for the high plasma protein levels found at these times.²¹ A close association of certain antibodies with particular globulin fractions has been noted,^{2, 4} as is seen by an increase in globulin following the subcutaneous injections of mixed typhoid vaccine. The destruction of red blood cells, as by the production of experimental anemias in dogs, has also resulted in an increase in globulin.¹⁵ The greater increases in globulin during malaria may, therefore, be attributed to the presence of an infection and the destruction of red blood cells. Since

the reticulo-endothelial system participates in the regeneration of globulin,²¹ one wonders whether stimulation of this system, said to occur during malaria,²² may also play some part.

The fibrinogen level during health is relatively constant for any one individual and is not altered by short periods of fasting or by food ingestion.²³ Injury to the liver causes the blood fibrinogen to fall rapidly, the degree of fall paralleling somewhat the severity of liver injury. Regeneration and repair of liver tissue result in a return of the fibrinogen values to normal.¹⁷ Injury to other tissues (as in infections) in the absence of liver injury is followed by an increase in fibrinogen.^{17, 23} Fibrinogen values obtained on our patients imply that liver damage occurs as a result of malaria. Values fell considerably, even during the incubation period of malaria, in one patient from 520 mg. to 260 mg. Fibrinogen values obtained on this latter patient during malarial fever remained much below the prefebrile level. The falling values obtained on two additional patients as the malarial fever recurred also point to increasing impairment of liver functions. Clifford has stated that malaria always results in liver damage.²⁴ Studies of liver function following malarial therapy at this clinic indicate that liver damage of a temporary nature does occur.²⁵ It is significant that the course of the falling albumin during malaria did not differ in the three patients with probable liver damage from the remaining 5 patients who exhibited no significant reductions in fibrinogen. The rapid rise of albumin following the termination of the malaria would indicate that plasma protein regeneration occurs rapidly after the termination of the infection regardless of the fibrinogen values and probable liver damage. It would also tend to stress the importance of the infectious process per se in interfering with the production of albumin. The increases in fibrinogen as a result of typhoid vaccine fever have been observed by others.²³ It should be stressed, however, that fever per se is probably not the cause of the abnormally increased fibrinogen found in many febrile diseases.²³ Increases in fibrinogen occurred in our patients even during the incubation period of malaria when no fever had occurred. The fall in fibrinogen from 380 mg. to 270 mg. in one patient after eight artificial fever treatments (Chart 3) is difficult to explain. This value was obtained at a time when albumin also had fallen to its lowest level. Though liver function studies have not been carried out in this clinic during artificial fever therapy, occasional instances of jaundice have been observed. Significant pathologic changes in the liver have been found when fever therapy has terminated fatally.

CONCLUSIONS

1. Fever produced by inoculation malaria results in marked changes in the plasma proteins consisting of a rapid and marked drop in albumin, and fluctuations in globulin and fibrinogen. Termination of malarial fever by quinine is followed by a rapid return to normal values.

Fever produced by typhoid vaccine and artificial means (inductotherm) causes only slight fluctuations in the plasma protein fractions.

2. The more marked reduction in albumin during malaria may be due in part to the greater amount and the more rapid recurrence of fever. The in-

fectious process per se present in malaria is probably the most important factor interfering with the synthesis of albumin in the liver even though dietary intake appears adequate.

3. The increases in globulin are greater during malaria than during fever induced by typhoid vaccine or artificial means. The presence of an infectious process and the destruction of red blood cells during malaria account for the greater increases in globulin.

4. Fibrinogen is increased during malaria and typhoid vaccine fever. The progressive fall in fibrinogen, which occasionally occurs during malaria, indicates probable liver damage.

LABORATORY METHODS

GENERAL

"ELECTROCARDIOGRAPHIC ANAGRAMS"*

A METHOD OF TEACHING ELECTROCARDIOGRAPHY

JOSEPH E. F. RISEMAN, M.D., BOSTON, MASS.

THE model described in this report has been used with considerable success in teaching electrocardiography in a simple logical manner. In principle it consists of cards of uniform sizes on which portions of P, Q, R, S, and T complexes are drawn to scale in such a fashion that the cards may be joined together or superimposed one upon another to form any of the more common electrocardiographic patterns. If only one portion of the electrocardiogram is changed at one time, the student soon learns to recognize the abnormality and to interpret its significance in a logical fashion. This method eliminates the necessity of textbook descriptions or patterns; it enables the student to lose some of his fear of electrocardiograms; and it allows him to test himself by creating characteristic patterns.

DIRECTIONS FOR PREPARING MODEL

Models of any size can be made. For classroom work, electrocardiographic complexes drawn to a scale of $\frac{1}{2}$ inch for each millimeter of amplitude or each 0.4 seconds of duration have been found most serviceable; these are drawn on cards 10 inches high and 3, 6, or 12 inches wide. A complete set consists of 90 cards; 16 cards, 10 by 12 inches; 14 cards, 10 by 6 inches; and 60 cards, 10 by 3 inches.

Materials.—The following materials are necessary; 38 pieces of heavy white noncurling cardboard, each measuring 10 by 12 inches; two sheets of transparent cellulose acetate, approximately 10 by 12 inches; ruler; pencil; soft wax pencil; black poster paint; drawing pen; camel's hair paint brush; scissors; sharp knife or razor blade.

Method.—With a pencil draw two lines, 1 inch apart and 12 inches long, through the center of each card; this represents the electrocardiographic base line, or a string shadow 2 mm. wide. On four of these cards this base line is inked in. Two cards are left intact (Fig. 1 *a*). One card is cut in two to form two models, 10 by 6 inches each (Fig. 1 *b*); one is cut to form four cards, 10 by 3 inches (Fig. 1 *c*). A black ink dot is placed in the upper left corner of each of these and subsequent cards to make possible rapid recognition of the upright position.

Received for publication, August 25, 1941.

Normal Complexes (Fig. 2).—Starting $\frac{1}{2}$ inch from the left-hand margin of one card, draw a P-wave, one inch high and approximately $1\frac{1}{2}$ inches wide. Beginning 3 inches from the left-hand margin, draw a QRS complex, 1.25 inches in width, the Q-wave should be approximately $\frac{1}{2}$ inch in amplitude, the R- and S-waves 3 to 4 inches in amplitude. Beginning 6 inches from the left-hand margin, a T-wave is drawn $\frac{3}{4}$ inch in amplitude and 2 inches wide; if desired the terminal limb of the T-wave can be drawn to dip $\frac{1}{4}$ inch below the base line, returning to the isoelectric level, 9 inches from the left-hand margin. By following these directions the P-wave will be the upper limit of normal in amplitude; the T-wave will be the lower limit of normal in amplitude; the QRS complex and the PR-interval will be the upper limit of normal in duration (Fig. 2 a). One piece of cellulose acetate is superimposed on this drawing; the contour of the

Fig. 1.

Fig. 2.

Fig. 3.

diagrammatic complex is traced with a wax pencil, and the resultant P-QRS-T-complex is cut out. This results in a templet, which can be used to draw normal complexes of identical characteristics. A total of six P-QRS-T-complexes are prepared from this templet, and the outlines are filled in with poster paint.

Lines are drawn on four cards to divide them into sections, 10 by 3 inches. By using the appropriate portions of this same templet, six P-waves (Fig. 2 b) four QRS complexes (Fig. 2 c) and six T-waves (Fig. 2 d) are drawn on 10 by

3 inch cards. With the same templet normal QRS-T complexes are drawn on four 10 by 6 inch cards to depict ST-segments of short duration (Fig. 2 e).

Abnormal P-Waves.—Six P-waves, 2 inches high (Fig. 3 a), and six notched P-waves (Fig. 3 b), $\frac{3}{4}$ inch high, are drawn on 10 by 3 inch cards after preparing the appropriate templets. Four cards (10 by 3 inches) are prepared showing normal T-waves on which abnormal P-waves are partially superimposed (Fig. 3 c).

Fig. 4.

Fig. 5.

Fig. 6.

A flutter wave, 2 inches in duration, is drawn, and from the templet four cards, 10 by 6 inches, are prepared, each bearing three flutter waves (Fig. 3 d). By making the base line of three cards irregular, the f waves of auricular fibrillation are depicted (Fig. 3 e).

Abnormal QRS Complexes.—QRS complexes to show axis deviation are drawn on three cards (Fig. 4 a), 10 by 3 inches, as follows: On one card a large R-wave and a small S-wave are drawn, and a templet is made. By inverting and reversing the templet, a complex with a small R-wave and a large S-wave is

drawn on a second card. The third complex is drawn to represent an average of these two types of QRS complexes.

QRS complexes of low amplitude are demonstrated (Fig. 4 *b*) on three 10 by 3 cards. Each card represents one of the three standard leads. The complexes are drawn less than $1\frac{1}{4}$ inches in width and less than $3\frac{1}{2}$ inches in amplitude.

Bundle branch block (spreading, slurring, and notching) is represented on three 10 by 3 inch cards (Fig. 4 *c*); the major deflection is upright on one card, and downward in another card; the third card represents an average of the first two.

Premature ventricular contractions of two different designs are drawn on 10 by 3 inch cards (Fig. 4 *d*). The abnormal QRS-T complexes should begin at the left-hand margin of the card and occupy 4 to 5 inches; the remainder of the card serves to depict the compensatory pause. Using a templet drawn from one of these extrasystoles, three additional cards, each containing two ventricular premature beats, are drawn so that when these are joined together they illustrate a run of ventricular extrasystoles or ventricular tachycardia.

Fig. 7.

Abnormal ST-Segments and T-waves.—Four types of abnormal ST-segments are illustrated on 10 by 3 inch cards (Fig. 5). These are drawn so that the left-hand margin of each can be superimposed on the normal S-wave, and the right-hand margin can be superimposed on the normal T-wave. One card depicts an elevated ST-segment parallel to, and 1 inch above, the base line (Fig. 5 *a*). A second card depicts a depressed ST-segment, also parallel to the base line (Fig. 5 *b*). A third card begins 1 inch below the base line, and then runs diagonally up to reach the peak of the T-wave (Fig. 5 *c*). The fourth card illustrates coving (Fig. 5 *d*). Four T-waves, $\frac{1}{2}$ inch high, are drawn on cards 10 by 3 inches (Fig. 6 *a*). One diphasic T-wave (Fig. 6 *b*) is drawn on another 10 by 3 inch card. Six T-waves, 3 inches in amplitude (Fig. 6 *c*), are drawn on 10 by 3 inch cards; these may be used to depict normal T-waves of high amplitude or T-waves on which P-waves have been superimposed.

Four 10 by 6 inch cards, illustrating combinations of abnormal ST-segments and T-waves, are drawn. One depicts an elevated ST-segment and inverted T-wave (Fig. 7 *a*); another, coving with an inverted T-wave (Fig. 7 *b*); a third, a depressed ST-segment, with an inverted T-wave (Fig. 7 *c*); and a fourth, a depressed ST-segment with diphasic T-wave (Fig. 7 *d*; digitalis T-waves).

To demonstrate these cards a stand can be made according to Fig. 8. This stand also serves as a container for the cards when they are not in use.

Fig. 8.—Viewing stand for demonstrating electrocardiographic patterns. (This viewing stand can be made of $\frac{1}{2}$ inch stock.) A, Hinged molding to hold upper edge of cards in place; B, container for large cards, $10\frac{1}{2}$ by $2\frac{1}{2}$ inches; C, container for small cards, $3\frac{1}{2}$ by $1\frac{1}{2}$ inches; and D, grooved molding to hold lower edge of cards in place.

Fig. 9.

Fig. 10.

Fig. 11.

METHOD OF USE

In use, normal sinus rhythm is first illustrated by joining end-to-end four normal P-QRS-T complexes (Fig. 9). Arrhythmias arising from the sino-auricular node are then illustrated: sinus bradycardia, by separating three normal P-QRS-T complexes (Fig. 10); sinus tachycardia, by partially superimposing the complexes so that five occupy the same horizontal area (Fig. 11).

Fig. 12.

Fig. 13.

Abnormalities of the P-waves are next illustrated. Auricular tachycardia is depicted by superimposing an abnormal P-wave on each of the normal P-waves of the sinus tachycardia (Fig. 12), or by further superimposition of the normal complexes so that the P-waves cover the T-waves, and then superimposing the combined P-T waves (Fig. 13), large T-waves, or inverted P-waves. In a similar fashion abnormalities of the PR-interval (varying degrees of block) are illustrated, then abnormalities of the QRS complexes, the ST-segment, and the T-waves. Practically all the electrocardiographic patterns, which one encounters clinically, can be created by this method.

SUMMARY

The model described consists of units of electrocardiographic complexes prepared in such a fashion that they can be joined together so as to illustrate diagrammatically most of the common electrocardiographic patterns. The model has proved to be of considerable value in teaching beginners how to interpret electrocardiograms.

SIMPLE METHOD OF EVALUATING BLOOD PLATELETS*

EVANS W. PERNOKIS, M.D., CHICAGO, ILL.

THE procedure for accurately seeing, identifying, and counting the blood platelets has become more important with the discovery that splenectomy cures a high percentage of patients afflicted with idiopathic purpura hemorrhagica. The methods used and recommended by most textbooks are based on dilution and counting with the hemacytometer. The most popular diluting fluid is that of Wright and Kinnicutt, though the fluids recommended by Rees and Ecker, and Guy and Leake are also extensively used. The Fonio method, so highly recommended by the German school, which uses the magnesium sulfate as a diluent before spreading the blood on the slide for a smear, also has been extensively used. After several years of trial with the dilution methods and the Fonio method with students in classes of Laboratory Diagnosis, it is our opinion that the following method is the simplest and least time-consuming for the accurate identification and counting of blood platelets.

The solution used is a 1 per cent brilliant cresyl blue in absolute alcohol. A drop of the solution is placed on the edge of a slide (thoroughly cleaned and flamed), and spread out in a manner similar to spreading blood for a blood smear. The solution evaporates readily, leaving a thin coat of stain. An ear puncture is made, and a drop of blood the size of a black pinhead is placed on a thoroughly cleaned cover slip and overlaid on the stained slide. A red blood cell count is also drawn at the same time. The size of the drop must not be too large so that it spreads out uniformly filling the cover slip area with a thin film of blood. The platelets take the brilliant cresyl blue stain and appear as pale blue bodies floating between the less colored red blood cells. Variations in shape and size are also readily noted in the preparation. A total of 1,000 red blood cells are counted on the film, and the number of platelets in the same area is noted. From the value of the red blood count, the platelet count is calculated. For example, if in counting 1,000 red blood cells, we encounter 75 platelets, and the patient's blood count is 4,750,000 red cells, by multiplying the first four figures of the red count with the number of platelets in 1,000 red cells we get the platelet count, which in the above case would be 75 times 4,750, or 356,250 platelets.

This method offers the advantage that reticulocytes may also be counted on the same preparation. If kept in a Petri dish lined with moistened filter paper, it may be kept several hours without the platelets disintegrating. After first observing the moist preparation, the cover slip may be removed with light pressure and counterstained with Wright's stain or May-Grünwald-Giemsa for further observation of the platelets and a differential count.

A SHAKING DEVICE USED IN THE COLLECTION OF BLOOD FOR TRANSFUSION*

L. W. DIGGS, M.D., AND H. B. TURNER
MEMPHIS, TENN.

A SIMPLE, noiseless and relatively inexpensive shaking device (Fig. 1) has been developed in the Blood Bank at the John Gaston Hospital. The power is supplied by a small electric motor from a portable victrola. The back and forth motion is obtained by a shaft attached to an eccentric disk. The carriage for the collecting bottle is swung from two metal supports 12 inches in length.

Fig. 1.—A shaking device used in the collection of blood for transfusion.

The fulcrum is placed at the level of the top of the bottle so that motion and vibration at this point are minimal. The carriage is open at the top so that the collecting bottles can be easily inserted and removed. The height of the instrument is 23 inches, the width at the base 10 inches, and the width at the top 5 inches.

*From the Division of Medicine and the Clinical Laboratories of the John Gaston Hospital and the University of Tennessee, Memphis.
Received for publication, November 3, 1941.

The shaking device has been used for the collection of approximately 2,000 flasks of blood for transfusions and has proved to be entirely satisfactory. The assistant is spared the tiresome and awkward task of keeping the flask of blood in motion during the three to fifteen minutes required to collect 500 c.c. of

Fig. 2.—The collection of blood from a donor by the closed citrate method using "the shaker."

blood. With the shaker it is possible for one person to collect the blood unassisted. The gentle agitation furnished by this instrument is adequate to prevent coagulation. In our routine collections the blood is simply allowed to run downhill without the use of negative pressure, but if negative pressure is desired, the suction pump may be connected as in Fig. 2.

The instrument was built by the students at the William R. Moore School of Technology under the direction of Mr. J. M. Smith.

THE RELATIONSHIP OF THE PLASMA PROTEINS TO THE CORRECTED SEDIMENTATION RATE*

ISRAEL KOPP, M.D., BOSTON, MASS.

MANY observers have demonstrated a suggestive relationship between the red blood cell sedimentation rate and the fibrinogen content of the plasma, and some have concluded that the fibrinogen content determines the sedimentation rate.^{1, 2} Others,^{3, 4} however, have failed to observe any such causal relationship and have found *no* correlation between the sedimentation rate and any of the plasma proteins. Marked changes in the sedimentation rate occur even without any changes in the plasma proteins.⁴ Increases in globulin and extreme degrees of lipemia are also known to affect the sedimentation rate.⁵

Repeated determinations of the plasma protein fractions and the sedimentation rate on patients undergoing therapeutic fever for central nervous system syphilis have afforded an opportunity to review again the problem of the relationship if any between the sedimentation rate and the plasma proteins.

MATERIAL AND METHODS

Five male patients with general paresis, ranging from 39 to 52 years in age, were hospitalized for fever therapy. The five patients were given the following therapy: tertian malaria to two patients; tertian and quartan malaria to one patient; tertian malaria and typhoid vaccine fever to one patient; artificial fever and malaria to the fifth patient.

Venous blood samples were obtained without stasis and with the patient in a fasting state. In most instances the patient was afebrile. Potassium oxalate, 2 mg. per cubic centimeter of blood, was used as the anticoagulant for the determination of the plasma proteins.

The total protein was obtained by the determination of the total nitrogen by a modified micro-Kjeldahl⁶; the nonprotein nitrogen by the method of Folin and Wu⁷; the albumin and globulin by the sodium sulfate method of Howe⁸; and the fibrinogen by precipitation as fibrin by the method of Cullen and Van Slyke.⁹ In the last series of studies the fibrinogen was precipitated as above,⁹ and the nitrogen content of the fibrin was determined directly.

The sedimentation rate of whole blood was determined by the method of Rourke and Ernstene¹⁰ and corrected for the hematocrit readings by their correction chart. Dry oxalate mixture, 6 mg. of crystalline ammonium oxalate and 4 mg. of crystalline potassium oxalate for 5 c.c. of blood, was used as the anticoagulant.

*From the Boston Psychopathic Hospital.
Received for publication, November 21, 1941.

The sedimentation rate of defibrinated blood was determined by the method of Ham and Curtis.² Fibrinogen was removed by rotating 5 c.c. of blood together with 12 small glass beads in an Erlenmeyer flask for from ten to fifteen minutes, and then filtering through two layers of gauze. The defibrinated blood was then mixed, and the sedimentation rate was determined as with whole blood. Because of the slow settling, readings were made over a period of three hours. Corrections were made for the hematocrit according to the charts of Ham and Curtis,² and Rourke and Ernstene.¹⁰

Chart 1.—○ Fibrinogen by difference. • Fibrinogen by direct method.

RESULTS

Ninety-two sedimentation rates were obtained during malaria, typhoid vaccine, and artificial fever therapy. Taken as a whole no linear relationship could be found between the corrected sedimentation rates and the fibrinogen values (Chart 1). The sedimentation rate varied more than 1,500 per cent for the same fibrinogen value. Fibrinogen values also varied widely for similar sedimentation rates, as for example, sedimentation rates of 0.60 mm. and 0.65 mm. per minute for fibrinogen values of 160 mg. and 630 mg., respectively. The sedimentation rates also bore no absolute relationship to albumin, albumin-globulin, or globulin-fibrinogen ratios.

It was observed frequently that when the more rapid sedimentation rates could not be explained on the basis of fibrinogen values alone, the accompanying globulin values were close to the upper limit of normal, 3 Gm. per 100 c.c. or above. However, wide variations in the sedimentation rate, as much as 2,200 per cent, occurred even for similar globulin values (Chart 2).

The sedimentation rates of each patient revealed a suggestive linear relationship with fibrinogen values in only two of the five patients, one during malarial therapy and the second during artificial fever therapy. Changes in the globulin fraction during treatment appeared less marked in the two patients than in the others. The subsequent administration of tertian malaria to the patient who had received artificial fever therapy resulted in more scattered sedimentation rates for nearly similar fibrinogen values (Chart 3). Globulin values, though higher at this time than during artificial fever therapy, were still within normal limits.

An attempt was made to evaluate the importance of globulin in the determination of the sedimentation rate by obtaining 54 defibrinated blood sedimentation rates on three patients during malarial therapy, and on one of this group during a course of typhoid vaccine fever. The removal of fibrinogen did not prevent an increase in the sedimentation rate, but the increases when present were less marked than those of whole blood, i.e., fibrinogen was not removed. It will be observed (Chart 2) that the sedimentation rates with and without the presence of fibrinogen follow about the same pattern when compared with the globulin values. No correlation was found between the defibrinated sedimentation rates and globulin values when the latter were 2.8 Gm. per 100 c.c. or less. Above this level, however, a suggestive linear correlation was present, the defibrinated sedimentation rates showing marked increases with only slight increases in globulin.

DISCUSSION

Our findings when taken as a whole reveal little correlation between the corrected whole blood sedimentation rate and fibrinogen values in therapeutic malaria and typhoid vaccine fever. The corrected sedimentation rates obtained during artificial fever therapy of one patient and malaria therapy of a second patient bore a suggestive linear relationship to fibrinogen values. Changes in the fibrinogen, globulin, and red blood cells are quite marked during malaria, less marked during typhoid vaccine fever, and least marked during artificial fever. It is probable that a better relationship between the sedimentation rate and fibrinogen may exist when changes in the plasma proteins and red blood cells are not rapid or marked. Ropes and co-workers,⁴ however, have observed marked changes in the sedimentation rate in both acute and chronic infections even without any change in the concentration of the plasma proteins. No absolute correlation was found by these workers between the sedimentation rate and any of the plasma protein fractions.

The sedimentation rates obtained with whole blood and defibrinated blood samples show the importance of globulin. Regardless of fibrinogen levels, globulin values of 2.9 Gm. per 100 c.c. and above were frequently accompanied by rather marked increases in the sedimentation rates of whole blood but less pronounced in the defibrinated samples. Defibrinated sedimentation rates with globulin values less than 2.9 Gm. per 100 c.c. ranged mostly from 0.01 to 0.2 mm. per minute (Chart 2) and were frequently above the normal range of 0.01 to 0.03 mm. per minute.² Defibrinated sedimentation rates increased consider-

Chart 2.

Chart 3.—• Malaria. ○ Artificial fever.

ably up to 0.95 mm. per minute, when globulin levels exceeded 2.9 Gm. per 100 c.c. Since it has been shown that albumin does not increase the sedimentation rate, but may even slow it,⁴ the increases in the defibrinated sedimentation rate must be attributed to changes in the globulin fraction, quantitatively or qualitatively, or to some other unknown factor. Ham and Curtis² have also noted marked elevations in the defibrinated sedimentation rate when serum globulin was abnormally increased. They have found, too, a rough correlation to exist between the concentration of serum globulin when above 3 Gm. per 100 c.c. and the defibrinated sedimentation rate provided lipemia is not present.

Other factors which may affect the sedimentation rate and account for its lack of correlation with the fibrinogen values obtained on our patients are the following: the mean corpuscular volume of the red blood cells, the presence of a lipemia, and liver pathology.

Changes in the mean corpuscular volume of the red blood cells are known to affect the sedimentation rate and are not taken into account when the corrected sedimentation rate is determined.² The mean corpuscular volume of the blood during therapeutic fever showed fluctuations as great as -12 to +17 cubic microns; these were especially marked during malarial therapy. The presence of a lipemia increases the sedimentation rate, but determinations on a number of our own patients and observations of others¹¹ reveal a reduction and not an increase of the cholesterol content of the blood in malaria. We do not know whether changes in the cholesterol occur during fever induced by typhoid vaccine or by artificial means. Gilligan and Ernstene¹ have stated that in liver diseases factors other than fibrinogen, among them globulin, may play an important role in the determination of the sedimentation rate. They, and others,² have observed a rapid sedimentation rate in acute hepatitis and cirrhosis of the liver. It is the feeling of Clifford¹² that the liver is damaged in malaria and liver function tests carried out in this clinic show occasional but transient liver damage. In addition progressive reductions in fibrinogen have been observed during therapeutic malaria which would tend to corroborate this. However, rapid sedimentation rates have been obtained on our patients even when fibrinogen has fallen to the lower limit of normal (190 mg. per 100 c.c. of blood) and globulin has remained within normal limits. This does not eliminate the possibility of qualitative changes in the globulin fraction.

An attempt has been made by Ropes and co-workers⁴ to explain the inconsistencies between sedimentation rates and fibrinogen values. These workers attribute the variations in the sedimentation rate to modifications in the physical state of the plasma colloids with consequent changes in the electric charges on the proteins and red blood cells. Changes in the colloidal state and increases in the sedimentation rate may thus occur without any change in fibrinogen or globulin values.

CONCLUSIONS

1. Corrected whole blood sedimentation rates and plasma protein values were determined repeatedly on five patients undergoing therapeutic fever (malaria, typhoid vaccine, and artificial fever) for general paresis.

2. No absolute correlation could be found between fibrinogen, albumin, albumin-globulin, or globulin-fibrinogen ratios on the one hand, and the corrected sedimentation rate on the other.

3. The corrected sedimentation rate was increased in most instances when globulin values rose to the upper limit of normal (3 Gm. per 100 c.c.) and above, regardless of fibrinogen levels.

4. Other factors which may influence the sedimentation rate during therapeutic fever are changes in the mean corpuscular volume of the red blood cells and products of probable liver damage.

DEHYDRATION IN EMBALMED SPECIMENS EXPOSED TO AIR

F. LLOYD HANSEN, M.A., AND N. C. PERVIER, PH.D.
MINNEAPOLIS, MINN.

ONE of the claims frequently made for glycerin and other polyhydric alcohols as embalming fluid ingredients, is that they retard the loss of water from the subject. We have made a study of this claim from both theoretical and practical viewpoints.

A fresh specimen or body may be regarded as a hydrophylic colloidal system, containing about 60 per cent water. This water content is composed of two components: free water, which provides the proper life environment, and bound water, that which is bound to the biocolloids of tissue through coordinate valence linkages. About 25 per cent of the total water may be in the latter form.¹ Such bound water is less susceptible to evaporation loss than the free water. Moreover, as a result of incipient putrefaction, the complex colloidal structures become degraded and begin to lose the power of binding water. Formaldehyde fixation causes profound changes in protein structures, converting them into insoluble inert products with little water-binding power. As a result of both of these processes, it is logical to regard most of the water found in dead animal bodies as free water. As such, the water is as free to evaporate as is the water in an open dish. The prevention of this loss of water is important in the preservation of museum specimens and bodies which must be preserved for a long time. Water loss from bodies placed in sealed glass top caskets presents a specially troublesome problem.

An obvious method of reducing the evaporation is to dissolve additional solutes in the injection fluid. All nonvolatile solutes reduce the vapor pressures of solutions, in accordance with the law of Raoult. Those which are hygroscopic and form hydrates are most efficient as evaporation retarders. In the tobacco industry² glycerin, ethylene glycol, and diethylene glycol have been successfully added in order to maintain the moisture content of tobacco under storage. It has seemed natural to expect that these compounds would also prevent the drying out of animal remains even though larger concentrations of water occur in them.

An inspection of the vapor pressure curves of solutions of these compounds shows that this expectation cannot be realized to any great extent. In the case of glycerin (Fig. 1) a solution must have a concentration of 80 per cent by weight in order to remain in equilibrium with air having a relative humidity of 50 per cent. If the relative humidity is even 95 per cent, so that evaporation is greatly retarded, the solution must still contain 33 per cent of pure glycerin. Thus a normal adult body would need to have injected into it over 2.5 gallons

Fig. 1.—Relative humidity over aqueous glycerol solutions.

Fig. 2.—Water loss from arterially injected specimens.

of pure glycerin in order to prevent water loss from occurring upon exposure to air at 95 per cent relative humidity. A greater amount of another compound is required if its molecular weight exceeds that of glycerin. In the case of glycol, which is the only nonvolatile alcohol having a molecular weight less than that of glycerin, about two gallons would be required. It is obviously impossible to inject these huge amounts of viscous liquids and we may, therefore, conclude that it is impossible to prevent the gradual loss of water from a body by adding these compounds to the fluid used in injecting it. None of the commercial fluids we examined privately contained over 6 per cent of glycerin or similar product when diluted according to directions, and it is evident that these would have only a slight effect in delaying the loss of water from a body.

EXPERIMENTAL

We have measured the desiccation losses of a large number of aridly stored hog kidneys which had been arterially embalmed with aqueous 2 per cent formaldehyde solutions containing various concentrations of nonvolatile organic solutes. Each kidney was injected through the renal artery with an amount of fluid equal to 37.5 per cent of its fresh weight. After injection the renal artery, vein, and ureter were tied off, and the kidneys were stored at room temperature in large containers over fused calcium chloride. The control kidneys were injected with plain 2 per cent formaldehyde solution, while the fluid used for the others contained in addition, 2.5, 5, and 10 per cent of the following compounds: glycerin, ethylene glycol, diethylene glycol, carbitol, and sorbitol. The kidneys were weighed every day to determine the loss of water from them.

Figs. 1 and 2 show the weight changes in the embalmed material with time in the case of the 10 per cent additions. All the plotted values represent average values on several specimens. Except for minor displacements up or down due to uncontrollable differences in the biological material, the graphs have identical slopes and shapes, and are nearly superimposable. Only slight differences in water loss are found, and we may conclude that very little can be done in reducing the water loss from embalmed bodies unless impracticably large amounts of hygroscopic agents are injected.

THE USE OF SS (SHIGELLA-SALMONELLA) AGAR FOR THE ISOLATION OF FLEXNER DYSENTERY BACILLI FROM THE FECES*

HARRY M. ROSE, M.D., AND MAXWELL H. KOLODNY, PH.D.
NEW YORK, N. Y.

SS (SHIGELLA-SALMONELLA) agar is a new culture medium for the isolation of microorganisms of the Shigella, Salmonella, and Eberthella groups from the feces. The medium is of the "selective" type, i.e., it is designed to favor the growth of these pathogens, but to inhibit the coliform bacteria. This selective inhibition of the fecal bacteria enables very large inocula of feces to be used, with a consequently greater chance of cultivating the pathogens when they are present in small numbers. Colonies of pathogens are colorless, whereas any colonies of the nonpathogenic lactose fermenters that develop appear red. The medium is similar in purpose to desoxycholate-citrate agar,¹ the value of which is well-established,² but differs considerably from it in composition.†

Mayfield and Gober³ have furnished the only report yet available on the use of SS agar. These authors examined more than one thousand stool specimens, of which 101 were positive for *E. typhosa*, and 171 were positive for *Sh. dysenteriae*, chiefly of the Flexner group. Each stool specimen was cultured on both desoxycholate-citrate agar and SS agar, and the results on the two media were compared. Of the 272 specimens containing typhoid or dysentery bacilli, 262 were positive on SS agar, and 249 were positive on desoxycholate-citrate agar. Cultures were positive on SS agar alone in 23 specimens, and on desoxycholate-citrate agar alone in 10 specimens. These authors concluded that SS agar was as efficient as desoxycholate-citrate agar for the isolation of dysentery bacilli. They also noted that differentiation between the fecal and pathogenic colonies was more clearly defined on the SS agar, and that the medium was economical.

We have recently had the opportunity to employ SS agar in the bacteriologic study of a small outbreak of Flexner dysentery. Seventeen clinical cases of dysentery were observed, nearly all of which were mild, although several pa-

Received for publication, December 4, 1941.

†SS agar is a product of the Difco Laboratories, Detroit, Mich. This medium and the others used in this study were purchased on the open market.

It has the following formula:

Beef extract	5.0 Gm.
Proteose peptone	5.0 Gm.
Lactose	10.0 Gm.
Bile salts	8.5 Gm.
Sodium citrate	8.5 Gm.
Sodium thiosulfate	8.5 Gm.
Ferric citrate	1.0 Gm.
Agar	17.0 Gm.
Brilliant green	0.23 mg.
Neutral red	0.025 mg.

Weights of ingredients are per liter. The formula for desoxycholate-citrate agar will be found in reference 1.

tients experienced a severe febrile reaction. Diarrhea persisted in most cases for from three to seven days. The stools contained much mucus, but were rarely bloody. There were no fatalities.

Bacteriologic examinations of the feces from patients and contacts were done in the diagnostic laboratory of the Presbyterian Hospital. This laboratory routinely uses for stool cultures desoxycholate-citrate agar and a nonselective medium, eosin-methylene blue agar. SS agar was introduced shortly after the outbreak began.

A total of 225 stool specimens were examined from patients and contacts. Dysentery bacilli of the Flexner group were isolated from each of the 17 clinical cases and from one of the contacts. Altogether, 70 of the 225 specimens were found to be positive on one or more of the three media. Of the positive specimens, 14 were cultured on eosin-methylene blue agar and desoxycholate-citrate agar. SS agar with either eosin-methylene blue agar or desoxycholate-citrate agar was used for 26 specimens. The remaining 30 specimens were cultured on all three media.

TABLE I

COMPARATIVE EFFICIENCY OF EOSIN-METHYLENE BLUE AGAR, DESOXYCHOLATE-CITRATE AGAR, AND SHIGELLA SALMONELLA AGAR FOR THE ISOLATION OF FLEXNER DYSENTERY BACILLI

70 POSITIVE SPECIMENS COMBINATIONS OF MEDIA USED	RESULTS ON INDIVIDUAL MEDIA					
	EMB AGAR		DC AGAR		SS AGAR	
	NUMBER POSITIVE	NUMBER NEGATIVE	NUMBER POSITIVE	NUMBER NEGATIVE	NUMBER POSITIVE	NUMBER NEGATIVE
EMB and DC, 14 specimens	7	7	13	1	-	-
EMB and SS, 20 specimens	9	11	-	-	20	0
DC and SS, 6 specimens	-	-	5	1	6	0
EMB, DC, and SS, 30 specimens	10	20	25	5	29	1
Total positive and negative on individual media	26	38	43	7	55	1
Per cent positive on individual media	40		86		98	

The results of cultures on the four combinations of media are given in Table I. Eosin-methylene blue agar yielded 26 positives out of 64 cultures in which this medium was used, an incidence of only 40 per cent. The cultures on desoxycholate-citrate agar were positive in 43 of 50 specimens, or 86 per cent. SS agar was positive in 98 per cent of cultures, only one specimen out of 56 being negative on this medium.

The data indicate clearly that a large proportion of the positive specimens would have been considered negative if the nonselective medium alone had been employed. Moreover, most of the isolations on eosin-methylene blue agar were obtained from patients early in the course of their disease, when many dysentery bacilli were being constantly excreted in the stools. After the diarrhea had subsided, however, and the pathogenic bacteria were excreted only intermittently and in small numbers, the value of the selective media became even more apparent. In 7 patients, from two to six weeks after symptoms had disappeared and the persons were apparently healthy, these media revealed 22 positive stools. The same stools were completely negative when cultured on eosin-methylene blue agar.

A comparison of the cultures on the two selective media shows that SS agar was somewhat more efficient than desoxycholate-citrate agar for the isolation of Flexner dysentery bacilli, although the number of specimens examined was relatively small, and no statistical evaluation of the media could be made. However, the SS agar was found to be superior to the desoxycholate-citrate agar in three noteworthy respects: (1) The inhibition of coliform bacteria was more marked; (2) the colonies of dysentery bacilli were more clearly defined; (3) the colonies of dysentery bacilli were usually more numerous.

Our findings, therefore, confirm those of Mayfield and Gober,³ and indicate that SS agar is a valuable selective medium for the isolation of Flexner dysentery bacilli from the feces.* We feel that the use of SS agar will increase the efficiency of methods for the bacteriologic examination of the feces, a matter of importance to the public health from the standpoint not only of diagnosing enteric disease, but also of recognizing carriers of the intestinal pathogens.

CONCLUSIONS

SS agar is as efficient as desoxycholate-citrate agar for the isolation of Flexner dysentery bacilli.

The medium is superior to desoxycholate-citrate agar as regards inhibition of coliform bacteria, colony differentiation, and growth-promoting qualities for the pathogens.

The combination of SS agar and a suitable nonselective medium furnishes a reliable method for the isolation of the intestinal pathogens. For maximal efficiency two or more plates of the selective medium should be employed.

*We have also used SS agar to culture a series of stools from two patients with typhoid fever, one with Sonne dysentery, and one with enteritis caused by *Salmonella panama*. The results indicated that the medium was equally effective for the isolation of these organisms.

A NOTE ON THE "BLACK LINE" IN HEMATOCRIT DETERMINATIONS*

J. PERCY BAUMBERGER,† D.Sc., STANFORD UNIVERSITY, CALIF.

IT MAY be a common observation that a narrow black band appears in hematocrit determinations at the top of the erythrocyte column, though the textbooks of hematology¹⁻⁵ and the literature⁷⁻⁹ here listed make no reference to it. Neither Hedin in his pioneer work on the hematocrit nor Koeppé, who first described the development of translucence of erythrocytes when blood is centrifuged in hematocrit tubes at high speed, makes mention of the black line. It is, therefore, considered worth while to mention this phenomenon and to describe some simple experiments which establish its nature.

Oxalated human blood drawn directly from the cubital vein is introduced into Wintrobe hematocrit tubes capped with rubber, and centrifuged at about 2,500 r.p.m. for ten minutes. The tubes then show a lower column of erythrocytes and an upper column of plasma with about one division (1 per cent) of leucocytes above the erythrocytes. Immediately below the leucocytes a dark line is present, varying in intensity and width, but usually equal to about 0.5 per cent by volume. When hemolysis is great, black lines are seen both above and below the leucocytes.

The plasma and leucocytes may be pipetted off without disturbing the black layer, but it disappears on standing exposed to air, becoming red. If saline solution is now added to the 100 per cent mark, and the erythrocytes are resuspended and then centrifuged down, no dark line appears, obviously because there are no leucocytes to consume the oxygen. However, if a few yeast cells, *S. cerevisiae*, are now added to the top of the saline, in the above experiment, and are then centrifuged down, so that they rest on the top of the erythrocyte column, the dark band reappears as a result of oxygen consumption by the yeast cells. If blood is chilled and, while ice cold, is introduced into the hematocrit, on centrifugation, no black line appears at first but develops after a few minutes' standing at room temperature, when it increases in width gradually until a maximum width is reached. If the temperature is now increased to 37° C., the black line again increases in width with time, finally reaching a new maximum width of not more than 1 per cent. The width of the line is a function of the rate of oxygen consumption by the leucocytes as influenced by temperature.

Evidently the black line is a layer of erythrocytes in which the oxyhemoglobin has been reduced to hemoglobin by the metabolic activity of the leucocytes.

*From the Research Department of the Barnard Free Skin and Cancer Hospital, St. Louis, Mo.
†Present address: Physiology Department, Stanford University, Calif.

The black line is thus reversible and can be produced by any agency using up oxygen locally at a rate greater than the diffusion rate of oxygen in the plasma or from distant erythrocytes. Perhaps the rate of increase in width of the line may be a useful indicator. For instance, if the width of the line is unequal in two samples of blood, while the leucocytic count is equal, one would expect a qualitative difference in the leucocytes.

I wish to acknowledge the helpful advice of Dr. Carl Moore, Washington University Medical School, and the kindness of Dr. W. C. Herold, St. Louis, in furnishing blood samples.

CHEMICAL

A MICROBIOLOGICAL ASSAY METHOD FOR SIX B VITAMINS USING LACTOBACILLUS CASEI AND A MEDIUM OF ESSENTIALLY KNOWN COMPOSITION*

MAURICE LANDY, PH.D., AND DOROTHY M. DICKEN, M.A.
CHAGRIN FALLS, OHIO

IT IS generally agreed that there is a great need in current vitamin research for rapid methods for the quantitative determination of vitamins. This is particularly true in the case of the vitamins of the B complex.

Since many B complex vitamins required by animals are essential in bacterial metabolism, microbiological assays, i.e., vitamin assays employing microorganisms as test agents, have rapidly gained approval. As our knowledge of bacterial nutrition has accumulated, these procedures have increased in number and have been revised and amplified. Microbiological assays are not only extremely sensitive to minute amounts of test material, but are accurate as well, and have the additional advantage over animal assays in being rapid and inexpensive. Furthermore, in the case of folic acid, microbiological technique is the only known method of assay.

Microbiological procedures in current use include assays for riboflavin (*Lactobacillus casei*),¹ pantothenic acid (*L. casei*),² pyridoxine (*Saccharomyces cerevisiae*),³ nicotinic acid (*L. arabinosus*),⁴ folic acid (*Streptococcus lactis*),⁵ and biotin (*S. cerevisiae*, *Clostridium butylicum*).^{6, 7} During the preparation of this manuscript a paper by Shull, Hutchings, and Peterson⁸ describing a microbiological assay for biotin utilizing *L. casei* appeared. From the foregoing examples it is obvious that microbiological assays of the various B vitamins have necessitated use of a variety of organisms, culture media, and test conditions. Although the majority of these assays has been satisfactory, it would obviously be advantageous to have a single acidimetric method for members of the B complex, using only one test organism and a simplified basal medium of known composition. The organism presenting the greatest possibilities as an assay agent under these conditions is *L. casei* because (1) its nutritional requirements have been extensively investigated and have been found to include a majority of the B complex vitamins; (2) its acid production, which is easily and accurately determined, is a function of its growth; and (3) many laboratories are already familiar with its use in riboflavin and pantothenic acid assays.

At the time this study was begun, the status of the nutrition of *L. casei* was as follows: It had been demonstrated that this organism required ribo-

Received for publication, February 27, 1942.

†American type culture collection No. 7469.

flavin,¹ pantothenic acid,¹⁰ nicotinic acid,¹⁰ and pyridoxine.¹¹ The essential growth factors of unknown composition, other than those possibly present in hydrolyzed casein, were supplied by yeast extract and could be separated by adsorption on norit A into "filtrate" and "eluate" fractions.¹¹ Evidence had been presented indicating that the activity of the eluate fraction was due to "folic acid."^{5, 12} However, the composition of the filtrate fraction was still unknown.

We, therefore, undertook (1) replacement of the yeast filtrate fraction with known substances which would permit maximum growth of *L. casei* in a medium of essentially known composition, and (2) thus, having determined the nutritional requirements of *L. casei*, to use this information in establishing assay procedures for the various vitamins this organism requires.

EXPERIMENTAL

At the time our studies on the nutrition of *L. casei* were begun, an investigation was in progress in this laboratory on the use of avidin in determining the biotin requirement of microorganisms.¹³ A correlation had been established between growth inhibition by avidin and the biotin requirement of an organism. In general, those organisms which have been found to require biotin supplied in the culture medium were inhibited by avidin, while those organisms which were found to synthesize biotin¹⁴ were not affected. The growth and acid production of *L. casei* were completely inhibited by avidin, and this inhibition could be readily reversed by the subsequent addition of crystalline biotin. This was taken as evidence that *L. casei* requires biotin as a growth essential.

Employing the basal medium of Snell and Peterson¹¹ containing pyridoxine and filtrate fraction of yeast extract as prepared by them, and with their norit eluate fraction replaced by "folic acid" in excess, we found that biotin would replace the filtrate fraction, yielding equivalent growth. Since we have not always been able to obtain maximum growth with the filtrate fraction, it was suspected that this constituent might contain insufficient biotin to support maximum growth. Biotin assay⁶ of the filtrate fraction revealed that when prepared and used according to Snell and Peterson, a culture would be supplied with 0.0001 γ of biotin. This amount was subsequently found insufficient for maximum growth of *L. casei*.² Peterson has recently stated, "the filtrate fraction can be replaced by biotin, thus leaving the eluate fraction as unknown."¹² However, no evidence was offered to support this statement.

In an effort to obtain maximum growth consistently the effect of a variety of growth accessory substances was investigated. As a result of the findings of Snell and Mitchell¹⁵ that purine and pyrimidine bases are growth substances for lactic acid bacteria, adenine, guanine, xanthine, and uracil were included in the medium. These bases, together with biotin and folic acid concentrate, consistently supported maximum growth. We later added asparagine, since Feeney and Strong¹⁶ had found it to be a growth accelerator, particularly

*From our tests with Snell and Peterson's filtrate fraction, and as a result of biotin assay of this material, it would appear likely that under their conditions of test, the filtrate fraction supplied only a portion of the total biotin necessary for maximum growth. The remainder of the biotin necessary for maximum growth was probably supplied by their norit eluate concentrates, since their method of preparation might also concentrate biotin.

during the first twenty-four hours of incubation. The vitamins and growth accessories, as given in Table I, completely replace yeast extract, which is considered¹¹ the best source of growth essentials for supporting maximum growth and acid production of *L. casei*.

Medium.—The composition of our complete basal medium is given in Table I. It is essential that all constituents be of the highest purity. Best results are obtained if the medium is prepared just before use. Stock solutions of tryptophane, cystine hydrochloride, salt solutions A and B, and purine bases may be kept on hand, using toluene as a preservative where necessary. Since the purine and pyrimidine bases are not readily soluble in water, it has been found convenient to dissolve them in the casein hydrolysate. After the addition of riboflavin to the medium, exposure to light should be avoided.

It is necessary that great care be taken in the preparation of the casein hydrolysate, since this is the only constituent whose composition is not chemically defined; it is, therefore, the only source of variation. Purified or "vitamin-free casein"¹² should be reprecipitated several times in order to remove traces of interfering vitamins, particularly nicotinic acid and pyridoxine. Reprecipitation is followed by the usual acid hydrolysis, and the resulting hydrolysate is treated with activated carbon, primarily for the removal of any biotin present. Culture medium containing casein hydrolysate prepared in this fashion supports maximum growth of the test organism and yields satisfactory blanks for all the six vitamin assays.

¹²Most caseins of this type are "vitamin free" to the extent of being satisfactory for animal assays, but they contain small quantities of vitamins sufficient to interfere with microbiological assays.

Reprecipitation of Casein.—To one liter of distilled water at 50° C. 100 Gm. casein are added gradually with stirring. This mixture is stirred for thirty minutes, 3 Gm. of sodium bicarbonate (dissolved in a convenient volume of water) are added, and the stirring is continued until the casein is dissolved. It may be necessary to add more water. When the solution is complete, the pH is adjusted to 4.6 with 10 per cent hydrochloric acid. The casein precipitate is allowed to settle and is removed by filtration. The reprecipitation procedure is repeated several times, depending upon the purity of the original casein. As a rule, several reprecipitations are necessary before satisfactory blanks can be obtained in culture medium prepared with the resulting hydrolysate.

Preparation of Casein Hydrolysate.—One hundred grams (dry weight) of the reprecipitated casein are hydrolyzed with 500 c.c. of 25 per cent sulfuric acid for ten hours at 15 pounds pressure. The sulfuric acid is neutralized with barium hydroxide and the barium sulfate is removed by filtration.

Treatment of Casein Hydrolysate With Activated Carbon.^{*}—Casein hydrolysate solution in a concentration of 10 per cent (total solids) is acidified to pH 3 and treated with Nuchar (1 Gm. of Nuchar to 10 Gm. of casein). The mixture is stirred for one hour and filtered through Filter-cel. The resulting hydrolysate may be preserved under toluene or sterilized by autoclaving.

Assay Procedure.—When we succeeded in obtaining maximum growth of *L. casei* in a medium of essentially known composition, we turned to the problem of establishing assay procedures. It was found that, for any one essential vitamin, growth and acid production were consistently proportional, within a limited range, to the amount of vitamin supplied. This quantitative response formed the basis for the following assay method:

For the assay of any one of the six vitamins, basal medium of twice the concentration given in Table I is prepared with the omission of the vitamin under test. Dilutions of the sample to be assayed are placed in culture tubes with sufficient distilled water to make a total volume of 5 c.c. in each tube. Five cubic centimeters of medium (twofold concentration) are added, giving a final total volume of 10 c.c. per tube. Similarly, dilutions of the vitamin used as a standard are prepared. The tubes are plugged with cotton and sterilized at 15 pounds pressure for fifteen minutes. After cooling, the tubes are inoculated with a suspension of *L. casei* and are incubated at 37.5° C. for seventy-two hours. Following incubation, the amount of growth is determined by titration of the acid produced, using 0.1 N sodium hydroxide. Titration may be colorimetric with bromthymol blue as the indicator, or electrometric, using either glass or quinhydrone electrode. Values obtained from the dilutions of the vitamin standard are used to construct a standard curve from which the vitamin content of any dilution of sample may be calculated. Typical standard curves for all six vitamins required by *L. casei* are presented in Fig. 1.

Preparation of Inoculum.—Stock cultures of *L. casei* are carried in yeast dextrose agar slabs and are transferred as recommended by Snell and Strong.¹ A twenty-four-hour culture of *L. casei* in 10 c.c. of yeast dextrose broth is centrifuged, and the bacteria are washed in 10 c.c. of 0.85 per cent sodium

^{*}Nuchar XXX, Industrial Chemical Sales Co., Inc., 239 Park Ave., New York, N. Y.

chloride solution. The washed sediment is resuspended in 4 c.c. of saline, and 1 c.c. of the resulting suspension is added to 85 c.c. of saline. One-tenth cubic centimeter of this dilute suspension per tube serves as the inoculum.

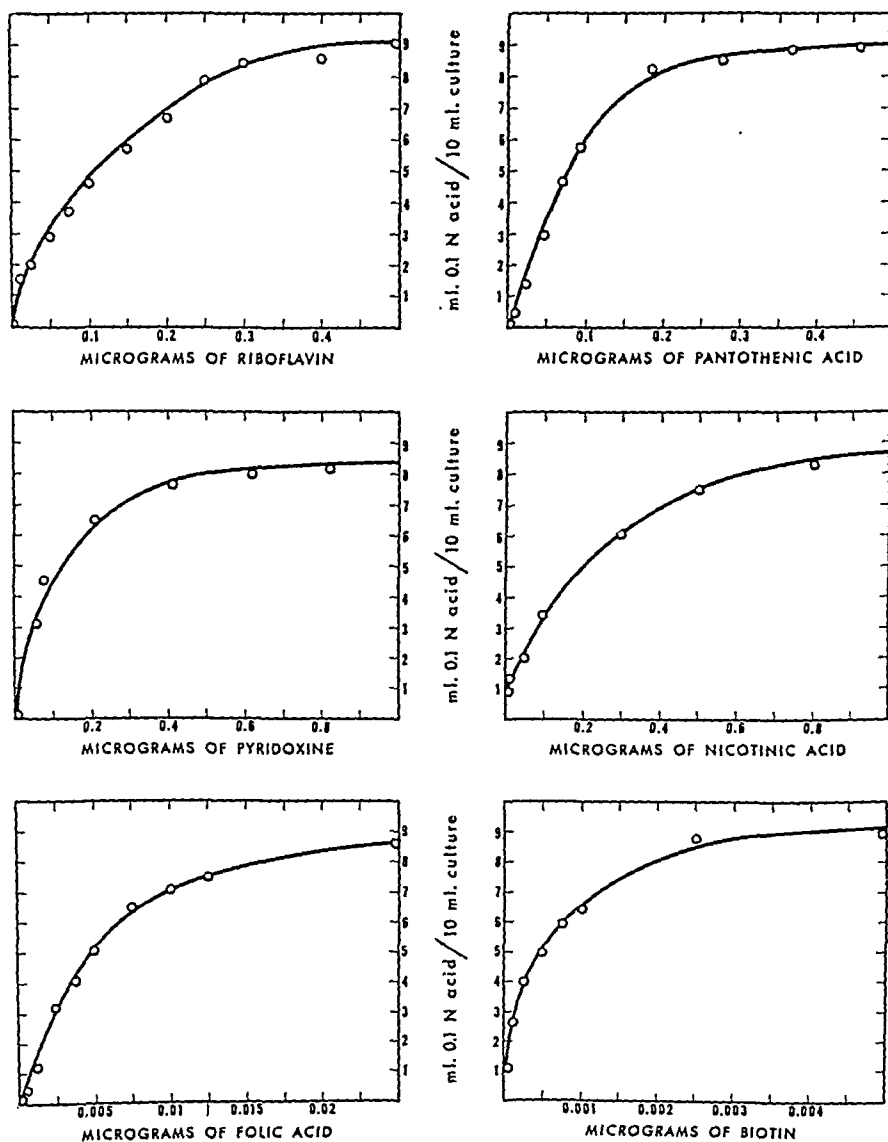

Fig. 1.—Standard assay curves for six B vitamins using *Lactobacillus casei* and a medium of essentially known composition.

DISCUSSION

From the data presented, it is clear that excellent growth of *L. casei* is obtained when riboflavin, pantothenic acid, nicotinic acid, folic acid, pyridoxine, and biotin are supplied in a suitable basal medium. Omission of any one of these essential vitamins will result in absence of growth and acid production. In the case of pantothenic acid, riboflavin, folic acid, and pyridoxine perfect blanks (no growth or acid production) were obtained. In the nicotinic acid

and biotin blanks a small amount of growth occurred, equivalent to approximately 1.0 c.c. of 0.10 N acid. Blanks of this magnitude are not prohibitive and do not interfere with accurate assay determinations. These blanks are due to traces of nicotinic acid and biotin which may ultimately be removed from the constituents of the medium.

For all six vitamins growth and acid production are, within a limited range, proportional to the concentration of the vitamin under test. The extreme upper and lower portions of the standard curve do not give reliable results, and only the portion of the curve which is linear, or approximately so, should be used for the calculation of assay values. When solutions or extracts of samples are run at several dilutions that fall within the accurate portion of the standard curve, values obtained at these different levels check closely.

The amount of each essential vitamin necessary for detectable growth of *L. casei* differs from one vitamin to another, but is minute in every case. This response to such small quantities provides sensitive tests for these vitamins. Because of this sensitivity, a sample to be assayed may be considerably diluted, thus eliminating or reducing the effect of nonspecific growth-stimulatory substances.

Preparation of the sample is an important part of the test, and one which, in the past, has not received the attention it merits. Liquid samples or water-soluble materials may be assayed without further treatment. Where the sample is particulate, autoclaving in large volumes of water at acid pH will, as a rule, provide quantitative extracts of most of the B complex vitamins. However, where the vitamin exists in combined form, as in the case of biotin, it is necessary to hydrolyze the sample in order to release the vitamin for utilization by *L. casei*. The methods for preparation of samples and the importance of such procedures, especially for biotin assay, have recently been reviewed.^{7, 17-19}

The vitamin content of various naturally occurring materials and concentrates was determined both by our assay procedure and by established microbiological methods. Such parallel comparison assays of yeast and rice bran concentrate for riboflavin by the Snell and Strong method and for pantothenic acid by the method of Pennington, Snell, and Williams were in excellent agreement, while results of our biotin assay of a biotin concentrate compared favorably with values obtained by the yeast growth method of Snell, Eakin, and Williams. Although comparison with other methods has not been made for nicotinic acid, folic acid, and pyridoxine, it is probable that satisfactory results would be obtained, since the response of *L. casei* to these vitamins is similar in sensitivity, magnitude of blank, and type of standard curve to that obtained with riboflavin, pantothenic acid, and biotin.

SUMMARY

1. Maximum growth and acid production of *L. casei* have been obtained in a medium in which all constituents, except casein hydrolysate, are chemically defined.

2. Using this medium of essentially known composition with *L. casei* as the assay agent, it has been possible to establish a general assay procedure

for the vitamins essential for growth and acid production by this organism, viz., pantothenic acid, riboflavin, nicotinic acid, pyridoxine, folic acid, and biotin.

ON THE DETERMINATION OF URINARY CHOLESTEROL*

MAURICE BRUGER, M.D., AND SYLVIA B. EHRLICH, A.B.
NEW YORK, N. Y.

IN 1933, Mirsky¹ described a colorimetric procedure for the estimation of urinary cholesterol based upon the observation of de Toni,² who found that the tungstic acid precipitate of blood contained all the cholesterol. The method proposed by Mirsky utilized the addition of a 50 per cent solution of sodium tungstate to urine, and the subsequent slow addition of concentrated sulfuric acid to precipitate the tungstic acid. When observations on the excretion of cholesterol in the urine in patients with cancer were begun in this laboratory,³ it was found that this procedure, at times, failed to recover satisfactory amounts of serum cholesterol added to the urine. It was assumed that urines, particularly from persons without renal disease, contained an insufficient amount of protein to carry down all the cholesterol. The addition of egg albumin to the urine was found to be a necessary step in order to obtain satisfactory recoveries of added cholesterol.

Preparation of Egg Albumin Solution.—The separation of the egg albumin from the yolk must be done carefully, since it is known that egg yolk contains appreciable quantities of cholesterol. The egg white was diluted with 9 volumes of distilled water and the solution was filtered through fluted filter paper. The cholesterol content of each batch of diluted egg albumin was determined; small amounts of cholesterol were invariably present, but the quantities in different batches were found to be remarkably constant (0.15 mg. in 100 c.c. of diluted egg albumin solution). Corrections for the cholesterol content of the added egg white were made in final calculations.

METHOD

One hundred cubic centimeters of urine are placed in a 150 c.c. beaker or other suitable container. The urine is acidified with 0.5 c.c. of concentrated sulfuric acid, and 10 c.c. of the diluted egg albumin solution are added. After mixing, the albumin is precipitated by the addition of 5 c.c. of 10 per cent solution of sodium tungstate. The contents are again well mixed, and the precipitate is allowed to settle out for five to ten minutes. The solution is now filtered through a fluted filter paper (previously rendered fat free by washing in alcohol and ether). The protein precipitate is washed repeatedly with hot distilled water; the extent of the washing varies with the quantity of urinary pigment in the protein coagulum (50 c.c. to 100 c.c. of water usually suffice).

*From the Medical Research Laboratory, Department of Medicine, New York Post-Graduate Medical School and Hospital, Columbia University, New York.
Received for publication, January 28, 1942.

The precipitate and filter paper are transferred to a 150 c.c. beaker, and 30 c.c. of a 3:1 alcohol-ether mixture are added. This is allowed to stand for fifteen to thirty minutes or, if more convenient, overnight. The beaker is then placed on an electric hot plate. The contents are brought to a boil and are then filtered through fat-free filter paper into another beaker of the same capacity.

2 x 300	3.947	3.750	1.316	1.250	2.6
2 x 300	0.444	0.460	0.148	0.153	1.6
2 x 300	0.559	0.547	0.186	0.182	1.1
2 x 300	0.556	0.559	0.185	0.186	0.3

Two additional extractions with alcohol-ether are made, and the filtrates are combined. The alcohol-ether extract is placed in an incubator (37° C.) and evaporated to dryness. To the dry residue in the beaker 30 c.c. of petroleum ether (B. P. 30° to 50° C.) are added. The beaker is placed on a hot plate and the petroleum ether is evaporated to approximately 10 c.c. volume. This is filtered through fat-free cotton or filter paper into another beaker; two additional petroleum ether extractions are carried out, and extracts are combined. This extract is placed in an incubator (37° C.) and is evaporated to dryness. The residue is extracted with 5 c.c. of chloroform, the chloroform extract is transferred to a graduated cylinder of 10 c.c. capacity; 2 c.c. of acetic anhydride and 0.1 c.c. of concentrated sulfuric acid are added. A standard solution containing 0.5 mg. of cholesterol in 5 c.c. of chloroform is prepared simultaneously for the development of the Liebermann-Burchard color reaction.⁴ A red filter (Wratten 71-A) is used to facilitate color matching.

Calculation.— $\frac{R_s}{R_u} \times 0.5 \times \frac{100}{X} = \text{mg. cholesterol in 100 c.c. of urine}$

Where R_s = reading of standard

R_u = reading of unknown

X = volume of urine extracted

For the determination of cholesterol in normal urine approximately 300 c.c. of urine must be extracted if the twenty-four-hour-urine volume does not exceed 1,500 c.c. With dilute urines, larger amounts must be extracted. This is done, preferably, by working with 100 c.c. quantities and combining the petroleum ether extracts.

RESULTS

Tables I and II are self-explanatory. The satisfactory recovery of added cholesterol to urine and the close correlation of duplicate determinations are shown in the protocols.

SUMMARY

A satisfactory colorimetric procedure for the determination of urinary cholesterol employing the addition of egg albumin to bind the cholesterol is described.

AN IMPROVED PYKNOMETER FOR BLOOD SERUM*

R. A. MORTENSEN, PH.D., LOMA LINDA, CALIF.

FOR the direct determination of the specific gravity of blood serum, as well as for the standardization and checking of the various indirect methods, a specially constructed specific gravity bottle, introduced by Moore and Van Slyke,¹ has been extensively used. However, precise adjustment of the volume of the liquid is generally troublesome. The uncertainty of seating of the ground stopper and the tendency of serum to seep up by capillary attraction between the stopper and the neck cause significant errors unless time-consuming measures are taken for their prevention. These difficulties are not encountered in a pycnometer of the pipette type, such as the one employed by Brown and Clark,² but it is always necessary to adjust the meniscus in the capillary exactly to a calibration mark. The pycnometer here described provides a more rapid and precise measurement by utilizing the principle of automatic volume adjustment employed in the well-known Trenner blood-diluting pipette.

This pycnometer, which is not difficult to construct, consists of a thin-walled bulb *D* sealed to bent capillary tubes *C* and *E*, as shown in Fig. 1. The internal diameter of *E* is about 0.5 mm., and that of *C* is somewhat greater, but the tip *A* is drawn down to approximately the same size as *E*. The end of the capillary at *H* is a ground and polished surface at right angles to the longitudinal axis, and represents the point to which the liquid is brought in filling the device. A small bulb *F* serves to prevent the liquid from entering the capillary *G* too rapidly after filling the main bulb.

Sizes from 1 to 2 ml. have been found to be satisfactory. If many samples are to be measured, a considerable saving in time may be effected by constructing the pycnometer to contain an integral number of grams of water at 20° C. This is accomplished conveniently by expanding or shrinking the bulb before bending the capillary stems. Subsequent bending of the tubes produces a slight decrease in volume, permitting final adjustment to be made by enlarging the capillary at *B* and grinding the tip.

In using the pycnometer, a rubber suction tube is attached to the end *I*, and the serum contained in the short test tube *T* is drawn up to the small bulb *B*. The test tube is then tilted at an angle while the end *E* is lowered, permitting the liquid to flow to *H* by gravity and capillary action. The pycnometer is next removed from the test tube and quickly wiped with a damp cloth, while *A* is maintained at a slightly higher level than *H* in order to lessen the chance of drawing the liquid away from the latter.

Measurements are made at room temperature and the weight at 20° C. is estimated by applying a suitable correction. The number of milligrams to be

*From the Department of Biochemistry, School of Medicine, College of Medical Evangelists, Loma Linda.

Received for publication, February 20, 1942.

added to, or subtracted from, the weight at room temperature to give the weight at 20° C. may be obtained from a chart prepared by Moore and Van Slyke.^{1, 2} In order to avoid warming the liquid, the pyknometer is filled as quickly as possible, care being taken to handle it only by the stems at points well removed from the bulb. Loss of liquid due to expansion during weighing may be prevented by forcing a small drop out of the capillary at *H*. With these precautions satisfactory results can be obtained without the use of a thermostat. Evaporation of the serum will ordinarily cause no significant decrease in weight. In one test the loss was less than 0.1 mg. when the filled pyknometer was left in the balance case for one-half hour.

Fig. 1.—Pipette pyknometer with automatic volume adjustment.

The pyknometer is capable of yielding results which are accurate within one or two units in the fourth decimal place, with a minimum expenditure of time and effort. In a long series of measurements on the same sample, using the 1 ml. size which was cleaned, dried, and refilled for each determination, the maximum deviation from the mean specific gravity was less than 2×10^{-4} .

Although designed for use with blood serum, the device obviously may be employed for determining the specific gravity of other aqueous solutions.

MEDICAL ILLUSTRATION

WAX-RESIN COMPOSITIONS FOR MOULAGE-MAKING

CARL DAME CLARKE, PH.D., BALTIMORE, MD.

IN THE April, 1942, issue of this JOURNAL¹ I, together with a co-worker, described a basic agar composition for making molds or negatives of living and dead tissue to be used in moulage work. Since a cast or a positive is made in such a mold, I wish to confine the present article to the basic materials used in making the positive. There are numerous materials that can be employed for this purpose, such as wax-resin mixtures, celluloid, rubber, and a synthetic fleshlike gelatin mixture. Rubber has been discussed in a previous article.² Celluloid, as well as wax-resin mixtures, has been discussed to some extent in my book *Molding and Casting*.³ Because of the shortage of rubber, experiments are in progress at the present time to develop a suitable substitute for making both positive and negative moulages. This work will be published at a later date.

The average novice has had greater success in working with waxes and resins for the positive; therefore, these materials will be considered here in some detail. Furthermore, the wax-resin mixtures lend themselves more readily to corrections. They also can be used over again in the event of a failure. When the moulage worker has become thoroughly familiar with rubber, celluloid, and gelatin mixtures, he will find that they are as simple to compound and use as the wax-resin mixtures. All these materials, when properly used, possess the translucency of flesh, which is the first essential in choosing any positive composition. In contrast to these materials, plaster of Paris and papier-mâché, which are among the most common positive materials, lack this translucency, and, for this reason, cannot be used with the same degree of success in making facsimile reproductions of protoplasmic objects.

Probably the greatest drawback to the use of wax-resin mixtures is the fact that the resulting cast is broken easily. This disadvantage is overcome when the cast is made of celluloid, rubber, or gelatin mixtures. However, the wax-resin cast is important because it is often used as an intermediate step in making casts of other materials. For example, in a rubber facial prosthesis a wax cast generally is made first and fitted to the patient before the rubber one is made. Necessary changes to obtain perfect fitting are easier to effect in wax than in rubber. Accordingly, a basic wax-resin formula will be considered in detail.

The wax-resin composition used for the positive impression should possess the following qualities:

1. It should be possible to brush or "paint" the positive composition into a plaster or agar mold without having the cast crack or lift from the surface of the mold.

2. The melting point should be so high that it will not be affected by natural heat in the hottest weather. A cast, no matter how thin, should never droop as a candle often does under normal summer temperatures.

3. It should not crack or shrink to any great extent when subjected to the normal cold of winter.

4. It should not crack under sudden changes of temperature, as does a thin layer of hot wax of a high melting point when poured into a cold mold.

5. The shrinkage of the positive wax should be so slight as to cause no cracks when it is shrinking against a rigid mold or after it has been mounted.

6. It should become set, yet remain pliable, at a degree of heat low enough for it to be bent or formed with the hands without breaking or cracking the wax or fear of burning the hands; nor should the composition stick to the hands. This pliability is advantageous, since it often becomes necessary to bend a positive composition into a more desirable shape. For example, it may be necessary to bend the positive to relieve it from some undercut surface on a rigid plaster mold. After the positive has been relieved of such an undercut, it can be rebent to its normal position.

These rigid requirements should be kept in mind when considering the published material on positive formulas.

ADVANTAGES OF BEING ABLE TO APPLY THE POSITIVE MATERIAL WITH A BRUSH

A positive wax-resin material that can be brushed, spread, or painted, instead of being poured into the mold, offers decided advantages which may be enumerated as follows:

1. It eliminates the danger of the much dreaded border lines, i.e., lines caused by the junction of hot and cold waxes on a smooth surface. The hot and cold waxes do not blend together, and as a result a line is formed where the waxes of different temperatures meet.

2. The application of the positive with a brush permits a freedom of working without the necessity of lifting heavy molds to turn them in various positions so that the wax will flow evenly and in the same thickness over the entire mold. This same method, when applied to large forms, will prevent a great outlay of physical strength and nerve-racking exertion, which also may require the assistance of helpmates to produce the cast.

3. It is far more economical to "paint" a mold than to pour one, because a quantity of wax may be lost or damaged beyond further use by dripping over the edges of the mold while the latter is being rotated, at the same time soiling one's clothing and burning the hands. The composition may fall on the floor, worktable, or any place except where it should go.

4. "Painting in" makes it possible to fill the separate sections of a piece mold before they are put in place and insures the surfaces of being well and evenly covered. After they have been put in their proper places, the positive pieces may be cemented together by the application of more wax, which may be poured or painted into the cracks between the positive pieces.

5. In painting with the positive substance rather than pouring it into the mold, it is possible to apply masses of different materials and colors next to

one another in the same layer. By the application of one translucent color over another, interesting and lifelike effects may be obtained. One may spread on the mold a wax composition to resemble the skin in color and texture to the edges of a gapping, moist, reddish wound, which would ordinarily glisten with high lights. This wound area of the cast can be painted in with a different material and color from that of the skin. While this second material may have a wax base, it can be incorporated with other materials, such as various gums, to produce the desired glossy effect.

Fig. 1.—A wax-resin mouldage of a hand affected with smallpox. This cast was made in a one-piece agar mold. A formula for pouring was used.

6. One may prepare a palette from an ordinary muffin pan and fill each cup with positive wax material which has been mixed with a different color. The caster may then use this muffin pan as an artist does his palette in painting a canvas; the caster paints his mold instead. The thin applications of the various colors on this mold must be strengthened or backed up by a thicker layer of wax, then reinforced with gauze, cheesecloth, or burlap fibers or threads.

In this manner the small blue vessels, which lie beneath the transparent skin, can be incorporated into the cast in the most naturalistic manner. Another indication for the use of color in the same way is a typical hemorrhage under the skin. The fresh flowing blood possesses a different color from stag-

nant blood. Thus the vessels may be painted red on a thin coating of semi-transparent positive formula which has been applied to the mold. These vessel details are then backed with more composition and finally strengthened with gauze, cheesecloth, or burlap. When the cast is finally removed from the mold, the vessels appear to lie under the skin rather than painted on the surface, as is so often done by the caster. It is interesting to note that *red* vessels under an ivory colored skin appear *blue* when viewed through the skin. This may be tested by placing a piece of ivory-colored tracing paper over dark red marks drawn on white paper. These red marks will seem to be blue, provided the right shade of tracing paper and the proper shade of red are used.

Fig. 2.—A wax-resin mouldage of a syphilitic gumma. This cast was made in a one-piece agar mold.

There are unlimited possibilities for the specific use of a positive material that can be painted into the mold rather than one that must be poured. In fact, these advantages are too numerous to mention. However, they will suggest themselves as the worker begins the making of molds and casts.

A simple basic formula for brushing into the mold is as follows:

	PARTS BY WEIGHT
Paraffin (about 55° C.)	8
Carnauba wax	1
Rosin, water-white, lump	8
Red oil-soluble dye	q.s.

The following is a suitable formula for pouring into the mold:

Paraffin (about 55° C.)	8
Carnauba wax (light)	1
Rosin, water-white, lump	2
Red oil-soluble dye	q.s.

RESIN*

In spite of the fact that such work is often called "wax" casting, resin is the basic substance in those formulas which are the most simple to use and have the most versatility. Resin gives the compositions toughness and the quality of bending without breaking; it hardens more slowly, and prevents warping and cracking to a great extent. Common rosin or colophony is generally used for this purpose because of its cheapness. Bleached resin (i.e., water-white) serves better where the chromatic intensity is to be kept low. *The resin content should amount to about half of the mixture*, otherwise brushing of the positive mixture into the mold is sometimes rendered difficult and leaves "lap lines" or border lines. Such lines are formed where a hot mixture meets a cold or set mixture of the positive material and causes a line to appear at the junction of the hot and cold mixtures. Compositions containing a large percentage of resin do not flow easily into fine details unless they are painted into the mold.

If the rosin is powdered or if too much is applied, it may oxidize quite readily, turn dark, and separate from the mixture as a nonsoluble precipitate in the bottom of the pot (see Compounding).

WAX

Low Melting Point.—The viscosity and viscidty, or internal friction, of resins are reduced by the addition of a wax. Such waxes are paraffin, white beeswax, ceresin, and spermaceti. Here again the cheaper product, paraffin, is generally chosen.

High Melting Point.—The melting point of a wax and resin composition may be raised by the addition of a wax having a high melting point. Such waxes are carnauba, montan, and Chinese wax. Carnauba, light, is usually selected. The amount of such a wax that is used in the composition should never be more than one-tenth the weight of the resin; otherwise shrinkage and brittleness of the entire composition will result.

In addition to raising the melting point of a wax-resin mixture, carnauba wax also improves the flowing qualities of the mixture and makes it possible to obtain a sharp impression of skin detail, such as the fingerprint pattern. If this wax is not included, the resulting cast may be soft and lack sharp, concise detail.

COLOR

Where it is desirable to have the wax-resin mixture of a basic flesh tone which is composed of red and yellow, a permanent red oil-soluble dye is added. A yellow dye is not used because the yellow of the carnauba wax and resin is sufficient. The red dye mixes with the yellow of the wax and resin to produce the flesh tint. Of course, such a dye must be used sparingly. A gram or so of dye is dissolved first in about 200 c.c. of turpentine. An eye dropper is then

*The term "resin" means an amorphous substance that exudes from plants. The term "rosin" indicates the residue remaining after the distillation of oil of turpentine. Generally, common rosin is the resin of the pine tree. It is also called colophony. Gum mastic, gum dammar, and similar substances are also resins but they are not rosins. Gum rosin darkens less rapidly than what is called wood rosin. Both are obtained from the pine tree. Gum mastic or gum dammar could be substituted for rosin (colophony) but these resins are decidedly more expensive.

used to place a drop at a time of this solution into the melted wax-resin mixture until the desired shade is reached. From time to time the resulting color may be observed by placing a few drops of the melted mixture on a piece of white paper. When this sets, it is carefully studied in daylight to see whether it is of the basic shade desired. The final monotone wax-resin cast is fixed with shellac or lacquer and then tinted with the proper oil-soluble pigments.

COMPOUNDING

Water is placed in the bottom section of a double boiler and brought to a boil. The fire is then cut down until the water just boils. Rapid boiling may cause the mixture to become too dark. This is important, because excess heat or prolonged heating causes the resin of the mixture to darken and separate as an insoluble resin. The waxes only are placed in the top section and allowed to melt completely before the resin is added. At no time must the pot be allowed to boil vigorously while the resin is mixed with the wax. Heating may be continued with occasional stirring, until the resin is melted completely. Prolonged heating causes it to darken. In fact, some workers prefer to melt the waxes thoroughly and then cut off all heat before adding the resin, depending on the stored-up heat in the waxes and the water section of the double boiler to melt the resin. This does not always suffice, but it will serve to impress upon the worker the importance of not getting the resin too hot.

The basic formulas herewith presented may be varied to suit specific purposes or they may be used as specified. Other waxes and resins may be substituted. Those given were chosen because their cost was decidedly less than waxes and resins having similar qualities, such as melting points and viscosity.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

CIRRHOSIS, Hepatic, Serum Proteins in, Post, J., and Patek, A. J. Arch. Int. Med. 69: 67, 1942; Ibid. 69: 83, 1942.

Of 61 patients with cirrhosis of the liver, 54 had an abnormal albumin-globulin ratio on admission to the hospital. These data confirm the reports of other authors.

The prognosis as to duration of life becomes increasingly grave as the level of serum albumin decreases. The levels of the serum globulin and the serum total protein have no such prognostic significance.

There is a direct correlation between the level of the serum albumin and the clinical course. Clinical improvement is associated with a rise in serum albumin toward normal. In instances of clinical failure there is no sustained rise.

The level of serum albumin is significantly lower in patients with ascites than in those without ascites.

Diuresis is associated with a rise in serum albumin. The mean value for serum albumin at which diuresis occurs is 3.1 Gm. per 100 c.c. (standard deviation, 0.2 Gm.).

From the data presented, it appears that a reduction in serum albumin is an essential factor in the formation of ascites.

Nitrogen balance studies were made on 5 patients with cirrhosis of the liver, ascites, and reduced serum albumin. Although the patients remained in positive nitrogen balance during the periods of high protein feeding, there was no correlated rise in the level of the serum albumin. In this respect these patients differ from persons with simple protein starvation.

The data recorded here indicate that patients with cirrhosis of the liver absorb and retain food protein. The evidence suggests that the mechanism for the synthesis of serum albumin is impaired.

VAGINAL SMEARS, New and Rapid Method of Staining Based Upon a Specific Color Reaction for Glycogen, Mack, H. C. Harper Hosp. Bull. 1: 54, 1942.

1. *Preparation of Smears.*—A moistened cotton applicator is inserted into the vagina and twirled slightly (one complete rotation) against the vaginal wall. The cotton end of the applicator is then rolled lengthwise over the surface of a clean glass slide. By rolling, rather than rubbing, a uniformly thin film of cells, with minimal clumping and cell distortion, results. The film dries almost immediately and may be stained at once.

2. *Staining of Smears.*—Staining is accomplished simply by laying the slide, face down, over a shallow dish containing a small amount of Lugol's solution. Iodine vapors which arise insensibly from the solution suffice to stain the glycogen-containing cells in two or three minutes. Microscopic examination may be carried out immediately. Although such stains fade in from twenty-four to forty-eight hours, restaining (by the same method) may be carried out repeatedly if later examinations are desired.

SYPHILIS, Biologic False Positive Serologic Reactions in Tests for, Mohr, C. F., Moore, J. E., and Eagle, H. Arch. Int. Med. 68: 1161, 1941.

The authors have reported the cases of 11 nonsyphilitic patients with various diseases in whom transitory biologic false positive serologic reactions for syphilis were observed.

When analyzed quantitatively, a low titer was usually revealed in these tests, but in the tests on 2 patients, one with a sore throat and one with pneumonia, a high titer, comparable to that seen in the early stages of syphilis, was observed.

It is suggested that a complement fixation test with spirochetal antigen (pallida test) may be helpful in differentiating false from true positive reactions.

In view of the enormous increase in the routine use of serologic tests for syphilis, the necessity for caution in their interpretation is emphasized.

NOSE, Normal and Abnormal Bacterial Flora of, Jacobson, L. O., and Dick, G. F. J. A. M. A. 117: 2222, 1941.

Cultures of nasal secretion were made as a matter of routine for 500 patients admitted to a general medical service, none of whom had been admitted because of a primary complaint referable to the nose or the paranasal sinuses.

The authors find in agreement with most observers that the normal nasal flora consists chiefly of *Staph. albus* and diphtheroid bacilli, and less frequently, of *Staph. aureus* and *M. catarrhalis*.

Green-forming streptococci and pneumococci are occasional transients in the nasal cavity.

The presence of streptococci, pneumococci, *B. mucosus*, Pfeiffer's bacilli, and diphtheria bacilli indicates disease of the nasal mucosa or sinus disease, or both.

The frequency with which green-forming streptococci, hemolytic streptococci, and pneumococci were isolated by culture of nasal secretion in cases of sinusitis, acute or chronic, shows the diagnostic value of this simple, inexpensive procedure.

ANEMIA, The Significance of Target Cells in, Bohrod, M. G. Am. J. M. Sc. 202: 869, 1941.

Target cells are commonly seen in the regeneration of blood, regardless of the cause of the blood loss.

In acute anemias they are present for only a short time early in the regeneration phase, and they have disappeared by the time a significant rise of erythrocyte count is evident. In chronic anemias they may be present over long periods of time.

The question of the normal shape of the circulating erythrocyte should be re-examined. It is possible, but not yet proved, that the target cell preserves the bowl shape of the intravascular cell in modified form and resists deforming influences which are responsible for producing the biconcave disc seen in blood outside the body.

The target cell is a hyperresistant cell produced by the bone marrow in response to the blood loss. Increased resistance to the hemolytic action of hypotonic saline and to acetic acid has been demonstrated.

The contention that the target cell represents the fundamental defect in Cooley's anemia seems to be unjustified. It is simpler, in the light of available evidence, to regard the target cell in this disease, as in sickle-cell anemia and many other anemias, as a response to the blood destruction rather than the cause of it.

SYPHILIS, The Kahn Verification Test, Chargin, L., and Rein, C. R. Arch. Dermat. & Syph. 44: 1031, 1941.

The reactions to the Kahn verification test were studied for 1,565 persons with various conditions, comprising syphilis, various nonsyphilitic dermatoses, questionable conditions, pregnancy, contagious diseases, pinta, malaria, leprosy, and miscellaneous conditions.

In the group of 319 syphilitic patients, who had received varying amounts of treatment, the verification tests gave the syphilitic type reaction in 100 per cent of those with strongly positive serodiagnostic reactions, in 76.5 per cent of those with weakly positive reactions, and in 40.2 per cent of those showing doubtful reactions. There were no reactions of the syphilitic type in the patients with negative serodiagnostic reactions. The incidence of the general biologic type of verification reaction in the group with negative serologic reactions was 7.1 per cent, and in the group with doubtful serologic reactions it was 12.1 per cent.

In the nonsyphilitic group, 269 in number, there were only 2 patients who had a syphilitic type of verification reaction. Syphilis could not be established in these patients. The incidence of biologic reactions in this group varied from 13.8 to 47.6 per cent.

In the questionable group of 253 members, 83 patients (32.7 per cent) gave a syphilitic type of verification reaction. Further study is necessary to determine whether they actually had syphilis. The incidence of the general biologic (nonsyphilitic) type of reaction in this group varied between 2.3 and 38.6 per cent.

In the group of patients with acute contagious diseases the general biologic (nonsyphilitic) type of verification reaction was obtained in between 29.3 and 64.0 per cent, and in the pregnant women this type reaction was obtained in between 21.2 and 55.5 per cent.

The highest incidence of the general biologic (nonsyphilitic) type of reaction is found to be associated with the doubtful serodiagnostic reactions in all groups.

The percentage of the syphilitic type of verification reaction increases with the increase in the titer of serodiagnostic reaction.

In the group of 268 patients with pinta, all of whom gave strongly positive serodiagnostic reactions, 83.9 per cent gave a syphilitic type of reaction to a verification test.

Agreements as well as discrepancies were observed in a number of blood specimens that were subjected to repeated verification tests.

ZIEHL-NEELSEN STAIN, Sulphonamides and the, Mary John, Sr. Am. J. M. Technol. 7: 256, 1941.

Observations are reported showing that after the administration of sulfonamide drugs the sputum may contain crystals which are acid-fast and which may rather closely resemble *B. tuberculosis*.

These are seen as long slender, acid-fast rods, sometimes curved, sometimes short and straight, sometimes in bristling clumps.

It is advisable that these drugs be discontinued before sputum examinations for tubercle bacilli are reported as positive.

TRICHINOSIS, A New Precipitin Test for, Roth, H. Acta Path. et microbiol. Scandinav. 18: 160, 1941.

Living infective larvae of *Trichinella spiralis*, when incubated at 37° C. in the sera of patients suffering from trichinosis or of guinea pigs or rabbits, experimentally trichinized, give rise to the formation in the sera of microscopically visible precipitates. However, no specific deleterious effect of such immune sera on the larvae has as yet been seen. The diagnostic value of this new microscopic test is compared with that of a simplified modification of the usual macroscopic Buchman precipitin test (using a filtrate of the saline extraction of dried trichina larvae as antigen). Both reactions seem to depend on the same antibodies present in immune serum, but the microscopic test may sometimes be more delicate in the demonstration of very slightly developed antibodies.

SPUTUM, Physical and Chemical Properties of, Basch, F. P., Holinger, P., and Poncher, H. G.: Am. J. Dis. Child. 62: 981, 1941.

The tracheobronchial tree of patients with bronchiectasis contains three essentially different types of sputum, which are not to be confused with the three layers into which the sputum of patients with bronchiectasis or abscess of the lung divides on standing.

To effect the series of the changes which occur spontaneously in the sputum during its movement from the lowest to the highest levels of the tracheobronchial tree, from which it may be coughed out, certain physical, chemical, and bacteriologic actions take place. The changes are not due to physical processes which cause liquefaction or thickening, because a parallel has not been found between the viscosity and the content of solid substances of the sputum.

The secretion from the most dependent portion of the tracheobronchial tree, designated as the third portion, is never coughed up, but is obtainable only by bronchoscopic suction. It has an extremely high viscosity and a high content of organic and inorganic substances. This sputum becomes even thicker after it is removed from the bronchi.

The third portion is moved to a higher level both by the tussive squeeze and by the pressure of secretions to form the second portion, which is found in the trachea and the larger bronchi. The second portion is a liquefied sputum which has a lower viscosity, a lower dried residue and a lower percentage ash than the third portion.

On the top of this secretion, after a rest period, a plug is found which has a moderately high viscosity but a dried residue and percentage of ash which are even lower than those of the second portion.

The sputum of patients with massive collapse of the lung shows a decrease in viscosity during the course of the disease in spite of a marked increase in its content of organic and inorganic material. This spontaneous dilution is probably due to bacterial action.

The characteristic properties of the sputum of patients with bronchiectasis, and post-operative massive collapse of the lung may be due to a variety of factors which may be summarized as follows: (1) selective secretion, (2) selective resorption, (3) speed of movement of secretions from one level to another, (4) bacterial action, and (5) combinations of the foregoing factors.

VAGINAL FLORA in Children, Hardy, G. C. J. Dis. Child. 62: 939, 1941.

In a study in which a limited attempt was made to ascertain the etiologic agents of vaginal infection in girls, the only bacteria which could be incriminated were the gonococcus, the group A streptococcus and, possibly, the diplobacillus of Petit.

In the case of the last two organisms, there is bacteriologic evidence, clinical evidence, or both, of an interrelation between infections of the upper respiratory tract and those of the genital tract.

The streptococcus found simultaneously in the upper respiratory and the vaginal tract were types 11, 24, 25, and 28.

Further study of the diplobacillus, which, superficially at least, may be confused with the gonococcus, is indicated. Gonorrhea should not be diagnosed without complete cultural studies.

Among the patients studied, very few, apart from the premature group, could be considered normal. The large number of purulent secretions found in the children in the hospital wards suggests that such a reaction may be the concomitant of a variety of illnesses or constitutional states. Saprophytic organisms appear to grow in the vaginas of such patients with little restraint. For information concerning normal vaginal flora of childhood the authors recommend study of a group of healthy girls.

More anatomic and histologic studies should provide a better understanding of vaginal infections, so that rational treatment could be devised. An attempt should be made, also, to give adequate clinical attention to patients with such infections as early in the course of the illness as possible.

CARBON DISULFIDE POISONING, Neuropathologic Changes in Experimental, in Cats, Ferraro, A., Jervis, G. A., and Flicker, D. J. Arch. Path. 32: 723, 1941.

Five cats were exposed to varying doses of carbon disulfide. The most important changes in carbon disulfide poisoning consist in (a) diffuse vascular involvement of the productive type, i.e., proliferation of capillaries and hypertrophy of the walls of blood vessels, often leading to endarteritis; and (b) diffuse neurocellular changes, ranging from chromatolysis to severe degeneration, diffusely scattered all over the brain and cerebellum.

Both cortical and subcortical structures are involved. The lesions are particularly evident in the corpora quadrigemina, the cerebellar nuclei, and the vestibular nuclei. The region of the cerebellar nuclei constitutes an area where the change is definitely predominant, and in 4 of 5 cases the pathologic involvement leads to bilateral softening of this region. Next to the cerebellar nuclei, the vestibular area is the one most intensely involved. In an animal in which the exposure to the action of the gas was most prolonged, softening was also found in the lenticular nucleus and in the substantia nigra.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

The Diseases of the Eye*

SURELY there are few medical students who have graduated since 1900 who are not well acquainted with May's little textbook. May has always kept it small, although it has perforce become a little larger during the years. A book which is now in its seventeenth American edition, has been translated into nine foreign languages, and has had forty-four editions in foreign lands scarcely requires review.

Infant Nutrition†

THE late Professor Marriott's excellent book has been revised by Dr. P. C. Jeans of the University of Iowa. The work starts with the growth of the infant and child and its physiologic development, particularly as regards nutrition. Then follow sections on the various types of metabolism, carbohydrate, protein, mineral, water, fat, and vitamin. The major portion of the volume is given to gastrointestinal and nutritional disturbances of infancy and childhood, with rather general discussion of remedial measures. General principles are emphasized. There is no padding with sample diets, case histories, and the like.

Diseases of the Digestive System‡

A ROUTINE book covering the field indicated by its title, *Diseases of the Digestive System* is written by fifty well-known contributors. It seems to cover the field adequately and should be of service to gastroenterologists and to men practicing more general medicine.

The Art and Science of Nutrition§

VERY profusely and well illustrated, this volume is written primarily for students of dietetics. It discusses normal nutrition, food requirements under special conditions, dietary therapy, and the choice, preparation, and serving of foods. In the last section, about 140 pages, there is a profusion of tables, recipes, and diets which should be of help to those whose interest is in the scientific preparation of foods.

*Manual of the Diseases of the Eye. For Students and General Practitioners. By Charles H. May, M.D., Consulting Ophthalmologist to Bellevue Hospitals, New York. Formerly Chief of Clinic and Instructor in Department of Columbia University, and Director of the Eye Service of New York. Revised with the assistance of Charles A. Perera, M.I. College of Physicians and Surgeons, Medical Department of Columbia University, New York. Assistant Attending Ophthalmologist, Presbyterian Hospital, New York. Cloth, ed. 17, 519 pages, 337 illustrations, including 32 plates and 93 colored figures. William Wood and Company, Baltimore, Md., 1941.

†Textbook of Infant Feeding for Students and Practitioners of Pediatrics. By McKim Marriott, B.S., M.D., Late Professor of Pediatrics, Washington University School of Medicine; Physician in Chief, St. Louis Children's Hospital, St. Louis. Revised by P. C. Jeans, A.B., M.D., Professor of Pediatrics, College of Medicine, State University of Iowa, Iowa City. Cloth, ed. 3, 475 pages. The C. V. Mosby Company, St. Louis, Mo., 1941.

‡Diseases of the Digestive System. Edited by Sidney A. Portis, B.S., M.D., F.A.C.P., Associate Professor of Clinical Medicine, Rush Medical College of the University of Chicago; Attending Physician, Michael Reese Hospital; Consulting Physician, Cook County Hospital, Chicago. Cloth, 532 pages, illustrated with 176 engravings, \$10.00. Lea & Febiger, Philadelphia, Pa., 1941.

§The Art and Science of Nutrition. A Textbook on the Nutrition. By Estelle E. Hawley, Ph.D., and Grace Carden, B.S., 1941. School of Medicine and Dentistry, Rochester, N. Y. Cloth, 619 pages, including 12 in color, \$3.50. The C. V. Mosby Company, St. Louis, Mo., 1941.

University of California Hospital Formulary*

A POCKET compendium of useful information for internes and fourth-year medical students which would be appropriate for any hospital or any school; this Formulary contains such subjects as prescription writing, materia medica, discussion of buffered and isotonic solutions, dosage tables for various drugs, endocrine products, vitamin preparations, etc. Its therapeutic index suggests the appropriate drug for various symptoms and pathologic states. There are sections on special diets, obstetrical data, laboratory methods, and emergency procedures.

The American and His Food†

A DELIGHTFULLY written history of food habits in the United States from pioneer days, this book presents the difference between menus on the farms and in the cities in early days that is especially interesting. Today, however, the farmer lives better than the city dweller did a century and a half ago.

The improvements in diet which were facilitated by improved transportation facilities rather naturally parallel the advances in commerce in general. The last portion of the book deals with present-day nutrition and needs for the future.

The March of Medicine‡

THIS is the sixth annual compilation of a series of lectures to the laity sponsored by the New York Academy of Medicine. The material covered may be inferred from the list of subjects and their authors: Humanism and Science by Alan Gregg; Paracelsus in the Light of Four Hundred Years by Henry E. Sigerist; Psychiatry and the Normal Life by William Healy; Philosophy as Therapy by Irwin Edman; The Promise of Endocrinology by Oscar Riddle; and What We Do Know About Cancer by Francis Carter Wood.

Essentials of Electrocardiography§

A COMPREHENSIVE discussion of basic principles, technique, and interpretation in the performance of clinical electrocardiography; this book is an excellent guide for students and a reference manual for clinicians.

Diagnostic Procedures and Reagents||

THIS is a reasonably small book detailing technique for the laboratory diagnosis and control of the communicable diseases, published by the American Public Health Association. It is primarily a book on laboratory methods rather than on control, and as such is authoritative. In addition to the bacterial contagious diseases it covers rickettsial infections, syphilis, rabies, and pathogenic fungi.

The Principal Nervous Pathways¶

THE *Principal Nervous Pathways* is a splendidly illustrated atlas of the nerve tracts of the brain, cord, and peripheral nerves, including the autonomic nervous system. Each plate has an adequate descriptive legend.

*University of California Hospital Formulary and Compendium of Useful Information. Cloth, 270 pages, \$2.00. University of California Press, Berkeley and Los Angeles, 1941.

†The American and His Food. A History of Food Habits in the United States. By Richard Osborn Cummings, Assistant Professor of History, Lawrence College. Cloth, 267 pages, \$2.50. University of Chicago Press, Chicago, Ill., 1940.

Physical Medicine*

THERE have been many volumes on physiotherapy. This is the first the reviewer has seen that appears to be fully authentic and free of overenthusiasm for one phase or another of physical therapy. It describes the methods of physical therapy as they are used at the Mayo Clinic. No section appears to receive undue emphasis. The author describes the application of heat and cold, light therapy, electrotherapy, diathermy, hydrotherapy, and mechanotherapy. A section deals with the application of the principles of physical therapy to various special diseases. Another section deals with the organization of physical therapy in hospitals. The introductory portion, which deals with the history of physical therapy, is especially interesting.

This volume will be useful not only to physiotherapists, but to others who wish to know the desirability of physical measures in special cases.

Immunity Against Animal Parasites†

THE first volume dealing with this phase of medical study was Taliaferro's *Immunology of Parasitic Infections*, published in 1929. Culbertson's book takes up where Taliaferro left off, bringing the studies up to date. Part I deals with natural resistance and acquired immunity. Part II discusses immunity in specific diseases, such as amoebiasis, leishmaniasis, trypanosomiasis, malaria, coccidiosis, trematodiasis, cestodiasis, nematodiasis. The third section is on applied immunology; it classifies parasites and discusses preventive vaccination and diagnostic procedures.

Students of bacterial immunity will find much of interest in the volume. There is also much of practical service to clinicians.

Pathology of the Oral Cavity‡

WRITTEN primarily for the dentist, this volume also contains sections on diseases of the jawbones and the oral mucosa. It is abundantly and well illustrated. All sections are short and concise. Emphasis is on diagnosis and significance of the lesions rather than upon therapeutic procedures.

Practical Methods in Biochemistry§

A STUDENTS' laboratory manual used in the department of biochemistry at the University of Chicago. Although it will find its greatest use in student laboratory instruction, it will undoubtedly also serve well as a laboratory reference manual since it contains detailed instructions for the technique of the various clinical laboratory procedures. Especially valuable for reference purposes is the appendix in which fifty pages of small type are given to the preparation of standard reagents and dilutions.

CLINICAL AND EXPERIMENTAL

PULMONARY CEREBRAL EFFECT TIME AS DETERMINED BY AMYL NITRITE*

I. ESTABLISHMENT OF A NORMAL RANGE

M. H. UHLEY, M.D., CHICAGO, ILL.

NUMEROUS methods have been devised for determining the rate of flow of blood from a given portion of the body to a distant designated locus. Since the work of Hering in 1827,¹ when he injected potassium ferrocyanide into one jugular vein of a horse, and tested samples of blood from the opposite jugular vein for Prussian blue, the greatest number of circulation time tests have involved the introduction of a chemical substance into a vein and the detection of that substance at some other point in the circulation by its objective or subjective manifestations.

Following in almost chronologic order is listed the evolution of circulation time studies: fluorescein²; calcium chloride³; concentrated salt solution producing distal electropotential changes⁴; radium C⁵⁻⁷; histamine flush reaction^{8, 17}; phenoltetraiodophthalein sodium⁹; Congo red¹⁰; acetylcholine, determining volume changes in an extremity¹¹; atropine and ephedrine, noting pupillary changes¹²; decholin^{13-15, 21}; saccharine¹⁶; ether¹⁸; calcium gluconate¹⁹; magnesium sulfate, calcium gluconate, sodium chloride, copper sulfate mixture²⁰; Kvale mixture,²² and cyanide method.²³

Other investigators have employed inhalation of various gases and have determined the rate of flow incidental to cardiac output studies, or the effect on the respiratory center; i.e., nitrous oxide method,²⁴ 5 to 7 per cent carbon dioxide inhalation,²⁵ rebreathing experiments with carbon dioxide,²⁶ ethyl iodide,^{27, 28} and 50 per cent carbon dioxide inhalation.²⁹

*From the Cardiovascular Department, Michael Reese Hospital, Chicago.
Aided by the A. D. Nast Fund for Cardiovascular Research.
Received for publication, July 19, 1941.

All of the preceding, excepting the inhalation methods, necessitate single or double venipuncture. Those not relying upon subjective responses and their attendant variations, require in many instances complicated techniques or apparatus, making them almost prohibitive of widespread clinical application.

The method proposed in this report is readily controlled by a single operator, and obviates the use of venipuncture. It involves the inhalation of amyl nitrite, and the detection of drug action on the vessels of the head. The inhalation of amyl nitrite vapor is followed by its absorption into the pulmonary capillary bed, its transport to the left side of the heart, thence to the cerebral and peripheral vessels where objective and subjective phenomena may be noted. The arterial system of the head and neck is affected before the rest of the systemic circulation by virtue of the lesser distance to be traversed. Since the quantity of the drug is relatively small, and since the drug action is rapidly dissipated, peripheral systemic effects are seldom noted. A means is thus afforded for measuring the pulmonary cerebral effect time. Reasons for the use of this term will be made clear as the subject is developed in this report, which is limited to the establishment of a normal range of values for the method employed.

Fig. 1.—Inhaler.

APPARATUS AND TECHNIQUE

The amyl nitrite inhaler used for the test is a small cylindrical chamber (Fig. 1), 2 inches in length, with an inner diameter of $\frac{1}{2}$ inch, and constructed of $\frac{1}{16}$ inch aluminum tubing. It is fitted with a screw cap at one end, the opposite end tapering to an opening $\frac{5}{16}$ inch in diameter. There are two $\frac{1}{8}$ inch drill holes in the body. Into one of these is inserted a plunger with which to break the perles of amyl nitrite. A stop watch is the only other instrument necessary.

A 3 minim perle of amyl nitrite is placed in the chamber through the screw cap end, and the plunger is withdrawn. The operation is greatly facilitated by holding the chamber in the left hand, thumb at the screw cap end, middle finger over the opening at the tapered end, and index finger closing the first drill hole. The plunger is forced down with the right thumb, breaking the glass perle, its contents filling the chamber which is still sealed as described.

The patient is instructed that following a normal expiration, he is to inhale slowly and deeply from the inhaler (usually for 2 seconds) when it is brought to his nostril, and then to breathe normally again. The presence of abnormalities of the septum or turbinates is determined before this step, since an obstructed nasal passage would not permit inhalation of the drug. He is told that the medication inhaled will produce a "new feeling" or "new sensation" in his head, which will appear as a slight dizziness or fullness, followed by a feeling of warmth in the face and neck. The entire reaction will disappear within one to three minutes. The patient is asked to signal the observer immediately upon perception of any sensory change. The signal, previously agreed upon, consists either in raising the hand or saying "now." The starting time for the test is the time at which inhalation is completed, and the end point is the time indicated by the signal.

Fig. 2.—Pulmonary cerebral effect time in 100 cases.

RESULTS

One hundred persons selected at random from the interne, nursing, and house staff of Michael Reese Hospital were tested by the advocated method, and the results were noted. They are assembled in a graph form, shown in Fig. 2.

The greater majority of measurements lie between 10 and 16 seconds. The average time for the 100 cases is twelve seconds. This spread is no greater than that obtained by other methods currently in use.

In the proposed method for determining pulmonary cerebral effect time, the first manifestations are noted in the distribution of the external and internal carotid arteries. Occasionally, throbbing in the arms, and perspiration and warmth of the hands are later noted. A few persons have coughed after the full effect has been reached.

The only untoward reaction found in the series, from the use of amyl nitrite in the dose administered, was the presence of headache, persisting from ten minutes to three hours in three persons.

DISCUSSION

A number of factors must be given consideration in evaluating any circulation study. As a matter of fact, no result may be properly called "circulation time," unless objective and mechanically recorded intervals along the course of a given segment of the vascular tree being investigated are noted. Any instance in which a sensory response is taken as an end point lends itself to errors of latency in perception and expression. There is another phase of rate of flow studies that is not sufficiently emphasized. In those techniques involving passage of a test medium through the lung (e.g., inhalation and ether), there is an inherent and quite variable "across membrane" delay in that structure. Thus it is obvious that a more accurate term encompassing flow rate and end point manifestation is desirable. The term "effect time" is suggested for this purpose.

The possibility exists that amyl nitrite changes the circulatory tree through which it passes. The reaction of amyl nitrite has been investigated by Lauder Brunton in 1871, who noted its pronounced but transient arterial dilatation, attributing the phenomenon to a direct effect upon the smooth muscle of the blood vessels, independent of any nervous mechanism.³⁰ His investigations have been verified by innumerable subsequent investigators, who found that cerebral vessels,³¹ pulmonary vessels,³² coronary vessels,³³ splanchnics,³⁴ and peripheral vessels,³⁵ respond by dilatation. Pilcher and Sollman in 1915³⁶ showed that the vasomotor center is not influenced directly by the drug when they observed that there was no blood pressure fall or rise following introduction of amyl nitrite only into the cerebral circulation. Vagal depression occurs only as a compensatory response to the systemic fall in pressure, and is, therefore, not due to an isolated action of the drug. This was adequately demonstrated by Filehne,³⁷ who showed that when the pressure was kept level by partial clamping of the aorta, no increase in rate occurred.

The time interval between the inhalation and manifestation of drug action is dependent upon two main factors, aside from the reaction time, assuming that the dose is fairly uniform and the technique is constant: (1) circulatory dynamic factor; (2) respiratory dynamic factor.

The first of these factors, i.e., the circulatory dynamic factor, refers more specifically to those changes associated with the occurrence of cardiac failure and concomitant slowing of the circulation. The test method can be interpreted as an index of the circulation of the left side of the heart, since the drug enters the circulation at the lung capillaries and has its effect after passing through the blood vessels of the head. It does not measure rate of circulation through the right side of the heart.

However, the second factor, the respiratory dynamic factor, comes into play. Alterations in the pulmonary ventilation, total capacity, or alveolar transport, will affect the measurement. Thus chronic pulmonary diseases, such as emphysema, bronchitis, bronchiectasis, and bronchial asthma, can affect the results noted.

The pulmonary cerebral effect time thus may be viewed as an additive phenomenon. Consequently, before a result is ascribed to an altered state of circula-

tion of the left side of the heart, the effects of pulmonary disease and abnormal reaction times must be considered in each case individually.

Furthermore, the circulation time itself is determined not only by the minute volume output of the heart, but also by the quantity of blood contained in the path from the lung capillaries to the head circuit. This is usually most variable in the pulmonary capillaries and veins, and next in the left auricle.

In short, amyl nitrite is a drug whose prime action is limited to a direct effect upon the vascular system, probably not associated with reflex dilatation or constriction. It may be used as a clinical test as suggested, even though the end point is a subjective one, necessitating recognition of the variations in individual reaction time. The discomfort associated with its use is relatively mild and disappears rapidly.

There is perhaps a single contraindication to the use of amyl nitrite, i.e., the presence of glaucoma, for as shown by Wessely,³⁸ it causes an increase in intra-ocular tension in spite of the lowering of systemic pressure.

CONCLUSIONS

A simple method for quantitating pulmonary cerebral effect time is described, which measures the effective pulmonary ventilation, the circulation time of the left side of the heart, and is affected by variations in the reaction time of the subject.

The normal values in 100 cases are presented.

Its use in determining the degree of failure of circulation of the left side of the heart circuit is thus limited to instances in which no disease of the pulmonary apparatus exists, and in which the reaction time of the subject is not abnormal. Conversely, it may offer an index of the degree of diffuse chronic pulmonary disease in the absence of cardiac disease. When abnormalities are present in both pulmonary and vascular systems, the combined effects may be measured, but without evaluation of the component parts.

I wish to thank Dr. L. N. Katz, under whose supervision this work was done, for suggestions made during the study and preparation of this report.

REGULATION OF THE RECIPROCAL ACTIVITY OF DESOXYCORTICOSTERONE ACETATE AND SODIUM IN ADDISON'S DISEASE*

THOMAS H. MCGAVACK, M.D., F.A.C.P., NEW YORK, N. Y.

THE early failure to understand the extent to which the physiologic activity of desoxycorticosterone acetate is dependent upon the sodium available in the organism has accounted for most of the complications following its administration to patients with Addison's disease. Six patients with this malady have been treated with the drug† over periods varying from three months to two and one-half years, during which time in each instance there have been wide variations in the amounts of sodium and desoxycorticosterone acetate employed. Patients were judged to be in a state of "adrenal sufficiency," that is, in good clinical condition, when a sense of well-being was subjectively experienced; a gradual gain in weight to normal and its maintenance achieved; a return of blood pressure to satisfactory levels attained; a cardiothoracic ratio between 0.45 and 0.50 observed; and normal values for sodium and potassium noted in both blood serum and urine.

By "trial and error" sodium and desoxycorticosterone acetate have been utilized in 47 different ratios in the above-mentioned six patients for not less than six weeks in any instance, unless severe insufficiency or a complication arose before such a period was completed. The longest time at any single dose level in any one individual has been nine months. When these average daily values for sodium ingested and desoxycorticosterone acetate administered were plotted against each other, it was found that patients in good clinical condition showed a definite reciprocal relationship between sodium intake and desoxycorticosterone acetate requirement which was capable of mathematical expression in terms of hyperbolic curves. Seventy-one per cent of these satisfactory observations lay on or between curves, the constants of which were 37.5 and 45.0, respectively (Fig. 1), while all other observations (29 per cent) in which the clinical condition of the patient was satisfactory were represented by similar parabolic curves, the constants of which ranged from 30 to 37.5, and from 45 to 55, respectively (Fig. 1.)

It is obvious that only portions of the hyperbolas are of practical value. If one uses large quantities of sodium, that is, more than 9 Gm. daily, and correspondingly small doses of desoxycorticosterone acetate, the clinical condition is not as good as though more desoxycorticosterone acetate were employed. If, on

*From the Department of Medicine, New York Medical College, and the Medical Services of Flower and Fifth Avenue Hospitals, and Metropolitan Hospital, New York.

†Desoxycorticosterone acetate for this work was kindly furnished by Dr. Max Gilbert of the Schering Corporation.

Received for publication, July 23, 1941.

the other hand, sodium is severely restricted, that is, to 1.5 Gm., and desoxycorticosterone acetate dosage is concomitantly increased, that is, to 30 mg. daily, some "packing" of sodium into the cells probably occurs.^{1, 2}

Fig. 1.

The formula $Na (Gm.) = \frac{k}{D (mg.)}$, where Na equals daily intake of sodium in grams, k is a constant, and D the desoxycorticosterone acetate in milligrams, is applicable to the management of patients with Addison's disease over a definite range of values, suggested by the shaded area in Fig. 1. In our experience, values for the daily intake of sodium should not exceed 9 Gm. or be less than 2 Gm., while less than 5 mg. or more than 20 mg. of desoxycorticosterone acetate daily do not afford as satisfactory relief as those attendant upon amounts between these two figures. Values for k should lie on or between 37.5 and 45. The area delimited by adherence to these figures (black in Fig. 1) may be spoken of as the "area of optimum dosage" in the use of desoxycorticosterone acetate for the management of Addison's disease. Values lying within this space can be apparently applied without danger of disaster from cortical insufficiency or fear of complications directly related to the therapy.

THE SIGNIFICANCE OF FIBRINOLYSIS IN MECHANISM OF COAGULATION OF BLOOD*

HENRY J. TAGNON, M.D.,† NEW YORK, N. Y.

BY FIBRINOLYSIS is meant an occasionally observed phenomenon which consists in the dissolution of the clot of fibrin formed by the coagulation of whole blood or plasma. This phenomenon has been observed and described by several authors, principally Denis (quoted by Nolf¹¹), Dastre,² Rulot,^{19, 20} Nolf,¹¹ Hougardy,^{4, 5} and Hirose.¹⁸ Since fibrinolysis appears only occasionally in the process of blood coagulation, it is necessary to devise some procedure for obtaining it consistently, in order to be able to investigate it on an experimental basis. The use of chloroform provides such a procedure, as will be shown by the subsequent considerations.

The effect of chloroform on blood coagulation has been investigated principally by Howell,⁶ Nolf,^{9, 14} Minot,⁷ and Bordet.¹ All these authors agree that this substance has a marked effect on the mechanism of blood coagulation; they have observed that chloroform was able to clot oxalated plasma. Nolf emphasized the fibrinolytic power of the serum obtained from oxalated recalcified plasma clotted by chloroform.

As far as fibrinolytic action is concerned, the best procedure to study the effect of chloroform is to observe the serum resulting from oxalated, recalcified plasma clotted by chloroform. Blood is taken by venipuncture from the jugular vein of an unanesthetized, fasting dog. Twenty cubic centimeters of blood are withdrawn in a syringe containing 1 c.c. of 3 per cent sodium oxalate solution. It is then poured into a paraffined centrifuge tube and is centrifuged twice for fifteen minutes at a speed of 3,000 r.p.m. The clear plasma is used to prepare:

1. Normal serum, by simply adding calcium chloride. After coagulation occurs, serum is obtained by centrifugalization.

2. So-called chloroform serum. Recalcified plasma is mixed with $\frac{1}{10}$ its volume of chloroform and is shaken for one minute in a carefully stoppered tube. The tube is maintained at a temperature of 37° C. for one hour. Then chloroform is removed from the mixture, first by centrifugalization and then by evaporation of its supernatant layer in the icebox for sixteen to twenty-four hours. After that time the mixture does not smell of chloroform. Distilled water is added to correct for the loss of water caused by evaporation. The serum is filtered before using.

Received for publication, July 31, 1941.

In the course of this study, other reagents were used:

Oxalated plasma: as such, or deprived of fibrinogen by heating at 56° C. for two minutes.

Prothrombin: globulin solution prepared from diluted oxalated plasma, precipitated at pH 5.3, following the method of Mellanby.⁸ It can be deprived of fibrinogen by heating to 56° C.

Fibrinogen: prepared according to Warner, Brinkhous, and Smith.²³ It was diluted with physiologic saline before being used, until the greatest dilution was obtained which gave, with the addition of thrombin, a coherent clot. This dilution is desirable because it decreases the amount of impurities remaining in the solution.

Thromboplastin: prepared according to Warner, Brinkhous, and Smith.²³

Oxalated plasma deprived of prothrombin: To remove prothrombin, tri-calcium phosphate was used in a thick creamy suspension in saline. Ten parts of oxalated plasma are added with one part of the suspension. After careful stirring, the mixture is warmed to 37° C. for fifteen minutes, and then the phosphate, together with the prothrombin, is removed by centrifugalization. Phosphated plasma does not clot on addition of calcium and thromboplastin. It clots readily on addition of thrombin. It can be deprived of fibrinogen by heating to 56° C.

Thrombin: prepared just before its use by adding calcium and thromboplastin to oxalated plasma or to prothrombin and removing the serum after coagulation.

All the foregoing blood preparations were made from dog blood.

To compare the thrombin content of different sera, successive dilutions of the sera were added to given quantities of fibrinogen. The most dilute amount which produces a clot and thereby contains an appreciable, effective quantity of thrombin is taken as the end point. Sera prepared by various methods—chloroform serum, normal serum—may thus be compared for thrombic activity.

In all the experiments a total volume of 1 c.c. was used. Physiologic saline was used as a diluent. In order to keep the quantity of thrombin tested at a constant known level, an excess of sodium oxalate was added to prevent further increment of thrombin by conversion of any prothrombin which might possibly be present. The experiments were performed at room temperature. Under these conditions the amount of thrombin in chloroform serum and normal serum was compared. Such a comparison is given in Table I.

It appears that chloroform serum contains 300 times as much thrombin as normal serum. Table I shows also that chloroform serum, after having clotted fibrinogen, dissolves it. In the first tube (Table I), the fibrinogen clots in four minutes. The following day the clot had disappeared. The solution was again perfectly clear, and its appearance was absolutely the same as before the occurrence of the clot. An important change, however, had occurred. The solution contained no more fibrinogen. It was impossible to obtain a clot in this solution by adding thrombin. Also, if the content of the first tube is heated to 56° C., fibrinogen precipitate does not appear. The same phenomenon oc-

curred in the two following tubes (Nos. 2 and 3). It occurred in the fourth tube (No. 4), but less intensively. This did not occur with normal serum. The disappearance of the clot is probably due to proteolysis.

TABLE I

COMPARISON OF THE THROMBIN CONTENT OF CHLOROFORM SERUM AND NORMAL SERUM

TUBES	REAGENTS IN CUBIC CENTIMETERS					RESULTS
	SODIUM OXALATE 1%	NaCl 0.90%	FIBRINO- GEN	CHLORO- FORM SERUM	NORMAL SERUM	
1	0.1	0.7	0.1	0.1		Clot in 4 min. Redissolved after 16 hr.

12	0.1	0.7	0.1		0.001	Clot in 12 hr. Not redissolved
13	0.1	0.7	0.1		0.0003	Clot in 12 hr. Not redissolved
14	0.1	0.7	0.1		0.0001	No clot

If the action of chloroform serum on diluted oxalated plasma is studied, it appears that a solution of the clot does not occur in plasma as markedly as in the fibrinogen solution. Table II shows that dilutions of chloroform serum, which are able to produce fibrinolysis in the fibrinogen solution, do not produce this when acting on diluted plasma. It can be seen in Table III that the quantity of plasma needed to prevent fibrinolysis caused by 0.1 c.c. of chloroform serum is between 0.04 c.c. and 0.01 c.c. (tube 6). The preventive action of plasma on proteolysis is not due to fibrinogen, since this inhibiting effect remains unchanged when plasma is deprived of fibrinogen by heating to 56°. This is apparent in Table IV. It will be shown later that the preventive action is due to the prothrombin of the plasma (Tables IX and X).

In the experiment described above, 0.01 c.c. of chloroform serum causes lysis of the fibrinogen clot after four minutes. Fibrinolysis may occur at an even more rapid rate, and in such cases a well-formed clot would have no time to appear. Table V illustrates such an experiment (tube 2). It can be seen that 0.1 c.c. of chloroform serum causes the production of flakes in the fibrinogen solution. These flakes disappear after two minutes, and thereafter there is no more fibrinogen in the solution. This shows that fibrinolysis may be completed

TABLE V

FIBRINOLYSIS OCCURRING IMMEDIATELY AFTER COAGULATION

TUBES	REAGENTS IN CUBIC CENTIMETERS				RESULTS
	SODIUM OXALATE 1%	NaCl 0.9%	FIBRINO- GEN	CHLORO- FORM SERUM	
1	0.1	0.6	0.1	0.2	No change
2	0.1	0.7	0.1	0.1	Flakes after 3 min. Redissolved after 2 min.
3	0.1	0.7	0.1	0.01	Clot in 5 min. Redissolved after 2 hr.

after two minutes. It may even occur so soon that the coagulation could not be observed. The solution of fibrinogen to which chloroform serum is added becomes opalescent and then clear again. No compact clot is formed. The solution, however, contains no more fibrinogen. This phenomenon is illustrated in Table V (tube 1). Nothing happens in the tube to which 0.2 c.c. of chloroform serum is added, but in the tubes to which is added 0.01 c.c. of the serum, coagulation occurs, soon followed by proteolysis. In the first tube, fibrinogen disappears, fibrinolysis having set in so fast that the fibrin flakes, if formed at all, are dissolved as soon as they are formed. At this dilution chloroform serum seems to have no clotting power. Moreover, a superficial observation would lead one to believe that it has an ant clotting power. However, this is not so, since fibrinogen originally present has disappeared. It is, therefore, impossible to obtain coagulation in the first tube. The disappearance of fibrinogen is the real cause for the incoagulability. Moreover, this interpretation is confirmed by the fact that the same quantity of serum, which produces no apparent coagulation in the fibrinogen, does clot oxalated diluted plasma. Fibrinolysis does not occur in plasma as it does in the fibrinogen mixture, probably because of some antilytic agents in the former.

Fibrinolysis usually occurs without apparent coagulation if serum kept in contact with chloroform for twenty-four hours is used. This is not usually the case with serum kept in contact with chloroform for only one hour. The fibrinolytic property is increased when the contact time with chloroform is prolonged, provided that this time does not exceed forty-eight hours (Table VI).

TABLE VI

COMPARISON OF THE FIBRINOLYTIC POWER OF CHLOROFORM SERUM AFTER ONE HOUR OF CONTACT WITH CHLOROFORM AND AFTER TWENTY-FOUR HOURS

In order to investigate further the relationship of fibrinolysis to the mechanism of blood coagulation, chloroform serum produced by allowing serum to remain in contact with chloroform for one hour at 37° C. and for twenty-four hours at room temperature, was used in the following experiments. Hereafter the expression "chloroform serum" will always refer to this particular twenty-four-hour-old serum.

It has been shown (Table V) that oxalated plasma contains antilytic substances. The substances contained in plasma, however, are not the only ones showing an antilytic effect. Thromboplastin exhibits it also. It can be seen in Table VII (tube 3) that 0.1 c.c. of thromboplastin, diluted ten times, counteracts the fibrinolytic effect of a quantity of chloroform serum able to fibrinolyze the fibrinogen without producing clot formation (tube 5). Consequently, if two identical mixtures of oxalated fibrinogen and oxalated chloroform serum are used, thromboplastin added to one of them will cause a clot to appear while the other one remains fluid and undergoes fibrinolysis without coagulation. This antilytic effect of thromboplastin is very powerful.

TABLE VII
ANTILYTIC EFFECT OF THROMBOPLASTIN

TUBES	OXALATED CHLORO- FORM SERUM	NaCl 0.9%	OX- ALATED FIBRINO- GEN	THROMBO- PLASTIN (DILUTED 10 TIMES)	RESULTS

5	0.1	0.8	0.1	0	Proteolysis without coagulation

In order to ascertain more accurately the fibrinolytic action of chloroform serum, the following procedure was undertaken: Chloroform serum was diluted with 15 volumes of distilled water and, with the use of N/10 acetic acid, mixtures of varying pH were obtained. The globulin precipitate obtained in every case was dissolved in saline, and its action was tested on fibrinogen and oxalated plasma. Only the product obtained at pH 6 showed any activity comparable with that of the chloroform serum which produced it. In addition, it revealed some interesting properties which explain the action of chloroform serum.

The detailed method of preparation was the following: Chloroform serum is diluted with 15 volumes of cold, distilled water in order to lower the salt concentration below 1 per thousand. Decinormal acetic acid is added until pH 6 is reached. The slightly turbid solution is centrifuged, and the precipitate is dissolved in a volume of saline equal to one-third that of the chloroform serum from which it was obtained. Sodium oxalate is added in order to obtain a concentration of soluble oxalate of 0.15 per cent. The solution is centrifuged, and its pH is adjusted to neutrality. This solution is called *solution A* in the experiments to be detailed.

The properties of solution A are:

1. It is not a solution of thrombin, since at no concentration does it clot fibrinogen. Unlike chloroform serum, of which a concentration can always be found which clots fibrinogen and dissolves it afterwards, every active concentration of solution A fibrinolyzes fibrinogen without clotting it. Dilute quantities of solution A leave it unchanged. Table VIII shows the difference in the effects of chloroform serum and of solution A (prepared from the chloroform serum) on fibrinogen.

TABLE VIII

COMPARISON OF THE EFFECT OF CHLOROFORM SERUM AND OF SOLUTION A ON FIBRINOGEN

2. Added to oxalated plasma, solution A has the same action as chloroform serum. It clots oxalated plasma, provided there is a sufficient amount of the latter (Table IX, tubes 1 and 2). If the quantity of plasma is too small, solution A fibrinolyses fibrinogen without clotting it, as shown in Table IX, tube 3.

3. Added to oxalated plasma deprived of prothrombin (phosphated plasma), solution A never clots it, but added in sufficient quantity solution A fibrinolyses the fibrinogen of phosphated plasma (Table X, tubes 1 and 2). Added in smaller quantities, it leaves it intact, as shown in Table X, tubes 3 and 4.

4. If thromboplastin is added to fibrinogen, solution A produces no clot, in contrast to chloroform serum the fibrinolytic power of which, as stated previously, can be transformed into clotting power by means of thromboplastin (Table XI).

5. From the foregoing experiments it may be concluded that solution A is not prothrombin. Prothrombin has no clotting effect in the absence of calcium.

6. Solution A is not thromboplastin because thromboplastin never clots oxalated plasma.

In summary, it may be said that solution A has an enzymelike, and probably a proteolytic effect on fibrinogen. Its activity, with respect to the phenomenon of blood coagulation, presents the following features: it clots oxalated plasma. Unlike chloroform serum, its mother substance, solution A never clots plasma deprived of prothrombin, nor does it coagulate fibrinogen to which thromboplastin is added. The clotting activity of solution A is probably due to its action on prothrombin, which is converted into thrombin even in the presence of an excess of sodium oxalate without participation of calcium platelets or thromboplastin.

There is a striking similarity of action between the enzymelike substance contained in solution A and trypsin. The effect of trypsin on blood coagulation was studied principally by Eagle and Harris.³ According to these authors, trypsin, like solution A, lyzes fibrinogen without clotting it, but it has a strong clotting action on oxalated plasma without the participation of calcium, platelets, or thromboplastin. Added to prothrombin, optimum quantities of trypsin change it into thrombin. Larger quantities fail to do so since they bring about the destruction of prothrombin. The same thing happens when trypsin is allowed to remain in contact with prothrombin for a long time. Both prothrombin and the thrombin which is formed are destroyed. Eagle and Harris conclude that trypsin acts in the mechanism of blood coagulation like the system calcium platelets or calcium thromboplastin does. The theory of blood coagulation, adopted by Eagle and Harris, according to which thrombin results from the interaction between prothrombin and thromboplastin plus calcium, permits no other conclusion.

In order to investigate further the identity of the action of trypsin and the enzyme contained in solution A, the effect of solution A on the prothrombin solution, prepared as described above, was studied. Varying quantities of solution A were added to 0.5 c.c. of oxalated prothrombin. They were allowed to

interact at 37° C. during different periods of time. The thrombin produced in every case was tested on fibrinogen, and the clotting time was recorded. To rule out an eventual spontaneous formation of thrombin from prothrombin, a control was made by allowing pure prothrombin to remain at 37° C. for the time of the experiment, and testing it on fibrinogen. The experiment was carried out at pH 6.7, 0.5 c.c. of phosphate buffer being added to each sample. The results (Chart 1) show that the activation of prothrombin into thrombin by solution A is soon followed by inactivation of both the prothrombin and the thrombin formed. This is consistent with the results of Eagle and Harris with trypsin.

Chart 1.—Production of thrombin from prothrombin and solution A.

The same procedure which furnished solution A can be applied to a chloroform serum, which is characterized by contact of the serum and chloroform for less than twenty-four hours. In this case the solution obtained has the properties of thrombin which are more marked the shorter the time of contact with chloroform.

The isoelectric precipitation at pH 6 of diluted chloroform serum is not the only means to isolate the active fibrinolytic principle from this serum. A highly satisfactory process consists in dialyzing chloroform serum in cellophane against running tap water below 10° for three days; the precipitate of euglobulin formed is treated as the precipitate obtained by isoelectric precipitation. Both solutions, obtained either by precipitation at pH 6 or by dialysis, exhibit exactly the same properties and may, therefore, be assumed to contain the same principle.

DISCUSSION

The experimental data indicate that chloroform serum prepared from the blood of dogs after twenty-four hours of contact with chloroform exhibits properties different from that obtained after only one hour of contact. While chloroform serum obtained after only one hour of contact with chloroform coagulates fibrinogen with subsequent fibrinolysis, that obtained from twenty-four hours contact in the same concentration produces complete fibrinolysis

without preliminary coagulation. Very low concentration of chloroform serum obtained after twenty-four hours contact will clot fibrinogen. The clot, however, disappears very rapidly.

The saline solution of the globulin fraction derived from chloroform serum after twenty-four hours (solution A), prepared by isoelectric precipitation at pH 6, or by dialysis, differs from chloroform serum itself in several particulars. While solution A can coagulate oxalated plasma, it cannot, unlike chloroform serum, in any concentration coagulate phosphated plasma or fibrinogen to which thromboplastin has been added or pure fibrinogen itself. Prothrombin must be added to fibrinogen solutions before coagulation takes place.

Solution A, however, does produce fibrinolysis but does so without any preliminary clotting activity. Chloroform serum does not require the presence of added prothrombin because it presumably already contains some of this substance, in either free or combined form. In certain concentrations, therefore, chloroform serum acts like thrombin, since it can produce coagulation of pure fibrinogen.

With respect to blood coagulation, solution A has enzymelike characteristics and resembles much in detail the action of trypsin reported by Eagle and Harris.³ So marked was this resemblance that one wonders whether this enzyme-like material could be of pancreatic origin. Pancreatectomized dogs, the pancreatectomy being confirmed by post mortem and microscopic verification,²² from whose blood chloroform serum was made at intervals over several months, disproved this hypothesis. The characteristics of the chloroform serum remained unchanged.

Eagle and Harris accept the two-stage theory of blood coagulation whereby:

From their studies on trypsin they propose an enzymatic modification of this reaction as follows:

From this substitution the conclusion must be drawn that trypsin replaces calcium, platelets, and thromboplastin in the blood coagulation reaction.

The possibility that trypsin, a substance not yet identified with any blood constituent, having any connection with blood coagulation, seemed remote. The evidence that solution A resembles trypsin in many of its reactions is important, since solution A is obviously of plasma origin, requiring only the addition of chloroform to oxalated recalcified plasma to activate it.

However, the experimental evidence presented in this paper does not permit the identification of solution A with any of the substances in the coagulation reaction presented by Eagle and Harris. It contains neither thromboplastin nor fibrinogen, and its calcium ion content, if any, must be infinitesimal. Certainly

no preformed thromboplastin was present since the parent plasmas showed no production of fibrin even after standing for eight days. Neither can solution A be said to be thrombin since it does not in pure form clot fibrinogen.

If it can be said that trypsin, a substance foreign to the blood, can replace calcium plus platelets or thromboplastin in the blood coagulation reaction, it would logically follow from the experimental data, and from the fact that solution A is a true blood derivative that it too can replace the calcium thromboplastin platelet system.

Solution A is of plasma origin and can produce thrombin from prothrombin. It is highly probable, therefore, that it plays an essential role in the blood coagulation reaction. Its role is of such a nature that it would appear that calcium thromboplastin or platelets are no longer necessary in the coagulation reaction or play only a minor role.

One may go even farther than this and speculate whether the theoretical outline of blood coagulation outlined above can any longer be true, since it obviously does not lend itself to the inclusion of the existence of an enzyme theory which the evidence of this communication would appear to indicate.

The evidence for the enzymelike character of this plasma derivative may be briefly summarized. It lyzes fibrinogen, except in the presence of prothrombin, when coagulation intervenes followed by fibrinolysis. Neither calcium nor thromboplastin plays any direct role in this reaction. Thromboplastin can play a secondary role, as shown by the fact that the addition of *chloroform serum* in an amount that would normally lyze fibrinogen without coagulation, may be made to coagulate the fibrinogen if thromboplastin is added. However, thromboplastin does not have even this effect on *solution A*. It can augment the effect of prothrombin in this regard but alone has no effect on *solution A*.

As remarked earlier in the discussion, chloroform serum prepared after one hour's contact with chloroform differs in essential characteristics from that prepared after contact for twenty-four hours. A discussion of the reasons for the difference seems appropriate.

During the initial shaking with chloroform, thrombin is immediately formed and in large concentration, as shown in Table I. Fibrin is also precipitated. As time goes on the fibrin undergoes fibrinolysis due to the apparent proteolytic properties now present in chloroform serum. At the end of twenty-four hours, at which time the chloroform is removed by centrifuging and aeration, there is no longer any fibrin present.

These facts are interpreted by reasoning that under the influence of chloroform an enzymelike substance is produced which forms thrombin from prothrombin in the presence of calcium ion. The result of this reaction is fibrin formation. During the subsequent twenty-four hours the enzymelike substance proteolyzes both prothrombin, fibrinogen, if any is still present, and fibrin. Table VIII and Chart 1 clearly indicate that the enzymelike material is able to produce both of these effects. With the disappearance of prothrombin the enzyme has no longer any ability to coagulate fibrinogen, but becomes purely fibrinolytic unless prothrombin is subsequently restored. The last traces of prothrombin are removed when solution A is formed by isoelectric precipitation or dialysis of the chloroform serum.

The possibility that thrombin itself may contain as part of that complex the enzymelike material described in this paper cannot be excluded by the experimental data here presented. The failure of certain thrombin preparations²¹ to display any such fibrinolytic activity would then be explained by the presence of thromboplastin as an impurity in such preparations. The data show that thromboplastin when present can inhibit fibrinolysis. The fibrinolytic properties of thrombin previously described by Nolf¹³ and ascribed to the presence of one of its constituent substances thrombozyme may indicate a possible identity between thrombozyme and solution A.

The fact that the enzymelike substance contained in chloroform serum is precipitated at pH 6 and by dialysis suggests the possibility of a similarity between the active principle of solution A and the plasma substance acting on hemophilic blood, investigated by Patek, Stetson, and Taylor.¹⁵⁻¹⁷ Should this be the case, hemophilia would be due to a lack of proteolytic fibrinolytic-clotting enzyme in the plasma.

SUMMARY

1. A method is devised for obtaining from oxalated plasma a proteolytic enzyme active in blood coagulation.

2. Similar to trypsin, this enzyme participates in the mechanism of blood coagulation by changing prothrombin into thrombin without calcium, thromboplastin, or platelets.

3. The proteolytic action of the enzyme on fibrinogen is counteracted by prothrombin. The action of prothrombin is reinforced in this respect by thromboplastin. Phosphated plasma and thromboplastin, without prothrombin, have no antilytic power. Prothrombin permits the enzyme to manifest its action by a clotting effect.

4. The antilytic action of thromboplastin explains why the proteolytic properties of thrombin were not found by many workers since their thrombin was prepared by means of thromboplastin.

5. The fact that the enzyme is extracted from plasma and that it reacts with prothrombin to form thrombin without intervention of calcium or thromboplastin is good evidence that the enzyme plays a primary role in the mechanism of normal blood coagulation. This role is discussed.

6. It is suggested that this enzyme is the substance, the absence of which causes hemophilia.

THE EFFECTS OF POLYVINYL ALCOHOL INJECTIONS ON BLOOD AND TISSUES*

WILLIAM R. YOUNG, M.D., A. S. MULAY, PH.D., AND AMOS CHRISTIE, M.D.
SAN FRANCISCO, CALIF.

POLYVINYL alcohol is a synthetic chemical.† Its colloidal nature, water solubility, and inertness suggested that it may prove valuable as a drug for increasing blood colloids and thus osmotic pressure and blood volume. Lowered oncotic pressure due to loss of plasma protein plays a large part in the production of nephrotic edema. Such substances as serum transfusion and intravenous gum acacia solution have been used successfully to counteract this lowered oncotic pressure. Effects of intravenous acacia were studied in this laboratory.¹

Hueper,² working with rats and rabbits, reports the pathology produced by oral and intravenous administration of repeated small doses of polyvinyl alcohol. This paper reports the results of a single massive dose of polyvinyl alcohol on kidney tissue and the blood of normal dogs.

*From the Department of Pediatrics and the Hooper Foundation for Medical Research, University of California Medical School, San Francisco.

†Developed by DuPont Company.

Received for publication, August 11, 1941.

Polyvinyl alcohol used in this work technically referred to as "RH-391 type B." A 5 per cent solution of this chemical in physiologic saline, warmed to body temperature, was administered to normal dogs intravenously, in one massive dose of 1 Gm. of the chemical per kilogram of body weight. Blood samples were taken before and at definite time intervals after the injection. Sedimentation rate (*Winthrop method*), cell volume, red and white blood cell counts, oxygen and carbon dioxide content, and oxygen capacity were determined on these blood samples. Blood and plasma smears were tested for the presence of polyvinyl alcohol by Lugol's solution as described by Hueper. Washed cells were also tested for the chemical before and after hemolysis and urine was also tested for the presence of the chemical. Polyvinyl alcohol particles stain blue with Lugol's solution. Animals were observed for clinical symptoms of any ill effects, and the tissues of sacrificed animals were grossly and microscopically examined for damage caused by this chemical.

TABLE I

BLOOD DETERMINATIONS ON A HEALTHY DOG BEFORE AND AFTER INTRAVENOUS INJECTIONS OF POLYVINYL ALCOHOL*

	BEFORE IN- JECTION	AFTER INJECTION				
		½ HR.	1 HR.	4 HR.	24 HR.	7 DAYS
Hemoglobin (per cent)	127	82	87	110	119	112

TABLE II

BLOOD DETERMINATION ON HEALTHY DOGS AFTER INJECTION OF POLYVINYL ALCOHOL
(Averages of all experiments)

	DAYS AFTER INJECTION				
	7	14	20	30	45
Hemoglobin (per cent)	100	115	110	100	120
White blood cells (thousands)	15.0	10.5	11.5	12.9	12.0
Red blood cells (millions)	6.2	5.9	7.3	6.6	6.6
Cell volume (per cent)	43.6	46.3	46.3	45.3	47.9
CO ₂ content (volume per cent)	52.5	51.5	52.3	46.6	50.4
O ₂ content	14.3	15.5	14.9	14.6	16.3
Sedimentation rate.	Stays increased even after forty-five days				

Eight dogs were used in these experiments. Injections were repeated on two dogs a second time. One was given a second dose of 0.5 Gm. of the chemical per kilogram of body weight twenty-one days after the first injection, and the other was given 1.0 Gm. per kilogram sixty days after the first injection. As the results of all the experiments show a similar trend, observations on only one

dog are recorded in the first table, and averages of all observations are given in the second.

Blood samples taken half an hour after the injection of polyvinyl alcohol show a marked decrease in all blood values, a dilution effect. The drop in the white blood cell count is relatively greater than the drop in other blood constituents. Unlike other blood values, the white blood cell count rises above normal after the initial drop and then comes back to normal gradually. Rise and

Fig. 1.—Early sections.

fall in hemoglobin, red blood cells, cell volume, and oxygen content values follow each other very closely. Carbon dioxide content of the blood falls only after twenty-four hours after the injection. Sedimentation rate is very rapid half an hour after the injection and does not even approach normal at the end of forty-five days after the injection. All other blood values return to, or approach, normal within one to three weeks after the injection. Oxygen-combining power of the hemoglobin as determined by oxygen capacity per unit of hemoglobin is undiminished.

Staining tests show that polyvinyl alcohol can be traced in the blood for forty to fifty days, and gives very strong and unmistakable reaction up to thirty

days after its injection. This chemical circulates in the plasma and does not enter the blood cells. It is excreted in urine, but to a very small degree. It accumulates in the liver, spleen, and kidney.

One dog became ill, refused to eat, vomited, developed diarrhea and a cold, lost weight, and died two weeks after the injection. The second dog lost his appetite and began to lose weight shortly after the injection, and was sacrificed. The remainder of the dogs showed an initial loss of appetite and weight, but returned to normal in a few days and remained so for the period of observation. The second injections were tolerated as well as the first.

Fig. 2.—After second dose.

Tissue examination showed rather marked tubular degeneration, damage to glomerular tufts, and endothelial swelling filled with polyvinyl alcohol (Fig. 1). The tubular lumina and epithelial lining also contained the chemical. Liver and spleen tissue also showed accumulation of polyvinyl alcohol. In the tissues of the dogs given second injections, many glomerular tufts were only one-quarter normal size due to fibrosis and round-cell infiltration (Fig. 2). Hueper, working with rats and rabbits, found similar damage to tissues after several subcutaneous or intravenous injections of polyvinyl alcohol in small doses.

Although polyvinyl alcohol is an inert chemical, and animals receiving it even in massive doses seem to be normal after initial loss of weight and appetite, blood and tissue examinations show that the animal body is unable to break up and eliminate this compound, thus causing its accumulation in tissues and tissue damage, the kidney in particular. This makes it unsuitable and probably dangerous as a therapeutic agent.

THE TREATMENT OF ARTHRITIS BY ELECTROPYREXIA INCLUDING SOME PHYSIOLOGIC STUDIES DURING FEVER THERAPY*

S. L. OSBORNE, M.S., PH.D., D. E. MARKSON, M.D., F.A.C.P., R. E. DRISCOLL, M.D., AND J. R. MERRIDIAN, M.D., CHICAGO, ILL.

NUMEROUS reports have appeared since our original communication^{1,2} evaluating artificial fever in the treatment of chronic arthritis. Marked differences of opinion exist as to the merits of this therapy.³⁻¹¹ Our study gives the results obtained with electropyrexia in 27 patients suffering from chronic infectious arthritis.

METHODS

The patients ranged in age from 17 to 68 years and were selected from the arthritis clinic of Northwestern University Medical School. Each patient was examined in the general medical clinic, and was followed by a re-examination in the arthritis clinic according to a definite routine. This ruled out many vague syndromes simulating arthritis, and at the same time gave us an opportunity to determine the patients' probable ability to withstand the treatment. Electropyrexia was advised after the routine measures of management had been tried without any improvement.

The treatment, given once a week, consisted of four hours of fever between 104° F. and 104.6° F. An effort was made to keep the temperature as close to 104° F. as possible. Each patient received from six to eight treatments.

At the time of the physical examination of the patients, a quantitative chemical analysis for total and fractional proteins was made, in addition to the usual laboratory test.

The patient's temperature was elevated by using a fever cabinet in combination with an inductotherm. Rectal temperature was read with an indicating

*From the Arthritis Clinic and the Department of Physical Therapy, Northwestern University Medical School, Chicago.

Received for publication, August 11, 1941.

pyrometer and recorded every fifteen minutes, together with the pulse rate and respiration. Fluids were administered to the patients in the form of 0.4 per cent sodium chloride solution. The fluid intake was limited to 250 c.c. for each fifteen-minute period unless more could be given without causing distress. In this way nausea or vomiting was seldom encountered.

None of our patients was given sedatives.

At the beginning of each treatment when the patient's rectal temperature reached 104° F., when this temperature had been maintained for four hours, and, finally, when the patient's rectal temperature had returned to normal the following physiologic tests were undertaken:

1. Blood pH determinations by means of the Dole glass electrode were made on 10 patients.
2. Blood density determinations, using the Barbour and Hamilton¹² falling-drop method, were made on 11 patients.
3. Ascorbic acid concentration of the blood was determined in 18 patients by the method of Farmer and Abt.¹³
4. Circulatory changes were measured in the ring finger of the left hand by means of the Johnson air conduction plethysmograph on 12 patients.
5. Blood pressure was recorded before and after each treatment for 10 patients.

RESULTS

Following fever therapy, the patients returned to the arthritis clinic where the clinicians of that department evaluated the improvement. The results are tabulated in Table I. The criteria used in evaluating improvement in this series included the patient's statement of relief of pain and stiffness. The degree of fatigue was less, and its occurrence was not so frequent. The objective evidence consisted of decreased swelling, increased motion of joints without pain, and gain in weight. Improvement was graded according to the period of time relief persisted.

Slight improvement consisted of temporary improvement, with decreased pain and stiffness in joints for a variable period of time. Moderate improvement consisted of decreased pain and stiffness, decreased swelling, and increased motion in the joints for three months or longer. Marked improvement consisted of decreased pain, stiffness and swelling, with marked increase in joint motion; patient able to return to work. The period of relief lasted for one year or longer.

It will be noted (Table I) that in only six (22 per cent) of the group were the results sufficiently striking over a period of one year or longer to be classified as markedly improved. In no case in the group was a complete permanent result obtained so that the designation "cured" could be used.

D. Blood Pressure Changes

	AVERAGES		DIFFERENCE	2 σ DIFFER- ENCE \pm		OBSERVA- TIONS
	BE- FORE	AFT- ER				
A. Systolic pressure	129	108	-21	7		24
B. Diastolic pressure	83	69	-14	6.4		
C. Pulse pressure	46	39	-7	-		

In Table II data of the laboratory studies are given. The average blood pH for the group was 7.415 for the control period, 7.55 at a temperature of 104° F., 7.52 four hours later, and 7.418 when the temperature dropped to normal. This shows an uncompensated alkalosis during the febrile period.

The greatest change in the blood density occurred during the induction of the fever, but inasmuch as the only significant figure was in the fourth decimal place, we have considered the change as insignificant.

Fig. 1 shows the typical finger volume changes of the average patient secured by means of the plethysmograph. The photographic record, Fig. 1, clearly shows the magnitude of the changes found. The maximum response occurred between a temperature of 103° F. and 104° F. Occasionally the maximum response was recorded at 102° F.

No significant changes in the ascorbic acid concentration of the blood plasma were found which could be attributed to the influence of electropyrexia.

The average of 26 determinations of total serum protein, albumin, and serum globulin of the blood prior to treatment are shown in Table III. The total serum protein of the blood ranged from 6.02 per cent to 9.2 per cent. The great majority (18) were within the accepted standard range of 6.0 to 8.0 Gm. per 100 c.c. Eight patients ranged from 8.1 to 9.2 per cent. Three patients showed a higher percentage of serum albumin than the normal range of 3.6 to 5.4 per cent. The serum globulin was lower than the normal range of 1.5 to 3.4 in four patients, and was higher in four. The albumin-globulin ratio was reversed in two patients. The average ratio for the 26 patients was 1.9. One patient was below the accepted normal range of 1.2 to 2.6, and six were above. The average value for fibrinogen was 0.42.

Fig. 1A.

Fig. 1A, B.—The effect of artificial fever on the blood volume of the finger as measured by the air conduction plethysmograph.

The systolic blood pressure averaged 129 mm. Hg before treatment, and the diastolic pressure averaged 83 mm. Hg. After treatment both systolic and diastolic pressures had fallen to 108 and 69 mm. Hg, respectively (Table II D). These were significant changes as can be seen by referring to Table II.

PATIENT REACTIONS

The majority of the patients tolerated the treatment quite well. The complaint of headache was not infrequent. Occasionally a patient had paraesthesia of both hands, and dizziness. One patient of this series vomited. An unlisted patient at the completion of his first treatment suddenly failed to respond to

questions, and then became irrational. There was a brief period of paralysis of the right arm and right leg. The left nasolabial fold was eradicated, and the mouth was drawn down on the left side. After a period of thirty minutes the patient was able to respond to questions but was still confused. Still another patient, L. B., developed an auricular fibrillation, was nauseated, had marked circumoral pallor, cold skin, and complained of faintness and abdominal pain. This instance of shock developed during the sixth and last treatment.

Fig. 1B.

Patient H. G. during his sixth and last treatment developed marked cyanosis as well as a twitching of the fingers of both hands. The heart tones were distant. The blood pH was 7.62. This patient's condition undoubtedly could have been relieved by the administration of carbon dioxide inhalations. Ten patients not listed completed only one or two treatments for various causes. One such patient after the second treatment developed a typical papular type of rheumatic rash, and treatment was, therefore, discontinued.

DISCUSSION AND SUMMARY

That none of our patients was "cured" has neither surprised nor dismayed us.

The current report¹⁴ of the American Rheumatic Commission recently published by Hench and his collaborators shows only too well how far we are from the solution of the problems of arthritis. It indicates that there is far from unanimity among recognized authorities as to a standard classification of the disease in its various manifestations. The multiplicity, as well as the variety of the therapeutic procedures used for its control, certainly shows that the fundamental concepts of the disease are as yet little understood. Hench¹⁰ states that fever therapy may benefit arthritis by (1) direct bacteriolytic or bacteriostatic effects due to an influence of heat itself on bacteria; (2) a local effect from vasodilatation providing an augmented blood supply to inflamed tissues; (3) increasing indirectly the formation or mobilization of immune bodies; (4) a general effect from the heightened metabolism incident to fever. Whatever may be the factor that accounts for the benefit of fever therapy in arthritis, Hench is certain that selection of the patient is of prime importance. We select our cases from the atrophic group alone, preferably those who have not had their arthritis longer than two years. Those whose arthritis is well advanced and arrested can hope for only slight improvement, such as gain in weight, less pain and stiffness, less fatigue, but very little improvement in joint function. Unquestionably no one yet can claim to have solved the problem of the correct temperatures to be employed, the duration of the fever or its frequency of application, nor have the possibilities of fever therapy used in conjunction with other procedures been fully explored.

Our patients were all referred to our clinic from outside sources for treatment and in most cases long after other forms of therapy had failed to give relief.

In this study it was our aim to evaluate further the results of the short fever curve maintained at 104° F. for four hours. These additional patients tend to confirm our previous impression² that improvement of the patient is greater and of longer duration when the fever is maintained for eight hours. In this series we also gave a minimum of six treatments, but undoubtedly this is far too few. It may well be that such a series of treatments repeated once or twice a year might produce much better results.

The plethysmographic records would seem to indicate that a rectal temperature exceeding 103° F. to 104° F. is neither necessary nor desirable. The maximum changes in the peripheral circulation apparently occur at this temperature level, and if increased circulation is the therapeutic objective, then these temperatures should not be exceeded. High temperatures are contraindicated for this type of patient because many of them give evidence of a vasomotor instability, and have a low threshold for exhaustion. Furthermore, it is our opinion that they should not be subjected to high environmental temperatures. It can be seen from Table II *D* that there is a very significant drop in blood pressure as a result of the fever treatment. This may be due to a low-

ered peripheral resistance, caused by the marked vasodilatation which is present, and to a lowered blood volume level.

Investigators vary markedly in their reports as to what constitutes the normal blood levels of ascorbic acid either in health or in disease. Abt and Farmer¹⁵ consider blood plasma values below 0.7 mg. per 100 c.c. to be suboptimal. Daum, Boyd, and Paul¹⁶ state that the normal ascorbic acid content of the blood ranges between 0.7 and 2.0 mg. per cent. The assumption has been made that fever therapy increases vitamin C requirement, but direct experimental proof is lacking. While the average ascorbic acid concentration of the blood for the group was 0.62 mg. before treatment, the range varied from 0.28 to 0.72. Many values found in these patients are considered to be very low normals. Thirty-three of the 77 determinations before treatment showed a level below 0.5 mg. This is of interest in light of Rhinehart's investigations. He found that subacute or chronic vitamin C deficiencies in guinea pigs produced an arthropathy with manifold similarities to rheumatoid arthritis, and that superimposed infection accelerated or accentuated the pathologic processes. Infection in the presence of vitamin C nutrition, he noted, failed to produce arthritis.

TABLE III
DATA OF BLOOD PROTEIN ANALYSIS
(26 Determinations)

	RANGE		AVERAGE
	MAXIMUM	MINIMUM	
Total blood proteins	9.2	6.02	7.37
Albumin	7.0	3.73	4.76
Globulin	4.7	1.02	2.53
Fibrinogen	0.82	0.17	0.42
A./G. ratio	5.2	0.84	1.9

It is apparent that artificial fever produces a significant elevation of the blood pH. The average pH value of 7.55 found at a temperature of 104° F. indicates a state of uncompensated alkalosis. The loss of carbon dioxide by the body through the lungs and sweat during the fever is undoubtedly of prime importance in increasing the alkalinity of the blood. The skin is a path of carbon dioxide loss of some importance. Koehler¹⁷ is of the opinion there is a direct correlation between cyanosis and certain types of alkalosis. Mild cyanosis is not an uncommon occurrence in fever therapy. Koehler believes that fever alkalosis is due to increased lung ventilation and the rapid elimination of carbon dioxide from the blood, thus causing a carbon dioxide deficit, which in turn results in the passage of sodium ions into the tissue fluids and partially into the urine. Landis and collaborators¹⁸ do not believe that hyperventilation is the sole cause of the pH change, but is dependent on several factors, such as the kidneys, the degree of sweating, and lactic acid formation.

Bischoff, Ullmann, Hill, and Long¹⁹ do not agree with Koehler that an anoxemia exists in the presence of a fever alkalosis. As a result of the lowered carbon dioxide tension in the blood and increased pH, the stability of the oxyhemoglobin increases. If the circulation and the metabolism did not increase at the same time, the question would be quite simple. With an increase

in circulation, however, the tissues are exposed to more blood per unit of time so that the effect of the hemoglobin stability might be offset if the demand for more oxygen due to increased metabolism were not too great. It would seem then that instead of supplying the very distressed patient with oxygen as has been the tendency during the past few years, that it might be far more effective to give 8.5 per cent of carbon dioxide or even have the patient rebreathe air from a rubber bag. The unusual symptoms described for four patients are those resulting from hyperventilation of varying degree. Recently, Hinshaw and Boothby²⁰ have described this syndrome. Recently, also, we have undertaken some rebreathing experiments using a Boothby-Lovelace-Bulbulian face mask and as a result it is our opinion that had rebreathing been instituted during the period of hyperventilation all these patients would have completed treatment successfully.

Several investigations have been made chiefly on animals, a few on human beings, but none under comparable conditions, on the effect of fever on hemoconcentration. Observed blood changes²¹ have frequently been explained as due to a concentration phenomena. According to Howell,²² the specific gravity of human blood may vary from 1.041 to 1.067, the average being 1.055. All of our determinations (Table II) came within this range. Gibson and Kopp²³ state that one of the major physiologic effects of artificial fever induced by physical means is a diminution in circulating blood volume. They state that the degree of reduction in plasma volume is determined by the difference in rate of outflow by skin, lungs, and kidneys, and of effective absorption of fluids administered. If insufficient fluids are given the tissues, fluids of the body are drawn upon for the maintenance of plasma volume with resultant dehydration. Undoubtedly, the blood density will be dependent upon the balance of fluid loss and fluid gain, and one might readily criticize our work in that we did not control these variables. As previously stated, we gave fluids both in regard to quantity and rate, according to our judgment of the patient's need. We were interested, primarily, in ascertaining changes in hemoconcentration under the conditions of our therapeutic regime. In the thirty determinations of the specific gravity of the blood no significant changes were found. Apparently hemoconcentration is not the mechanism involved to account for the changes occurring in the blood cell count when fluids are administered during the course of treatment.

Our analysis of the blood serum proteins does not support the work of Davis.²⁴ Davis studied the blood plasma of nine patients with rheumatoid arthritis and found an increase of the globulin and fibrinogen as well as a lowered albumin of the blood plasma. The average albumin:globulin ratio of his nine patients was 0.9, while ours was 1.9. Two of our patients showed a reversal of the usual ratio (0.84 and 0.85, respectively). In both instances the reversal was due to an increase of the globulin fraction. Block²⁵ seems to believe that the albumin:globulin ratio is shrouded in a considerable degree of empiricism. Peters²⁶ states that studies of protein disturbances without simultaneous data on salt and fluid balance are valueless.

The average values for the total serum proteins, albumin, globulin, and fibrinogen of our patients conformed very well to the average normal values.

CONCLUSIONS

1. Twenty-seven patients suffering from chronic infectious arthritis were submitted to a fever of 104° F., maintained for four hours, and induced by electromagnetic induction.

2. Various physiologic observations, such as blood pH, ascorbic acid concentration of the blood, the specific gravity of blood, finger volume changes, total and fractional blood proteins, and blood pressures are reported.

3. Twenty-two per cent of the patients were markedly improved; 22 per cent moderately improved; 33 per cent slightly improved; and 22 per cent unimproved.

4. This form of therapy is not specific for chronic infectious arthritis but should be used in properly selected patients.

THE AMOUNT OF PLASMA AND WHOLE BLOOD IN THE LUNGS OF DOGS*

JOHN L. KEELEY, M.D., CHICAGO, ILL., AND
JOHN G. GIBSON II, M.D., BOSTON, MASS.

FEW previous studies concerning the amount of blood in the lungs are available. Stewart¹ calculated the quantity of blood in the lungs in dogs from the cardiac output per minute and the pulmonary circulation time, using the formula $V = Q \frac{60}{T}$. He expressed it as per cent of the total blood volume (estimated to be one-thirteenth of the body weight). His figures ranged from 11 to 26 per cent, and averaged 17 per cent. Kuno's² figures of 8.8 per cent to 19.44 per cent of total blood volume (estimated at one-fourteenth of body weight) in both lungs were obtained by colorimetric determination of the blood content of lungs from heart-lung preparations. Blumgart and Weiss³ determined cardiac output and net pulmonary circulation time in human beings and, using Stewart's formula, calculated that the lungs contain 10 to 41 per cent of the total blood volume (estimated to be one-thirteenth of the body weight), the average being 21 per cent. Bruns⁴ found that 6.3 per cent of the total blood volume in rabbits was in the lungs. Drinker, Churchill, and Ferry⁵ tabulated the results of some previous investigators⁶⁻⁹ and found, in three series of experiments, that in the rabbit the lungs contained 1/10.7 to 1/12.5 of the total blood volume at the end of inspiration and 1/15.3 to 1/17 of the total blood volume at the end of expiration. We have attempted to reinvestigate the question by a direct method of measuring the amount of plasma and (by calculation) whole blood in a single isolated lung.

PROCEDURE AND METHOD

Large normal mongrel dogs were used. Anesthesia was induced by the intravenous administration of pentobarbital (nembutal) in doses of 32.5 mg. per kilogram of body weight. After intubation of the trachea the chest was opened through the left fourth intercostal space. Adequate pulmonary ventilation was maintained by means of an Erlanger respirator. The pericardium was opened. The left branch of the pulmonary artery and the three left pulmonary veins were isolated and encircled separately by pieces of No. 1 chromic catgut, which were brought out through glass tubes, so that tension on the catgut closed the lumina of the encircled vessels. These tubes were bent in such a way as to conform to a space between the heart and the left lung, so that neither chambers

*From the Laboratory for Surgical Research and the Department of Medicine, Harvard Medical School, Boston.

Received for publication, August 13, 1941.

of the heart nor portions of the left lung would be collapsed by mechanical interference. The glass tubes protruded from the chest wall, the layers of which were closed tightly about the tubes. Just before completing the closure of the wound, the lungs were fully inflated. To prevent pneumothorax, the ends of the glass tubes which protruded from the chest wall were sealed with bone wax through which the catgut ligatures passed. A moderately stout rubber band was then fastened to each catgut ligature. In Experiment 1 the intratracheal tube was removed, and spontaneous respiration was established. In Experiments 2 and 3 intermittent insufflation was continued throughout the remainder of the experimental period. After allowing several minutes for stabilization of the

Fig. 1.—The concentration of dye in the circulating plasma is charted in relation to the intervals following (1) a single injection of dye, and (2) release of the ligatures. By extrapolation of the slopes thus obtained the circulating plasma volume before and after the release of the ligatures was determined. The difference represents the amount of plasma contained in the left lung.

circulation, the left lung was isolated from the general circulation by simultaneous traction on the four rubber bands. The plasma volume in the remainder of the circulatory system was then determined by the dye method of Gibson and Evans.¹⁰ After twenty-one, twenty-one, and twenty-two minutes, respectively, in the three experiments, the ligatures were released, allowing the undyed plasma trapped in the lung to re-enter the general circulation. Blood samples for total plasma volume determinations were taken at intervals during the following twenty minutes.

The volume of plasma in the left lung was calculated as follows (see Fig. 1): The amount of circulating plasma was determined on the basis of the slope of the disappearance of the dye from the blood stream with the ligatures closing the lumina of the vessels of the left lung. On release of the ligatures the undyed plasma contained in the left lung further diluted the remainder of the plasma, and the total plasma volume was determined from the new disappearance slope (extrapolated to the time of the dye injection) obtained from the dye concentration of the blood samples taken after mixing was complete. The difference between the two volumes was taken to represent the amount of plasma contained in the left lung while it was isolated from the general circulation. Blood for hematocrit determinations was taken during both phases of the experiment.

TABLE I

CIRCULATING PLASMA VOLUME AND AVERAGE HEMATOCRIT BEFORE AND AFTER RELEASE OF THE LIGATURES; CALCULATED VOLUME OF PLASMA TRAPPED IN THE LEFT LUNG AND PERCENTAGE OF TOTAL PLASMA VOLUME IN THE LEFT LUNG AND IN BOTH LUNGS

	PLASMA VOLUME (C.C.)	AVERAGE HEMATO- CRIT	PLASMA VOLUME IN LEFT LUNG (%)	PLASMA IN BOTH LUNGS (%)	REMARKS
Exp. 1, 19 kg. Ligatures closed Ligatures open Volume of plasma in left lung	619 669 50	50.5 50.25	7.4	18.5	Animal breathing spon- taneously No pneumothorax
Exp. 2, 27 kg. Ligatures closed Ligatures open Volume of plasma in left lung	910 962 52	58.4 59.7	5.4	13.5	Intermittent inflation Pneumothorax devel- oped
Exp. 3, 27 kg. Ligatures closed Ligatures open Volume of plasma in left lung	920 995 75	57.2 60.1	7.5	18.7	Intermittent inflation No pneumothorax

RESULTS

The results are shown in Table I. The left lung contained 7.4, 5.4, and 7.5 per cent of the plasma volume, respectively, in these three experiments. It has been shown that in dogs, the quantities of blood in the right and left lungs are in the proportion of 3:2.^{2, 4} On this basis, the portion of the plasma volume in both lungs in these three animals was estimated to be 18.5, 13.5, and 18.7 per cent. The results in Experiments 1 and 3 are in close agreement, but the lower value in Experiment 2 may have been due to a pneumothorax of undetermined extent which was detected at the end of the experiment, as it has been shown that the quantity of blood in a lung decreases with collapse of lung tissue.^{4, 11} Hematocrit values are shown in relation to closure and release of the ligatures in Fig. 2. There was little change throughout the procedure in Experiment 1, but in the other experiments there was a marked tendency for the hematocrit to rise for some time after the release of the ligatures. The possible significance of these findings is considered below.

DISCUSSION

The validity of the results obtained depends upon several factors affecting the accuracy of the method of plasma volume determination employed and upon the physiologic effects of the experimental procedures upon the circulation.

The accuracy of the plasma volume determinations by dye methods depends upon the complete mixing of the dye and plasma, and this, in turn, depends upon maintaining an adequate circulation as to both volume and speed. It has been demonstrated that under similar experimental conditions the sudden occlusion of one branch of the pulmonary artery does not cause a significant change in the cardiac output.¹² Thus, the same amount of blood goes through one lung as formerly went through both lungs, so that the circulation time is

decreased. Mixing of the dye and plasma was, therefore, thought to be satisfactory. The reliability of the so-called "indirect" method of determining changes in plasma volume with a single dye injection depends upon (1) the constancy of the intrinsic color (or optical density at a given wave length) of the plasma itself, and (2) the accuracy with which sudden changes in plasma volume are reflected by the differences in the disappearance slopes obtained. In the former instance, if there is marked blood concentration or dilution due to shifts in protein and pigment-free fluid, the optical density of the serum itself

Fig. 2.—The hematocrit values in relation to the release of the ligatures.

will increase or decrease, and the net optical density, presumably due solely to the dye present, will give a distorted value. The magnitude of this error varies inversely with the concentration of dye used. Since the density value of dye in these experiments was from ten to twenty times that of dye-free serum, this source of error can be disregarded. There is little doubt that the extrapolation of a disappearance slope of the dye affords the most accurate dilution value upon which to determine the plasma volume. But if during such a control period, any great quantity of the dye disappears from the circulation, then the volume calculation based upon a second slope obtained after a sudden dilution, based on the same colorimetric constant for the original amount of dye injected, will be in error. In these experiments, not over 2 per cent of the dye left the blood stream during the time the initial slope was being obtained. Also, not over 2 c.c. (or about 1 per cent of average plasma volume) was withdrawn in any one experiment. Therefore, this objection may be dismissed as insignificant.

Far more serious criticisms may arise on the basis of the physiological change produced by the experimental procedure itself. It has been demonstrated that

no communication exists between the bronchial and pulmonary arteries, but there is a communication between bronchial arteries and pulmonary veins.¹³ This communication is by means of capillaries, and the differences in size between the bronchial and pulmonary vessels do not suggest the possibility in these experiments of any great degree of mixture between dye-stained blood in the systemic circulation and dye-free blood in the pulmonary vessels of the left lung. However, such a communication might permit a small quantity of whole blood to enter the pulmonary circulation from the systemic circulation, but this quantity of blood would be added to that already isolated in the lung, there being no normal avenue by which blood may escape when once it is trapped in a lung by occlusion of the pulmonary veins. The disappearance of dye from the circulating blood stream through the bronchial arteries would not affect the determination of circulating plasma volume, because both dye and plasma would leave the systemic circulation in such proportions as to be without effect upon the concentration of dye in the systemic circulation. Similarly, when the tourniquets were released, the dilution which followed would be due to the original amount of dye-free plasma trapped in the lung.

Some anoxia may have occurred in the isolated lung, and the resultant increased permeability of the parenchymal capillaries may have permitted an escape of plasma, or of fluid poor in protein (and hence, dye) from the vascular bed. The rise in hematocrit in Experiments 2 and 3 (Fig. 2), after the release of the ligatures, suggests that this may have occurred. However, if the rise in hematocrit of the peripheral blood were due entirely to its mixture with the blood trapped in the left lung, the hemoconcentration should have been limited to the period in which dilution of dye occurred and should not have persisted thereafter (Fig. 1).

If stagnation of blood in capillaries in the dependent portions of the left lung occurred during the period in which it was isolated by the ligatures, it is possible that all the blood trapped in the lung was not carried out when the circulation was re-established. This possibility cannot be ruled out, but in that event the values for the amount of plasma contained in the lung would be too low.

We believe these results represent with reasonable accuracy the amount of plasma contained in the lungs of the dog in the resting state. No attempt has been made to determine the total blood volume in the lung from the change in plasma volume and the corresponding hematocrit values. It is not known definitely whether the ratio of plasma to cells is the same throughout the circulation, but there is increasing evidence that the corpuscular concentration is much less in capillaries than in large central or peripheral vessels, and that total blood volume calculated from the plasma volume and the hematocrit of blood from a large peripheral vessel are too high. It seems probable, however, that the hematocrit values of blood from the jugular vein (source of blood samples for hematocrit here) should not differ greatly from that in the pulmonary artery or veins, and it seems fair to say that the percentage of total blood volume in the lung is roughly equivalent to the percentage of plasma volume in the lung.

The results of this short series of experiments would not in themselves be of great significance, but there is close agreement between two of the determinations (Experiments 1 and 3), and it is believed that the presence of a pneumothorax accounts for the difference in the third (Experiment 2). The average value (17 per cent) is higher than that of Plumier (10 per cent), but compares favorably with that of Stewart (17 per cent). Our results in animals cannot be assumed to apply to human beings, yet it is interesting to note that Blumgart and Weiss³ found that in man an average of 21 per cent of the total blood volume was contained in both lungs.

SUMMARY

The quantity of blood contained in the left lung was trapped by the simultaneous occlusion of the vessels to that lung while both lungs were fully expanded. From determinations of the circulating plasma volume, during this period and after the release of the occlusion, the quantity of plasma trapped in the left lung was measured.

In three experiments, 7.4, 5.4, and 7.5 per cent (average 6.8 per cent) of the plasma volume was contained in the left lung. On the basis that, in the dog, the right lung contains one and one-half times as much blood as the left lung, the quantity of plasma in both lungs averaged 17 per cent. For reasons explained, a similar percentage of total blood volume may be assumed to be contained in the lungs.

IODINE ALLERGY*

LOUIS PELNER, M.D., BROOKLYN, N. Y.

THE widespread use of iodine and its salts in modern diagnostic and therapeutic techniques makes the finding of unusual reactions to these drugs extremely likely. Although the use of tincture of iodine as an antiseptic has fallen off in recent years, the use of the iodides, organic and inorganic, has increased because of their value in diagnosis. Prolonged intake of iodine or its salts gives rise to cutaneous eruptions more often than does the continued intake of any other single drug. However, these cases have to be distinguished from others that react in an unusual way to only a minute quantity of iodine. The latter patients are said to exhibit iodine hypersensitivity or allergy.

A patch test made with a drop of tincture of iodine, and read twenty-four hours later revealed marked redness and swelling over the site in all the hypersensitive patients. If this can be shown to be a general finding in other cases, it can be used as a diagnostic test. Other nonsensitive persons tested in this way did not show this reaction.

CASE REPORTS

CASE 1.—Reaction following the drinking of a saline laxative containing a minute quantity of iodine.

G. B., an 18-year-old girl, took a teaspoonful of an imported Italian salt, which was found to contain a very small quantity of iodine. Twelve hours later her eyes became red, her face started to swell, and she developed a pin-point, reddened eruption over her entire body, closely resembling that of scarlet fever. Her temperature was normal. An iodine patch test was markedly positive, and the qualitative examination of the urine for iodine and iodides was negative. The white blood cell count and the differential were within normal limits. The rash cleared rapidly after the administration of 10 grain capsules of sodium chloride every two hours for six doses. This patient had no previous history of sensitivity to iodine in any of its forms. She had used the salt repeatedly for years, but only occasionally during the preceding year.

CASE 2.—Reaction following the taking of a commonly used throat lozenge containing anesthesin and calcium iodide.

R. F., an 18-year-old girl, took a lozenge for relief of sore throat. Twelve hours later she developed a slight fever, swollen neck glands, slight edema of the face, and a generalized, reddened pin-point cutaneous eruption resembling that of scarlet fever. Her throat was slightly red; differentiation from scarlet fever in this case was difficult. However, the Schultz-Carlton test was negative, and an iodine patch test was markedly positive. The white blood cell count was 9,200, with 84 per cent polymorphonuclear cells. The qualitative

*From the Department of Medicine, Jewish Hospital, Brooklyn, and Department of Surgery, Beth Moses Hospital, Brooklyn.

Received for publication, August 20, 1941.

examination of the urine was negative for iodine and iodides. The symptoms cleared up in twenty-four hours after the taking of several fruit drinks containing large quantities of ordinary table salt, and without other medication.

After careful questioning this girl gave a history of having had a similar eruption many years before, which was diagnosed as scarlet fever. She had no sore throat at the time. She recollected having bruised her knee and applying tincture of iodine. The bruise turned a livid red, and a generalized rash appeared approximately twelve hours later.

CASE 3.—Cutaneous reaction following the insertion of a small piece of iodoform gauze after removal of a lipoma of the neck.

P. S., a 45-year-old male, had a lipoma removed under general anesthesia. A small amount of iodoform gauze was placed in the wound as a drain. Several hours later his temperature rose to 102° F. He showed lassitude, refused to take food, and had swelling of the face, eyes, and hands. The white blood cell count was 8,800, with 82 per cent polymorphonuclear cells. An iodine patch test was positive. The iodoform pack was removed. The patient's symptoms cleared within twenty-four hours following administration of 5 grains of sodium chloride every four hours.

CASE 4.—Thrombocytopenic purpura following the application of iodine percutaneously.

A. G., a 55-year-old Italian male, developed pains in his right shoulder and left ankle. He applied a thick layer of tincture of iodine to both areas. Several hours later he developed purpuric spots all over his extremities, chest, and abdomen. There was marked swelling of both hands, as well as of the face, and especially over those areas where iodine had been painted. There was no palpable liver or spleen, and the temperature was normal. The platelet count was 80,000. The bleeding time was fifteen minutes, coagulation time was five minutes, and clot retraction was still absent the following day. The white blood cell count was 8,200, with 78 per cent polymorphonuclear cells. There was a positive tourniquet test. An iodine patch test read the following day showed marked redness. On the assumption that this was a case of thrombocytopenic purpura, based on an allergic reaction to iodine, this man was given 5 grains of sodium chloride every four hours. The purpuric spots steadily cleared up, the redness in his face disappeared, and the swelling of both hands slowly receded. One week later the platelet count was 140,000, the bleeding and coagulation times were within normal limits, and there was good clot retraction in two and one-half hours.

About two weeks after the initial episode, he came to the office feeling very well and asked to have a Wassermann test done. An iodine swab was accidentally used to sterilize the patient's antecubital fossa preparatory to venipuncture. This was immediately swabbed with alcohol. Eight hours later the patient had a chill, swelling of the skin of the antecubital fossa, and a reappearance of purpuric rash. The platelets were again depressed to 70,000, the bleeding time was prolonged to ten minutes, the coagulation time to five minutes, and there was absence of clot retraction. These findings again cleared up after 5 grain sodium chloride capsules every four hours for three days. Within ten days the platelets had returned to 200,000, and the bleeding and coagulation times became normal. The Wassermann reaction was negative.

CASE 5.—Cutaneous eruption following the application of tincture of iodine.

A. B., a 15-year-old girl, developed a fever of 102° F., redness and swelling of the hands and face following the application of tincture of iodine to a bruise on the skin. The bruise was surrounded by an erythematous, raised red area, resembling erysipeloid. Diagnosis was made after the patient gave a history of a previous similar experience three years

before. The iodine patch test was markedly positive. Urine determinations for iodine and iodides were negative. The symptoms cleared up promptly after several doses of sodium chloride in 5 grain capsules.

COMMENT

Considering the widespread use of iodine and iodides, the incidence of allergic reactions to these substances appears to be low. That they must be considered, however, is brought out by the many deaths reported in the literature. Hollander and Fetterman¹ reported the eleventh case of fatal allergic reaction in 1936. Since that time there have been at least seven more recorded instances. In our series we were fortunate in not having deaths, although some of the reactions were quite severe.

Three of our cases showed general reactions to cutaneously applied tincture of iodine. One developed a scarlatiniform eruption, another had a history of such an eruption many years before. The third patient developed a case of thrombocytopenic purpura, typical in all respects save enlargement of the spleen. The literature on hypersensitivity to the cutaneous application of iodine is covered in Seymour's article,² in which he adds a very instructive case. The patient was tuberculous, and iodine was applied prior to the institution of pneumothorax treatment. After several moderately severe reactions every time iodine was exhibited, a very severe reaction occurred which resulted in death. Before death the patient developed an exfoliative dermatitis.

The question of the use of iodoform packs following operation is a moot one. Cushny³ stated that iodoform was almost useless as an antiseptic. He showed that microbes drawn from wounds under iodoform treatment were not retarded or weakened in their development. Indeed, he quoted work showing that the emigration of leucocytes from the blood vessels was hindered by the local action of iodoform. This would tend to retard healing. Iodoform slowly decomposes into iodine in the body, but the quantity so formed per unit time cannot be sufficient to sterilize the wound. It leads to a false sense of security, and when the question of sensitivity is taken into account, one wonders whether its use is justifiable.

The incidence of thrombocytopenic purpura following iodine allergy has not been so adequately discussed. Osler⁴ described a case which commenced twenty-four hours after the taking of 10 drops of compound of tincture of iodine. Dennig⁵ described three cases, all in elderly women with Basedow's disease. One followed the taking of potassium iodide in 6 drop doses daily for three weeks. Purpura developed. The platelets dropped to 20,000. Several weeks later the platelets increased and the patient finally recovered. Another of his cases is confused because of the coincident use of sedormid, together with tablets of an iodide compound. A third patient developed purpura following the consumption of sodium iodide for a short time. Both of these patients subsequently recovered.

There are several other cases with hemorrhagic symptoms in the literature, but unfortunately blood studies are lacking. Lobsenz⁶ reported fatal iodine poisoning following the use of iodoform gauze drains. He attributed the severe

hemorrhagic symptoms that the patient developed to vitamin C deficiency, but this appeared to be an impression unsupported by laboratory tests. Rowell⁷ reported a case showing hemorrhagic blebs on the extremities. The clotting time was between six and seven and one-half minutes. No figures were available on the platelet count.

All our cases showed local cutaneous sensitivity to tincture of iodine on patch test. This consisted of marked reddening and itching, perceptible in five to six hours. When observed at twenty-four hours, the erythematous area usually had extended slightly and was edematous. Since this reaction was invariable, irrespective of the method of intake of iodine or its salts in these patients, it was used as a method of detecting sensitivity, and called the iodine patch test. Jacobs⁸ found essentially the same result in his case, although he used other iodine products and iodine ointment as well. However, in an unduly sensitive person, even one drop of tincture of iodine might conceivably cause a marked reaction. Hence it might be better to wipe off the iodine with some alcohol after a minute. Since our patients did not have marked reaction to one drop, we have not as yet used this precaution.

In our patients, the dose of iodine taken into the body was so small that qualitative tests for iodine and iodides in the urine were negative. Sodium chloride in 5 or 10 grain doses appeared to ameliorate the symptoms. This appears to be the usual method of treatment. One author⁹ used sodium chloride intravenously. There are several reports of the use of epinephrine.¹⁰ If the mechanism is indeed one of allergy, this latter treatment seems more logical. The rationale of the sodium chloride treatment is that the chlorine ion displaces the weaker iodine from the iodide. In very severe cases the use of adrenal cortex hormone, because of its action on the sodium chloride in the blood, would seem to be indicated along with the other means at our disposal.

The mechanism of iodine allergy is unknown. The Wolf-Eisner theory of the combination of iodine with a protein in the body to produce the antigen is not substantiated by Jacobs. This theory, although intriguing, still awaits proof.

The patient who has iodine allergy must be told of his condition. Failure to do so may place his life in jeopardy at a later date. The physician who plans to use iodine or one of the iodides in diagnosis or treatment should ask the patient whether he has any iodine sensitivity. The ideal procedure would be to patch test every prospective user of these compounds. However, this is not often possible because of the time element involved.

SUMMARY

1. Five cases of hypersensitivity to iodine and its salts are described.
2. A patch test for the detection of this sensitivity is described, and was present in all five patients.
3. Several types of cutaneous eruption followed the use of iodine or its salts in these patients, appearing in from eight to twelve hours. Scarlatiniform eruptions developed in two, and a purpuric rash in another.

177 KINGSTON AVENUE

A BACTERIOLOGIC CHECK ON RESIDUAL DENTAL INFECTIONS*

MAYNARD MURRAY, M.D., AND EILEEN O'FERRELL, R.N.
CINCINNATI, OHIO

THAT the mere removal of infected teeth does not always suffice to eradicate dental infection has been taught by several authors. Martin H. Fischer's recent book, *Death and Dentistry*,¹ clearly re-emphasizes the problem. Removal of infected teeth alone "cures" the constitutionally afflicted in only some one-third of the cases, and "improves" the state of another third. There is abundant clinical and roentgenologic evidence that when teeth are extracted in the ordinary fashion, residual infection in the surrounding alveolar tissues may be left in place. Root fragments and bone rarefactions are conceded to be a source of systemic infection by most oral pathologists, but we would here emphasize the still larger importance of the infection remaining in the alveolar structures when such grosser evidences of pathology are nonexistent.

We have added to clinical and x-ray examination a bacteriologic study of cultures made from the alveolar structures. X-ray photographs of the full mouth were taken of patients presenting constitutional signs of chronic infection, after other possible sources for systemic invasion had been ruled out. These films showed an irregularity and furriness of the alveolar processes assumed by us to be caused by residual infection. The matter is illustrated by Figs. 1 and 2. In all the patients observed the teeth had been extracted at least five years previous to this study.

In a first series of edentulous patients who showed signs of residual infection by x-ray, as described above, a general anesthetic (pentothal sodium) was administered intravenously. When it had taken effect, the jaws were held open and the alveolar areas to be examined were scrubbed with soap and water.

*From the Laboratory of Physiology, University of Cincinnati, and the Longview State Hospital, Cincinnati.

Received for publication, August 30, 1941.

This was followed by a topical application of tincture of iodine, then alcohol, and finally, tincture of merthiolate. Swab cultures made from the surfaces thus prepared were negative in 8 of 10 patients studied, the remaining two patients showing organisms in no way related to the organisms cultivated from the

Fig. 1.—Note furriness and irregularity of the alveolar processes of a patient from whom all cultures made by puncture or grinding yielded a streptococcus.

Fig. 2.—Note smooth contour of mandibular surfaces in comparison with Fig. 1. Stab and incision cultures from this patient proved negative.

underlying structures. After this sterilization of the surface, 1 c.c. of sterile saline solution was injected into the alveolar processes, allowed to remain there a few moments, and then withdrawn without removal of the needle in the interim. We could thus recover approximately 0.25 c.c. This was squirted into sterile tryptose broth. Twenty-four hours later subcultures were made. In the 10 patients showing no more than the alveolar furriness described above, organisms were recovered from all. In a control series of 6 patients presenting smooth alveolar ridges, cultures taken in a like manner always proved negative.

In a second series of 16 patients incision was made, and the alveolar bone was exposed after proper precedent cleansing. This time cultures were made of the bone grindings. Growth of organisms was obtained in every instance. The grinding was done with a sterile burr. Check of the organisms recovered at times from the buccal surfaces against those recovered from the alveolar processes showed them to be wholly nonrelated.

The foregoing indicates that the removal of teeth is not synonymous with the eradication of a locus of infection, that mere irregularity and furriness in contours of after-remaining alveolar processes as revealed by the x-ray are evidence of the continued existence of such a locus.

THE SIGNIFICANCE OF ELECTROCARDIOGRAPHIC CHANGES IN MALIGNANT HYPERTENSION*

J. DAVID MARKHAM, M.D., AND NATHAN BLOOM, M.D.
RICHMOND, VA.

INTRODUCTION

THE changes that occur in the electrocardiogram of patients who have essential hypertension have been studied extensively. The exact nature of these changes is not fully understood, and there is much disagreement as to their significance.

In an attempt to clarify the controversy, a study of the fatal cases of malignant hypertension recognized at the Medical College of Virginia over a seven-year period was undertaken. Care was exercised in the selection of cases in order to eliminate any extraneous factors, such as valvular defects or coronary thrombosis, which might be present. Thirty-seven cases were available for study, comprising 54 electrocardiograms and 16 autopsy examinations.

The malignant phase of hypertension was chosen for several reasons. The course of the disease is very rapid, telescoping into a few months or years the changes that occur in essential hypertension over many years. The short time interval reduces the possibility of accidental occurrences which might alter the electrocardiogram. The disease usually terminates before senile degenerative changes have begun to appear. In practically all of these cases the patient died of uremia. Heart failure was not clinically present to complicate the electrocardiographic picture. It may be stated categorically that the changes seen in these electrocardiograms and observed at the autopsy table arose because of the presence of malignant hypertension.

THEORETICAL CONSIDERATIONS

Many authors have noted changes in the electrocardiogram which occur when there is marked left ventricular preponderance. Master¹ states that there is a definite relationship between the appearance of these changes and the size of the heart, and implies that the size of the heart is the sole factor involved. Barnes and Whitten² suggest that the size of the heart may be responsible for some of the changes, but not all, and that certain changes in the T wave are indicative of "left ventricular strain" or myocardial damage. In this study an attempt has been made to correlate post-mortem findings with the electrocardiographic changes.

*From the Division of Internal Medicine, Department of Medicine, Medical College of Virginia, Richmond.
Received for publication, September 8, 1941.

Willius¹ was among the first to provide indication that in hypertensive heart disease there is a change in the T wave. He found that in cases exhibiting T-wave negativity in Lead I, or in Leads I and II, the predominant disease was hypertension. This was not true of other combinations of T-wave changes. Barnes and Whitten² found that where lesions increased the work of the left ventricle, inversions of the T wave were often present in Lead I, or in Leads I and II; similarly, right ventricular preponderance produced T-wave inversion in Leads II and III, although the correlation was not as close as in left ventricular preponderance. They found that in nearly two-thirds of the patients with simultaneous inversions of the T wave in all leads there was no evidence of ventricular preponderance. From this they concluded that the factors producing ventricular preponderance were not the same as those producing T-wave inversions. They hypothesized further that the changes were evidence of ventricular strain, and were not dependent on the size of the heart.

Master⁴ holds a different opinion; he contends that the changes occurring in arterial hypertension are due solely to the increase in the size of the heart over a rather long period of time. His study consists largely of correlations between the electrocardiograms of patients with essential hypertension and the size of the heart as determined by the cardio-thoracic ratio in the teleroentgenogram. He states¹ that, as enlargement of the left ventricle begins, left axis deviation develops in the electrocardiogram. With further increase in the size of the left ventricle, T-wave inversion in the first lead occurs, followed by inversion of the T wave in the second lead. Roesler and co-workers⁵ noted a steady increase in the percentage of cases with electrocardiographic final deflection changes as the radiologic examination showed an increase in the size of the heart, but they found that an absence of final deflection changes and of left axis deviation was compatible with a marked degree of cardiac enlargement. They state that some factor other than cardiac enlargement is necessary to produce these changes.

Odel⁶ found structural changes in varying degrees of severity in the arterioles of the myocardium in a series of 35 cases of malignant hypertension. The presence of diffuse fibrosis in the myocardium in these cases added further evidence to the supposition that the electrocardiographic changes were due to myocardial damage. The electrocardiograms of these patients revealed depression of the S-T segment in Leads I or II in 59 per cent, and abnormal T waves in those leads in 47 per cent. Gouley⁷ states that myocardial pathology is a common occurrence in uremia with severe hypertension, while Wood and White⁸ attribute associated electrocardiographic changes to the toxic effect of uremia on the myocardium.

PRESENT STUDY

The present study may be divided into several parts. They consist of a consideration of the predominant trends in the electrocardiograms of 37 patients who died of malignant hypertension; the correlation of T-wave changes to myocardial damage as proved at autopsy; the relationship of cardiac weight to cardio-thoracic ratio; the relationship of myocardial damage to cardio-thoracic ratio; and the prognostic significance of the changes observed.

I. PREDOMINANT CHANGES IN THE ELECTROCARDIOGRAM

A detailed analysis of all important features of the electrocardiograms in the cases studied is shown in Table I. The total number of electrocardiograms showing the particular changes are noted under each heading. From this basic chart Table II is derived. It was felt that all abnormalities of the T wave should be considered, and we believe that the results justify this procedure. A total of 75.9 per cent of the electrocardiograms showed abnormalities of the T wave in Lead I and/or Lead II. Left axis deviation was present in 59.3 per cent, while depression of the S-T segment in Lead I and/or Lead II was found in 50 per cent.

TABLE I

FUNDAMENTAL DATA: ANALYSIS OF 54 ELECTROCARDIOGRAMS IN 37 PATIENTS

CHANGES	LEADS						
	I	II	III	I AND III	II AND III	I AND II	I, II, AND III
Notched P	0	3	1	1	4	0	1
Diphasic P	0	1	0	0	0	0	0
Negative P	2	0	3	0	0	0	0
High voltage P	0	2	2	0	2	0	0
High voltage R	8	3	0	0	0	2	2
High voltage QRS	1	2	0	0	0	0	5
Deep S	0	1	25	1	11	0	0
Q wave	8	0	0	0	0	0	0
Depressed S-T	9	7	0	0	3	11	0
Starred QRS	2	3	10	5	2	0	3
Elevated S-T	0	0	9	0	0	0	1
Prolonged S-T	0	0	0	0	0	0	1
Convex S-T	5	1	1	0	1	0	0
Concave S-T	0	0	3	0	0	1	0
Depressed S-T, upright T	3	4	0	0	0	1	0
Depressed S-T, negative T	7	7	0	0	1	4	0
Elevated S-T, upright T	0	1	3	0	0	0	0
Elevated S-T, negative T	1	0	3	0	0	0	0
Low T	7	2	3	3	2	1	0
Flat T	2	3	0	1	1	0	0
Diphasic T	8	8	3	1	3	2	4
Negative T	5	1	2	1	1	2	1
Total T changes	22	14	8	6	7	5	5
Left axis deviation was present in 32, absent in 22.							

TABLE II

RELATIVE INCIDENCE OF PREDOMINANT CHANGES IN THE ELECTROCARDIOGRAMS OF 37 PATIENTS WITH MALIGNANT HYPERTENSION (54 EKG)

	PER CENT
Changes (low, flat, diphasic, or negative) in T ₁ , T ₂ , or T ₁ and T ₂	75.9
Deep S ₃ , or S ₂ and S ₁	69.3
Left axis deviation	59.3
Depressed S-T ₁ , S-T ₂ , or S-T ₁ and S-T ₂	50.0
Deep S ₁	46.3
Depressed S-T ₁ , S-T ₂ , or S-T ₁ and S-T ₂ and negative T ₁ , T ₂ , or T ₁ and T ₂	33.3
High voltage R ₁ , R ₂ , or R ₁ and R ₂	24.1
Elevated S-T ₁	16.7
Depressed S-T ₁ , S-T ₂ , or S-T ₁ and S-T ₂ with upright T complexes in those leads	14.8
Q wave, Lead I	14.8

These results show that in malignant hypertension the variations in the T wave and the S-T segment must be considered a concomitant of the disease. When S-T depression is associated with abnormalities of the T waves, it means there is a more severe effect of the disease upon the heart than the T-wave changes alone would indicate.

II. ELECTROCARDIOGRAPHIC CHANGES AND MYOCARDIAL DAMAGE

In view of the controversy as to the presence or absence of myocardial damage in cases showing T-wave changes in the electrocardiogram when hypertension is present, we have analyzed the cases in our records which were autopsied. The high incidence of myocardial damage in cases showing T-wave changes in the electrocardiogram, and the absence of changes in cases where no damage was demonstrable, show that the changes indicate myocardial damage. This is demonstrated in Table III. A positive correlation is present in 68.75 per cent of cases.

TABLE III

CORRELATION OF T-WAVE CHANGES IN LEADS I AND/OR II WITH PRESENCE OR ABSENCE OF MYOCARDIAL DAMAGE ON POST MORTEM (16 CASES)

	CASES	PER CENT
Damage with EKG changes	7	43.75
Damage without EKG changes	2	12.50
EKG changes without damage	3	18.75
No damage and no EKG changes	4	25.00

A positive correlation is present in 68.75 per cent of the cases, and a negative correlation in 31.25 per cent. While these figures are derived from too small a series to prove the point beyond question, they confirm the impression that the T-wave changes in malignant hypertension are due to myocardial damage, and not to enlargement of the heart.

III. CARDIAC WEIGHT, MYOCARDIAL DAMAGE, AND CARDIO-THORACIC RATIO

Fourteen patients were available for analysis of the cardiac weight. Nine of these had a determination of the cardio-thoracic ratio before death. The mean cardiac weight was 586 Gm., and the mean cardio-thoracic ratio was 55 per cent. The deviations from the mean were considerable, the smallest heart weighing 400 Gm. and the largest 820 Gm., while the cardio-thoracic ratio ranged between 45 and 66 per cent. The interesting part of the analysis is the lack of correlation of the size of the heart to the cardio-thoracic ratio. There are many reasons for this, as shown in the footnote to Table IV.

We have analyzed our data in 20 cases in which the cardio-thoracic ratio was known. T-wave changes indicative of myocardial damage were present in 15 of these cases; the cardio-thoracic ratios in these cases ranged between 45 and 66 per cent, covering the entire range of our series. On the other hand, electrocardiograms showing no T-wave changes in five cases were also found to cover the entire range of cardio-thoracic ratios. The results are tabulated in Table V.

These findings suggest that there is no definite correlation of cardiac size with cardio-thoracic ratio, nor of electrocardiographic changes with cardio-thoracic ratio. The cardio-thoracic ratio is a totally unreliable guide in interpreting the changes in the electrocardiogram. It cannot be assumed that a high cardio-thoracic ratio means that the electrocardiographic final deflection changes are without significance.

TABLE IV
CORRELATION OF CARDIAC WEIGHT TO CARDIO-THORACIC RATIO

CASE NO.	CARDIAC WEIGHT (GM.)	C-T RATIO (%)	WEIGHT DEVIATION FROM MEAN	RATIO DEVIATION FROM MEAN
S1234F	400	52	-186	- 3
S13460F	470	45	-116	-10
S52132M	500	45	- 86	-10
S38192M	500	56	- 86	1
S42537F	530	--	- 56	---
S40224M	550	66	- 36	11
S13584M	580	60	- 6	5
S32122F	590	58	4	3
M51122F	600	55	14	0
M27562M	610	--	24	---
S4019M	650	--	64	---
S32128M	660	54	74	- 1
M45348M	750	--	164	---
S45189M	820	59	234	4

The mean cardiac weight is 586 Gm. The mean cardio-thoracic ratio, as determined by teleroentgenogram is 55 per cent. Statistical analysis of this very small series shows that, although there is a positive correlation, it is not greater than that which could occur by chance (coefficient of correlation is 0.435, standard error of coefficient of correlation is 0.354). Factors modifying the C-T ratio, such as degree of dilatation of the ventricles, the rotation of the heart in the body, and the anteroposterior diameter of the chest, render this an unreliable method of determining the true size of the heart.

TABLE V
RELATIONSHIP BETWEEN T-WAVE CHANGES INDICATIVE OF MYOCARDIAL DAMAGE AND THE
CARDIO-THORACIC RATIO IN THE SAME PATIENTS

As shown above, no correlation exists between the cardio-thoracic ratio and T-wave changes indicative of myocardial damage.

IV. THE PROGNOSTIC SIGNIFICANCE OF THE ELECTROCARDIOGRAM OF MALIGNANT HYPERTENSION

It is recognized that the prognosis of malignant hypertension is serious, death usually occurring a few months to a few years after the disease has been discovered. It is still impossible to predict for the individual patient whether or not he will have the greater life expectancy of one or two years.

In an attempt to provide a more exact prognosis, we studied the electrocardiograms of each patient who had more than one electrocardiogram taken before he died, with special regard for the changes in the S-T segment and

*Consistent with pericarditis.

†Digitalis effect is present in this electrocardiogram.

Eighty-one per cent of these patients showed changes in the S-T segment or T wave characteristic of malignant hypertension in at least one electrocardiogram. All of them died in uremia; nevertheless, the electrocardiographic changes have considerable prognostic significance. Malignant hypertension is a diffuse arteriolar disease. When the coronary arterioles have become involved to a degree sufficient to produce myocardial damage, renal failure is near.

T wave. Eleven cases were available, with 27 electrocardiograms. It was found that 81 per cent of these patients showed characteristic S-T or T changes in at least one electrocardiogram. This may be explained, since the single electrocardiogram in the other cases might not have been taken at the most opportune time to demonstrate the changes. As shown by Bellet and McMillan,⁹ terminal uremic pericarditis often elevates the S-T segment in all leads. It is likely that in some of our cases it raised the depressed S-T segment to the isoelectric line. The study indicates that in a very large majority of cases, characteristic electrocardiographic changes can be demonstrated at some time during the patient's life.

There was no uniformity in time from the appearance of the characteristic electrocardiogram to the death of the patient. However, as shown in Table VI, the appearance of these changes meant that death was near. When the widespread vascular process had proceeded long enough to produce changes in the heart muscle sufficient to give the characteristic electrocardiographic picture, the kidneys were usually on the verge of complete failure. While the electrocardiogram cannot predict the exact life expectancy, its changes indicate a more serious prognosis for the immediate future than does the normal electrocardiogram with the same degree of hypertension.

TABLE VII

FREQUENCY OF DEATHS FROM MALIGNANT HYPERTENSION AT VARIOUS AGES, GROUPED AT FIVE-YEAR INTERVALS

AGE IN YEARS	NUMBER DYING
15-19	1
20-24	2
25-29	3
30-34	7
35-39	10
40-44	8
45-49	6

Table VII shows that the greatest mortality is after the third decade, with no deaths after 50 years of age. This indicates that the changes found in the electrocardiograms of these patients are due almost entirely to the malignant hypertension. The degenerative senile processes, which may alter the electrocardiographic picture in essential hypertension, have not yet made their appearance.

Finally, in evaluating the significance of the electrocardiographic changes in malignant hypertension, a tabulation was made of the age at which each patient died (Table VII). The greatest mortality was in the group 35 to 39 years old. The majority of deaths occurred after the third decade was reached, while none occurred over 50 years of age. This indicates that the electrocardiogram is a reliable guide in following the progress of malignant hypertension, and has some prognostic value. Senile degenerative changes, which may modify its usefulness, have not appeared. It is evident that the characteristic changes observed in this series are due solely to the effect of the malignant hypertension on the heart.

CONCLUSIONS

1. Low, flat, diphasic, or negative T waves and depressed S-T segments are characteristically found in Lead I, Lead II, or Leads I and II of the electrocardiogram in malignant hypertension.

2. These changes indicate the presence of myocardial damage, and are only coincidentally related to the cardiac size.

3. The cardio-thoracic ratio is not a reliable guide in interpreting the electrocardiographic picture, nor has it any prognostic value.

4. The presence of typical changes in the electrocardiogram indicates a serious prognosis for the immediate future.

TEMPERATURE STUDIES ON INTRAVENOUS FLUIDS*

NELSON A. MURRAY, M.D., TAMPA, FLA.

THE purpose of this presentation is to show the temperature at which preheated or precooled fluid actually enters the vein of the patient, and not to dictate at what temperature such fluid shall be given.

Fig. 1.—Details of thermometer assembly.

For the experimental work a standard intravenous set was used, and the fluid (normal saline) was allowed to fall one meter through regular gum rubber tubing (5 mm. diameter). A No. 20 needle was used. The needle was attached to the lower end of a Taylor Centigrade thermometer (-10 to $+150^{\circ}$ scale) by a rubber band, so that the fluid flowed directly out of the needle onto the thermometer bulb. The fluid was allowed to collect in a one liter flask, the thermometer bulb resting on the bottom of same. The flow was adjusted so that one hour was consumed in allowing one liter to run out. The temperature of the fluid was adjusted from $+10$ to $+90^{\circ}$ C. in 10° intervals. Three different arrangements were used originally, similar to the ones actually used in this hospital by various

*From the Tampa Municipal Hospital.
Received for publication, September 2, 1941.

physicians. First, no extra external heat was applied after the solution was preheated. Second, two regular hot water bottles, containing 1,500 c.c. each of water at 55° C. (usual temperature of hot water in the taps in this hospital), were tied around the flask containing the fluid. Third, the tubing was "sandwiched" between two hot water bottles, 15 cm. from the needle. This last arrangement corresponds to the hot water bottles lying on the bed beside the patient's arm.

Fig. 2.

An attempt was made to read the temperature at the end of the first minute, but due to cooling by evaporation, and also due to the fact that not enough fluid had collected in the flask to cover the thermometer bulb, the readings were not considered accurate enough to include in the final report.

A fourth method was tried, in which the thermometer was inserted in a trap as shown in Fig. 1. The results are summarized in Fig. 2.

CONCLUSIONS

1. Preheated or precooled intravenous fluids tend to adjust themselves rapidly to a figure near room temperature, no matter what may be the original temperature of the original solution.

2. The customary methods of keeping intravenous fluids "warm" by the application of external heat in the form of hot water bottles are ineffectual.

A NOTE ON THE INEFFECTIVENESS OF SULFONAMIDE COMPOUNDS IN THE TREATMENT OF POLIOMYELITIS OF MICE*

JOHN A. KOLMER, M.D., AND ANNA M. RULE
PHILADELPHIA, PA.

ALTHOUGH sulfanilamide and other sulfonamide compounds have been found ineffective in the treatment of experimental poliomyelitis of monkeys,¹⁻⁵ we have thought it advisable to determine whether or not they possess any therapeutic properties in poliomyelitis of mice.

Two hundred and thirty adult white mice (*Mus musculus*) were inoculated intracerebrally with 0.03 c.c. of a 5 per cent suspension in saline solution of the hind brains of mice removed after the development of flaccid paralysis following inoculation with the Lansing strain of poliomyelitis virus which has been adapted to these animals by Armstrong⁶ from the eastern cotton rat (*Sigmodon hispidus hispidus*). While the virus has certain marked similarities to, as well as marked differences from, the spontaneous mouse virus first described by Theiler,⁷ Lillie and Armstrong⁸ have found that the pathologic changes produced by the virus in the central nervous system of mice and rats were closely similar to the reactions of poliomyelitis virus in man and monkeys.

As shown in Table I, 20, or 50 per cent, of 40 untreated controls developed paralysis and died within two to eight days after inoculation; 17, or 42.5 per cent developed paralysis and died in from ten to twenty-four days after inoculation, while only 3, or 7.5 per cent, escaped infection. All 37 of the 40 controls developing infection died within one to two days after the onset of flaccid paralysis of one or more of the legs or of the respiratory center, so that the disease in mice is so rapidly fatal after paralysis has developed that it is not well adapted for treatment purposes, although the incubation period following the intracerebral inoculation of virus is sufficiently prolonged in the majority of mice to permit the administration of repeated doses of compounds for the determination of therapeutic effects.

Sulfanilamide, sulfapyridine, and sulfathiazole, as well as two new compounds, sulfathiazoline (2-sulfanilyl 3-5 dihydrothiazole) and 2-sulfanilyl-aminopyrazine (No. 3032), synthesized by Raiziss and Clemence,⁹ and kindly supplied by them, were administered orally in a dose of 0.005 Gm. per mouse twice daily (10:00 A.M. and 3:00 P.M.) for ten days in succession, or until paralysis and death occurred (2 to 20 doses). The first dose of each was given twenty-four hours after inoculation. As the mice averaged from 20 to 25 Gm. in weight, each dose was equivalent to about 0.2 Gm. per kilogram, or about 0.4 Gm. per kilogram per day.

SULFONAMIDE COMPOUNDS IN THE TREATMENT OF POLIOMYELITIS OF MICE*

COMPOUNDS†	NO. MICE	PARALYSIS AND DEATHS; DAYS AFTER INOCULATION														NO PARALYSIS; SURVIVALS
		2	4	6	8	10	12	14	16	18	20	22	24	26		
Sulfanilamido	40	3	4	2	2	1	1	5	3	4	4	3	3	0	5 (12.5%)	
Sulfapyridine	40	8	8	3	5	2	1	2	2	2	2	1	1	0	3 (7.5%)	
Sulfathiazole	40	2	6	2	2	4	3	1	5	3	3	4	1	0	4 (10.0%)	
Sulfathiazoline	40	4	8	2	2	6	4	0	6	6	0	2	0	0	2 (5.0%)	
No. 3032‡	30	4	6	2	2	2	2	3	1	3	2	1	0	0	2 (5.0%)	
Controls	40	3	8	5	4	2	2	2	2	4	1	2	2	0	3 (7.5%)	

*Inoculated intracerebrally with 0.03 c.c. of a 5 per cent suspension of the Lansing strain adapted to mice (Armstrong).

†Orally in dose of 0.005 Gm. per mouse twice daily (10:00 A.M. and 3:00 P.M.), first dose twenty-four hours after inoculation.

‡2-sulfamthyl-4-amino-pyrazine.

As previously stated, 3, or 7.5 per cent, of 40 untreated controls survived. Of 40 mice treated with sulfanilamide, 5, or 12.5 per cent, survived; of 40 treated with sulfapyridine, 3, or 7.5 per cent survived; of 40 treated with sulfathiazole 4, or 10 per cent, survived; of 40 treated with sulfathiazoline, 2, or 5 per cent, survived, while of 30 treated with 2-sulfanilyl-aminopyrazine (No. 3032), 2, or 5 per cent, survived.

The administration of the compounds was continued after the development of paralysis, but with completely negative results, since all treated and untreated paralyzed animals died within one to two days after the onset of paralysis, permitting the administration of only one to three additional doses.

CONCLUSION

While the percentage of survivals among mice treated with sulfanilamide and sulfathiazole were slightly higher than that in the case of untreated controls, it is concluded that these compounds, as well as sulfapyridine, sulfathiazoline, and 2-sulfanilyl-amino-pyrazine, have proved ineffective in the treatment of mice inoculated intracerebrally with the Lansing strain of poliomyelitis virus (Armstrong). These results are in confirmation of the ineffectiveness of the sulfonamide compounds in the treatment of monkeys inoculated intracerebrally with the M.V. and other strains of the virus.

CLINICAL CHEMISTRY

THE CHANGES IN THE BLOOD VOLUME PRODUCED BY DIABETIC ACIDOSIS*

SAMUEL D. JACOBSON, M.D., AND RICHARD H. LYONS, M.D.
ANN ARBOR, MICH.

ALTHOUGH it has been recognized that diabetic acidosis is associated with hemoconcentration,¹ very few observations have been made on the volume of circulating blood under these circumstances.^{2, 3} During studies on the relation of dehydration to the plasma volume, observations were made on two patients who developed diabetic acidosis under controlled conditions.

METHODS AND PROCEDURES

Blood volume determinations were made with the method of Gibson and Evans,⁴ as modified by Gibson and Evelyn.⁵ Venous pressure measurements were made by the direct method,⁶ using 10 cm. above the level of the back as the point of zero pressure. Serum protein measurements were made by the falling-drop method described by Barbour and Hamilton.⁷ The carbon dioxide combining power of the plasma was determined by the method of Van Slyke and Cullen.⁸

The patients observed were both males with diabetes who had previously been treated with diet and insulin for many years. Both were controlled on a 4,000 calorie experimental diet, consisting of 100 Gm. of protein, 265 Gm. of fat, 300 Gm. of carbohydrate, and insulin. After control values of the blood volume, venous pressure, serum protein concentration, plasma carbon dioxide combining power, and body weight were determined, insulin was discontinued. Daily urinalyses were done for sugar and ketone bodies.

RESULTS

Patient 1 was observed without insulin for nine days. Although the entire 4,000 calorie diet was regularly consumed, there was a 5 kg. weight loss during this period. There was a loss of 1.5 kg. during the first twenty-four hours coinciding with the onset of severe glycosuria. Ketonuria appeared on the fourth day and gradually increased in severity. During the night of the eighth day nausea and vomiting developed, followed in the morning by drowsiness, Kussmaul respirations, anuria, low blood pressure, clammy extremities, and

marked collapse of the veins. The plasma carbon dioxide combining power at this time had fallen to 14.0 volumes per 100 c.c. The arterial blood pressure, usually 130/80, was now 90/60. The veins were collapsed.

There was a severe reduction of 860 c.c. (23 per cent) in the total blood volume due entirely to a 36 per cent decrease in plasma volume. In spite of the loss of 5 kg. of weight, there was a marked decrease in the blood volume and plasma volume per kilogram of body weight from 60 c.c. to 52 c.c. (13.4 per cent) and from 38 c.c. to 26 c.c. (31.2 per cent), respectively. The hematocrit and serum protein concentrations were increased 30.6 per cent and 21.4 per cent, respectively. These changes are recorded in detail in Tables I and II. There was a prompt recovery within eight hours following the intravenous administration of 4,000 c.c. of 5 per cent glucose in normal saline, insulin, sodium bicarbonate, and forced fluids by mouth.

Patient 2, who was not as severe a diabetic as Patient 1, was observed without insulin for fifteen days. Although the high calorie intake was maintained, there was a 5.1 kg. loss in weight, most of which occurred after the plasma carbon dioxide combining power had decreased.

TABLE II
PERCENTILE CHANGES

PATIENT	% CHANGE BODY WEIGHT	% CHANGE IN TOTAL BLOOD VOLUME	% CHANGE IN PLASMA VOLUME	% CHANGE IN TOTAL BLOOD VOLUME/KG. BODY WT.	% CHANGE IN PLASMA VOLUME/KG. OF BODY WT.	% CHANGE IN HEMATO- CRIT	% CHANGE IN CON- CENTRATION OF SERUM PROTEINS
1	-8.0	-23.0	-36.2	-13.4	-31.2	+30.6	+21.4
2	-5.7	-14.7	-21.8	- 7.1	-15.9	+12.5	+20.0

By the fifteenth day there was an 800 c.c. (21 per cent) decrease in plasma volume and a marked reduction in total blood volume and plasma volume per kilogram body weight from 84 c.c. to 78 c.c. (7.1 per cent) and from 51 c.c. to 43 c.c. (15.9 per cent), respectively. The loss of blood volume was largely at the expense of the plasma volume; the hematocrit and serum protein concentrations were increased 12.5 per cent and 20 per cent, respectively. The venous pressure was reduced from 130 mm. to 100 mm. of water (23 per cent). These changes are recorded in detail in Tables I and II. The patient promptly recovered with the administration of insulin, fluids, and glucose by mouth.

DISCUSSION

The data presented here indicate that the blood volume is significantly decreased in diabetic acidosis, the reduction being entirely at the expense of the plasma volume. Both the total blood volume and the plasma volume per kilogram body weight were also reduced. There was an increase in the hematocrit and plasma protein concentration that closely paralleled the decrease in plasma volume. These results are in agreement with those of Chang, Harrop, and Schaub,² who used the carbon monoxide method to determine blood volume and who found a reduction in the blood volume per kilogram body weight and an average decrease in plasma volume of 19 per cent. Peters¹ reported details

on 13 patients who had an average decrease of 16 per cent in the concentrations of serum proteins with recovery from diabetic acidosis. The large decreases in plasma volume in man, as determined by the dye method and the carbon monoxide method, as well as the changes in hematocrit and serum protein, indicate that the plasma volume shares an important part in the dehydration associated with diabetic acidosis.

Sundermann and Dohan,³ using vital red dye for the measurement of blood volume, in a study of ketosis in 6 pancreatectomized dogs, found an average decrease of 10 per cent in total serum volume and an actual increase of 29 per cent in the serum volume per kilogram body weight. None of these dogs, however, developed a marked acidosis, as measured by the carbon dioxide content of plasma. It is possible that under these circumstances the acidosis was not sufficiently severe or prolonged to cause a greater depletion of the extracellular fluid. Atchley, Loeb, and others,⁹ in a study of the electrolyte changes in two patients with diabetes, found that with the withdrawal of insulin there was an increase in the excretion of both potassium and sodium which would indicate a loss of both intracellular and extracellular fluid. They have pointed out that the initial electrolyte and water loss was dependent upon the sudden appearance of marked glycosuria.

The demonstration of the marked fall in blood volume in man associated with the decrease in venous pressure may well explain the cause for the peripheral circulatory collapse often seen in severe diabetic acidosis. It has been observed¹⁰ that the diminution in plasma volume produced by mercurial diuretics or ammonium chloride acidosis is associated with a nearly proportionate decrease in venous pressure in normal persons. It has been established that changes in venous pressure in dogs and man will produce significant alterations in the cardiac output.¹¹⁻¹³ Thus in diabetic acidosis the low blood volume and its accompanying fall in venous pressure may produce a decrease in the cardiac output. The low arterial pressure, anuria, clammy extremities, and the clinical picture of peripheral circulatory collapse seen in diabetic acidosis may, therefore, be the result of the decrease in the volume of circulating blood.

The marked reduction in blood volume in diabetic acidosis, particularly when associated with peripheral circulatory collapse, should indicate immediate replacement of the blood volume as an important step in the management of this type of patient. Although there may be an increase in the concentration of serum proteins at the time of the acidosis, the parenteral administration of normal saline or glucose may not necessarily be expected to increase the plasma volume immediately,¹ since the fluid may be lost to dehydrated tissues. Blood transfusion, or better still serum transfusion, should be especially helpful in the replacement of plasma volume and the relief of the circulatory collapse.

CONCLUSIONS

1. Diabetic acidosis observed in two patients was associated with a marked reduction of blood volume due to the loss of plasma volume and a fall in blood volume per kilogram body weight.

2. Associated with the fall in blood volume there was also a significant fall in venous pressure.

3. It is emphasized that the circulatory collapse sometimes found in diabetic acidosis is in part at least the result of the accompanying decrease in blood volume and venous pressure.

THE VALUE OF BLOOD CHLORIDE AND SODIUM DETERMINATIONS IN THE DIAGNOSIS OF DEHYDRATION*

WILLIAM S. HOFFMAN, PH.D., M.D., AND BESS OSGOOD, M.S.
CHICAGO, ILL.

IN A typical case the syndrome of dehydration is not difficult to recognize. The patient shows dryness of the mouth and tongue; shocklike weakness and apathy; diminished skin turgor; sunken, softened eyeballs; lowered blood pressure, associated frequently with a rapid pulse rate and other signs of circulatory distress, and marked diminution in urinary output, which occasionally approaches anuria. Frequently, however, the clinical picture is not so straightforward as thus presented. It may be obscured by other symptoms associated with the disease producing the dehydration, or it may even be produced by the therapeutic measures undertaken to control the disease. Not infrequently, because the scanty urine may contain some albumin and a number of casts and even red blood cells, and may be associated with nitrogenous retention, the condition is diagnosed as acute nephritis. This diagnosis usually causes a paralysis of all efforts at controlling the dehydration.

Since severe clinical dehydration is always associated with a loss of salt, and since this loss is reflected in the concentration of chloride and sodium in the blood,¹ it should be possible to recognize the condition by the appropriate blood chemical determinations. It is the purpose of this paper to present evidence that determinations of whole blood chloride are usually misleading in the information they impart concerning the state of hydration, because the whole blood chloride concentration varies with the degree of the anemia. It will be shown also that, though serum chloride values are not affected by the red blood cell concentration and though they are a more satisfactory gauge of dehydration than whole blood chloride values, they are also at times unreliable; for the serum chloride may be normal or even higher than normal in many cases of excessive water loss. On the other hand, evidence will be offered to show that a lowering of serum sodium concentration always accompanies severe dehydration and that its determination, now feasible in all clinical laboratories, should be used in conjunction with serum chloride analysis in the diagnosis of dehydration.

METHODS

To determine the influence of red blood cell concentration upon the whole blood and serum chloride levels, a study of the distribution of chloride between

*From the Departments of Physiological Chemistry and Medicine, the Chicago Medical School.

Received for publication, February 20, 1942.

cells and serum (or plasma) was made in 80 persons. These persons were either healthy medical students or technicians or were ambulatory dispensary patients with varying degrees of anemia. No cases of pernicious anemia or other types of hyperchromatic anemia were chosen. No patient had any clinical or laboratory evidence of disturbance of water or electrolyte balance.

For the analysis, blood was drawn from an arm vein with a minimum of stasis into dry syringes. The portion for whole blood was immediately transferred to a tube containing potassium oxalate. For the determination of red blood cell volume percentage, Van Allen² hematocrit tubes were filled to the mark and diluted with 1.3 per cent sodium oxalate. The tubes were sealed with wide rubber bands and then centrifuged at 2,500 r.p.m. for at least twenty minutes, until the column of red blood cells no longer diminished in height. Blood for serum analysis was transferred under oil to centrifuge tubes, stoppered and allowed to clot, and then centrifuged for ten minutes. The serum was separated and recentrifuged to remove the last trace of red blood cells. Both whole blood and serum chloride determinations were made by the microphotoelectric iodate method of Sendroy,³ as modified by one of us (W. S. H.).⁴ All analyses were made in duplicate and averaged. Hematocrit estimations were made in triplicate. The red blood cell concentration was estimated from the equation

$$R = \frac{100 W - (100 - H) S}{H} \quad (1)$$

where R and S are the red blood cell and serum chloride concentrations, respectively; W, the whole blood concentration; and H, the volume percentage of red blood cells or the hematocrit reading.

For the determinations in the later clinical studies in this paper mentioned in Table II, the following methods were employed: sodium, Hoffman and Osgood;⁵ carbon dioxide-combining power, Van Slyke;⁶ protein and nonprotein nitrogen, Hoffman and Osgood;⁷ hemoglobin, Sheard and Sanford.⁸ In all the photoelectric methods the Cenco-Sheard-Sanford Photometer was used. The average normal concentration of serum sodium was found to be 143 meq. per liter, the range being 138 to 148 meq. per liter.

WHOLE BLOOD CHLORIDE

For the sake of brevity, the results of the analyses are expressed in frequency charts in Fig. 1 and as scatter curves in Fig. 2. Serum chloride concentration (Fig. 1a) varied from 100 to 110 meq. per liter, the great majority of values falling between 102 and 107 meq. per liter. The average serum chloride concentration was 104.4 meq. per liter, with a standard deviation of ± 2.0 meq. per liter (610 ± 12 mg. NaCl per 100 c.c.). The solid circles in Fig. 1 represent cases of anemia, that is, patients with hematocrit readings less than 40 per cent. It can be seen that there is no difference between the distribution of the serum chloride values of anemic persons and those with normal red blood cell volume. All the values fit into a compact probability curve. Similarly, the red blood cell chloride values are independent of the hematocrit reading (Fig. 1b). Their range is relatively wider than that of the serum

chloride values, and the probability curve arrangement is not so definite. However, this fault can be explained by the greater error of the calculation of the red blood cell chloride. An error of 1 meq. in either whole blood or serum chloride produces an error of 2 to 5 meq. in the red blood cell chloride concentration, depending upon whether the hematocrit reading is high or low. Nevertheless, the distribution of the values for anemia cases is the same as that for normal cases. The range is from 47 to 57 meq. per liter, with a mean value of 52.3, and a standard deviation of ± 2.5 .

Fig. 1.—Frequency distribution of chloride concentrations in *a*, serum *b*, red blood cells and *c*, whole blood in 80 cases. Solid circles represent cases of anemia, that is, hematocrit readings of less than 40 per cent.

On the other hand, the values for whole blood chloride (Fig. 1c) are much more widely distributed than those for serum or red blood cells. The range is from 77 to 100 meq. per liter. The average value is 84.6 meq. per liter, and the standard deviation is ± 4.6 meq. per liter. However, the values fit so poorly into any probability curve that the mean value and the standard deviation have very little significance. The anemia cases are distributed all to the right side of the chart, indicating that the whole blood chloride is dependent upon the degree of anemia. If there had been more severe anemia cases, there would undoubtedly have been more weighting to the right, and an increase in the standard deviation.

If the red blood cell and serum chloride concentrations are independent of the hematocrit reading, then the whole blood chloride *must* vary with the hematocrit reading. This can be seen from equation (1), which may be rewritten as

$$W = S - \frac{S - R}{100} H \quad (2)$$

where *S* and *R* (the serum and red blood cell chloride concentrations, respectively) are regarded as constants, and *W* and *H* (the whole blood chloride and the hematocrit) are variables. The lower the value of *H*, the higher the value of *W*. When the hematocrit becomes zero, the whole blood chloride equals the serum chloride, a conclusion which is obvious without reference to the equation. Choosing *S* as 104.4 meq. per liter, and *R* as 52.3 meq. per liter, equation (2) becomes the line AB in Fig. 2a, where *W* is the ordinate and *H* is the abscissa. This is the curve of expected values for whole blood chloride,

based on the assumption of the constancy of the serum and red blood cell chloride concentrations. The curve is an oblique line passing through the base ($H = 0$) at $W = 104.4$. The observed values for whole blood chloride, plotted against the hematocrit with the same coordinates as the curve AB, form the scatter curve which follows closely the theoretical curve. The deviations from the points on the theoretical curve are no wider than those in the scatter for serum chloride plotted along with the theoretical equation, $S = 104.4$ (line AC, Fig. 2b).

Fig. 2.—a, Scatter curve showing the relationship between whole blood chloride concentrations and the hematocrit readings in 80 cases. The line AB represents the theoretically expected curve. b, Scatter curve showing the relationship between serum chloride concentrations and the hematocrit readings in the same 80 cases. The line AC represents the theoretically expected curve.

Thus these data offer statistical confirmation of the proposition first stated by Norgaard and Gram⁹ that the serum and cell chloride concentrations are independent of the degree of anemia, but that the whole blood chloride concentrations must necessarily vary with the red blood cell volume percentage. Failure to recognize this fact has made whole blood chloride determinations worthless in most clinical laboratories. It would probably be better that the determination be abandoned altogether for clinical purposes. But where it is carried out, the expected normal range must be determined from a chart such as Fig. 2a. For this purpose, Table I has been constructed from the data in Fig. 2a and from the hemoglobin concentrations determined in the 80 cases. The range of probable values for any given hematocrit was determined by drawing two lines parallel to the theoretical curve AB, so as to include all the observed values. Table I should be of aid in recognizing low blood chlorides in those cases where such a finding confirms the diagnosis of dehydration. The following two cases illustrate the failure to interpret properly whole blood chloride determinations.

TABLE I

VARIATIONS OF WHOLE BLOOD CHLORIDE WITH THE HEMOGLOBIN CONCENTRATION AND RED BLOOD CELL VOLUME IN BLOOD OF PATIENTS WITH NO ELECTROLYTE DISTURBANCE

0 (Serum)	0	585-643	100-110	608	104

CASE 1.—A girl of 21 was brought to the hospital suffering from fever, jaundice, repeated vomiting, and oliguria, following an attempted abortion. The patient did abort, but her condition grew worse. The urine was scanty and showed some albumin, red blood cells, and several casts, and there was some nitrogenous retention. A diagnosis of acute nephritis was considered. The hemoglobin was 10 Gm. per 100 c.c., and the whole blood chloride was 450 mg. of NaCl per 100 c.c. This value was regarded as within normal limits, since the range of whole blood chloride is usually given as 450 to 500 mg. of NaCl per 100 c.c. When it was pointed out that the expected whole blood chloride for such a degree of anemia was 514 mg. of NaCl per 100 c.c. and that the probable lower limit for normal was 491 mg. of NaCl per 100 c.c. a serum chloride analysis was made. The serum chloride concentration was 538 mg. of NaCl per 100 c.c. or 92 meq. per liter, a value 11 per cent below the average normal. The patient was given 4 liters of physiologic saline intravenously within twenty-four hours. She began to urinate and made a complete recovery.

CASE 2.—A man aged 65 years, five days after a prostatectomy, developed secondary hemorrhage. Following this accident, the quantity of urine diminished rapidly, and the blood chemical analysis showed increasing nitrogenous retention. The patient had been on a low salt diet previous to the operation and had little salt following the operation. The condition was diagnosed as uremia following renal failure. The hemoglobin concentration was 8.9 Gm. per 100 c.c., and the whole blood chloride concentration was 465 mg. of NaCl per 100 c.c., which was thought to be well within normal limits. But with this degree of anemia, the whole blood chloride should have been within the limits of 503 to 555 mg. of NaCl per 100 c.c. When this fact was made clear, intravenous saline therapy was instituted, and improvement soon followed. With adequate urinary output the blood nonprotein nitrogen concentration soon decreased to normal, and the patient eventually recovered.

SERUM CHLORIDE VERSUS SERUM SODIUM

The foregoing data unequivocally indicate the diagnostic advantages of serum chloride determinations over those of whole blood chloride. In many uncomplicated cases of dehydration, the serum chloride is sufficiently lower than normal to confirm the clinical diagnosis. However, this is not always true. The data assembled in Table II from our own cases indicate that serum chloride may be low, normal, or even high in proved cases of dehydration. The 15 cases in Table II were chosen to illustrate the findings in dehydration associated with a variety of disease processes. In all these cases the clinical symptoms of dehydration were pronounced, and clinical improvement followed immediately upon the intravenous injection of sufficient physiologic saline solution (usually along with Hartmann's solution) to restore the electrolyte balance to normal. The quantity of fluid required for an adult usually was about 4,000 c.c. in the first twenty-four hours.

In 8 of the 15 cases the serum chloride values, as well as the serum sodium values, were lower than normal, but in the remaining cases the chloride values were normal, at the upper limit of normal, or even higher than normal. When vomiting is a prominent symptom in the disease producing dehydration, chloride is usually depleted at the same rate as sodium. In those cases where partial restitution of electrolyte balance is attempted either unwittingly or therapeutically by ingestion of sodium chloride, chloride may rise to normal or above normal while the sodium concentration still remains low. This is particularly likely to occur in Bright's disease and in Addison's disease, when the kidneys, because of either organic or functional derangement, cannot readily excrete the excess chloride. Case 5 illustrates the development of dehydration and acidosis during an uncontrolled intake of ammonium chloride. Here, dehydration was present in spite of extremely high serum chloride concentration, yet the serum sodium value properly reflected the clinical state.

In all 15 cases the serum sodium concentration was lower than the minimal normal value of 138 meq. per liter. The deviation from normal was not very great, if one uses as a criterion the changes that can occur in urea or glucose concentrations. But even a 5 per cent drop below the average normal value indicates marked dehydration, for in the early stages of dehydration the sodium concentration still remains within normal limits. Even in the alkalosis of pyloric obstruction and gastrocolic fistula (Cases 12 and 13) there was a sodium deficit. It was not as great as the chloride deficit, but it determined the degree of dehydration in these cases. In the first hours of pyloric vomiting the chloride may drop rapidly below normal, but not until the sodium loss, in the vomitus and in the urine, produces a serum sodium concentration lower than normal, is severe dehydration present.

When, as in Case 6, the serum sodium is as low as 116 meq. per liter, it is scarcely compatible with life. Along with the usual symptoms of dehydration, there is marked oliguria and azotemia. The symptoms and signs may be difficult to distinguish from true uremia. The patient, in this case, had had labor induced because of eclampsia. At the time of the blood chemical analysis she had scarcely urinated at all for several days. She was bloated, had pallid facies, was weak and apathetic, and was obviously in serious condition. The blood nonprotein nitrogen concentration was 108 mg. per 100 c.c., and the blood pressure was 170 mm. systolic and 100 mm. diastolic. In spite of the risk of recurrence of convulsions saline injections were recommended. The patient was given 3,000 c.c. of physiologic saline solution intravenously during the first twenty-four hours, and 2,000 c.c. the following day. The blood pressure rose slightly, but no convulsions occurred. The urinary output was 1,200 c.c. on the day following onset of treatment and rose to 3,000 c.c. daily. The non-protein nitrogen dropped to normal, and the patient recovered completely in several weeks.

The data in Case 3 illustrate the changes in the blood chemistry after adequate water and salt therapy. The serum sodium, chloride, and carbon dioxide-combining power rose to normal value. At the same time the increase in plasma volume produced a dilution of hemoglobin, red blood cells, serum protein, and nonprotein nitrogen. Thus, though it was true that the period

of dehydration was associated with hemoconcentration, this could not have been ascertained at the time by analysis for hemoglobin, red blood cell volume, or serum protein, for all these values were well below normal. Yet the serum sodium and chloride indicated the true condition. (It should be noted that the whole blood chloride was within so-called normal limits.) Only in 4 of the 15 cases was the serum protein above the normal limits, even though hemoconcentration was undoubtedly present in all these cases.

The determination of serum sodium, it has been seen, may be of lifesaving importance. It should not necessarily replace the determination of serum chloride. The two analyses, along with that of the carbon dioxide-combining power, should be performed in all cases of suspected water and acid-base disturbance. The three determinations together give adequate information in severe cases of dehydration, not only in regard to the volume and mineral content of the extracellular fluids, but also with respect to the degree and type of acid-base balance disturbance. If, for example, the sodium and chloride are equally lowered and yet the carbon dioxide-combining power is low, then the acidosis is due to the retention of acid ions other than chloride. In nephritis these ions are almost always phosphate and sulfate, but in other diseases they are usually organic acids—acetoacetic and hydroxybutyric acids in diabetes and starvation; lactic acid in cardiac failure and in convulsions.

Moderate or incipient dehydration is not associated with changes in serum chloride or sodium. There is at present no laboratory aid for the detection of such early dehydration. However, if the dehydration is not severe enough to have produced electrolyte changes, it is seldom a factor in the differential diagnosis. Moreover, it is usually not difficult to recognize the condition by clinical observation. As Simeone¹⁰ has recently pointed out: "Long before ionic changes are demonstrable in the blood, the withdrawal of interstitial fluid causes a diminution in the blood flow through the salivary glands, the secretions from which are thereupon impoverished. Thus the best index of early dehydration is the old clinical observation of dryness of the buccal and oral mucous membranes. Dysphagia is usually present. . . . The value of blood chemical determinations is not to be belittled, however; they at least demonstrate the degree of dehydration, and the nature of the shift in electrolyte pattern serves as a guide for replacement therapy."

SUMMARY

A study of the distribution of chloride between red blood cells and serum was made in 80 persons who had varying red blood cell volume percentages but who had no evidence of dehydration or electrolyte imbalance. The serum chloride ranged between 100 and 110 meq. per liter, with a mean value of 104.4 and a standard deviation of ± 2.5 . The red blood cell chloride concentration was also independent of the anemia. The whole blood chloride, however, varied directly with the red blood cell volume in a predictable manner. From the scatter curve of variations of the whole blood chloride with the hematocrit reading, a table was prepared which indicated the expected whole blood chloride value for any particular hemoglobin concentration or hematocrit reading. It was shown that failure to interpret whole blood chloride concentrations

according to such a table has prevented clinicians from recognizing dehydration, particularly when such dehydration was the cause of oliguria and nitrogenous retention.

In a study of 15 cases of severe dehydration in a variety of disease processes, serum sodium was found always lower than the minimal normal of 138 meq. per liter. In these cases, serum chloride, though at times correspondingly low, was occasionally within normal limits or even higher than normal.

The conclusion was reached that a proper evaluation of the water and mineral content of the body in dehydration, both from the point of view of diagnosis and therapy, can be achieved by analysis of the serum for sodium, chloride, and carbon dioxide-combining power.

THE EXPERIMENTAL PRODUCTION OF HYPOALBUMINEMIA BY FASTING*

ROBERT ELMAN, M.D., LEO A. SACHAR, M.D., ABRAHAM HORVITZ, M.D.,
AND HARRIET WOLF, A.B., ST. LOUIS, MO.

ALTHOUGH the causal relationship of a protein-deficient diet and nutritional edema has been known since World War I, hypoproteinemia was not recognized as a crucial phenomenon, largely because there were few determinations of plasma protein in dietary deficiency until the extensive clinical observations of Peters and his co-workers,¹ beginning about 1926. A summary of most of their findings and a review of the literature was published by them in 1933.² Prominent among the contributions of Peters was, first, the fact that the fall in serum protein in malnourished patients was confined to the albumin fraction, the globulin remaining relatively unaffected; second, that the fall in serum protein might be masked by dehydration, the lowered value not becoming evident until the dehydration was corrected; third, various infections often produced a rise in serum globulin, thus creating a normal total serum protein, even though there was a depletion in the albumin fraction.

Experimental hypoproteinemia was induced with a protein-deficient diet by Frisch, Mendel, and Peters,³ who were able to lower the serum protein in white rats to 3.0 Gm. per 100 c.c. Much more extensive observations on the dog were made by Weech and his co-workers,⁴ who used a low protein diet, consisting of carrots, sucrose, lard, rice, cod-liver oil, and a salt mixture. Confirming the clinical observations of Peters, they noted that the fall in serum protein was confined to the serum albumin, the globulin fraction remaining unchanged. A second, and very important observation, was the fact that the fall in serum albumin began at once and continued progressively during the first month or more the animal was on the diet.

Though the influence of a complete fast on the concentration of serum protein has received considerable attention, the findings are much less conclusive. As early as 1882 Burekhardt⁵ found that the concentration of total protein fell slightly when dogs were fasted for four days. Hanson,⁶ in 1918, reviewed the earlier literature and concluded that "a wide disparity in the results obtained by different workers is the rule rather than the exception." Hanson himself studied six rabbits during alternate periods of fasting and feeding, the longest period of fasting being six days. Though no very marked differences were noted, there was a tendency for the albumin concentration to be slightly lower after the longer periods of fasting. Bloomfield⁷ and Torbert⁸ studied rats which were fasted, killed at intervals, and the serum protein determined. Though the total protein concentration dropped initially,

*From the Department of Surgery, Washington University School of Medicine and Barnes Hospital, St. Louis.

Aided by a grant from the Louis D. Beaumont Fund.

Received for publication, February 23, 1942.

the findings in general were not very conclusive. However, Torbert noted that the initial drop was in the albumin fraction; he found, furthermore, that the blood volume decreased during the experiment so that the total circulating protein diminished, even though the concentration remained relatively unchanged. The same finding was reported in a carefully controlled experiment by Holman, Mahoney, and Whipple⁹ in a dog that was fasted for twenty-four days. These workers concluded that "fasting usually does not modify the total protein concentration in the plasma, and the albumin-globulin ratio may not be changed, but fasting does cause conspicuous shrinkage of the blood plasma volume and, therefore, the total amount of circulating protein may decrease to 70, 60, or even 50 per cent of normal."

During a complete fast there is, of course, an increased breakdown of protein in order to supply calories, thus leading to a release of large amounts of nitrogen, much of which may remain as amino acids. The idea has been expressed that this extra nitrogen might spare serum protein depletion or even lead to its regeneration. Indeed Weech and his collaborators,¹⁰ and Melnick and his collaborators,¹¹ each found that during a period of starvation, there was an increase in the concentration of serum protein in a dog with chronic hypoproteinemia.

EXPERIMENTAL PROCEDURES

Two series of experiments were carried out in 15 dogs. In Experiment I 5 dogs were given by gavage for three weeks a solution containing Karo syrup, Ringer's solution, and vitamin B complex,^{*} and were allowed water *ad libitum*; the energy value was 500 calories per day, due entirely to carbohydrate, and nitrogen was 0.07 Gm. per day. In Experiment II 10 dogs were fasted completely; water was allowed *ad libitum*, but 3 did receive in addition Ringer's solution by gavage. Samples of heparinized blood were removed at the beginning of the experiment and each week thereafter by puncturing the jugular vein and removing a sample with as little stasis as possible. The red cell volume was determined after centrifugalization, and the supernatant plasma used for the determination of albumin and globulin, separation being carried out by the method of Campbell and Hanna.¹² Determinations of the nitrogen were carried out by a micro-Kjeldahl, as described by Sobel, Yuska, and Cohen.¹³

EXPERIMENTAL FINDINGS AND COMMENT

The present findings show that hypoalbuminemia occurs on a protein- and fat-deficient diet regardless of whether or not there is any caloric intake. Thus the serum albumin concentration declined both in the 5 dogs given a solution containing carbohydrate, Ringer's solution, and vitamin B (Table I), as well as in the 10 animals fasted completely (Table II). Moreover the changes were progressive and started from the very beginning of the experiment.

The average fall in the albumin was twice as great in the dogs receiving calories as in those completely fasted (29 per cent as compared with 14 per cent). Inferences cannot be drawn from this striking difference, which was due in part at least to hemoconcentration occurring in the fasted dogs, as

^{*}Labco was obtained from The Borden Company, Bainbridge, N. Y.

indicated by comparing the behavior of the hematocrit values in the two groups. Thus, while the average red blood cell volume fell in Experiment I, there was a slight increase in Experiment II. Though there was considerable individual variations in the group of fasted animals, as can be seen by studying each of the experiments in Table II, the increase in the red blood cell volume was so pronounced in several instances that the fall in serum albumin not only was masked but even gave way to a rise. (See the italicized values in Table II.) This effect of dehydration on the concentration of serum albumin was first observed in human beings by Peters and co-workers,¹ as already mentioned.

One can only speculate on the influence exerted by caloric intake on the magnitude of the albumin loss in view of the striking influence of a complete fast on the red blood cell volume as just pointed out. Whether the protein-sparing action of glucose would affect the plasma as well as tissue protein cannot be answered from the present data; it would require experiments in which both the plasma volume and the nitrogen excretion were measured.

The independence of the globulin fraction of the plasma during the intake of the protein-deficient diet in these experiments confirms previous clinical observations of Peters,¹ experimental findings by Weech and his co-workers,⁴ as well as other experiments from this laboratory.^{11, 15} In other words, removal of protein and fat intake affects only the albumin fraction of the plasma, and not the globulin.

Worthy of mention is the fact that in the present experiments and in others,¹⁴ as first shown by Weech and associates,⁴ the fall in albumin begins at once, and is progressive, initially at least, as long as protein is withheld from the diet. If there is such a thing as "deposit protein," or "reserve protein," it certainly fails to manifest itself under the conditions of these experiments. It would seem, therefore, that hypoproteinemia due to deficiencies in dietary protein cannot be prevented by body protein, or some other source of endogenous protein, which suggests that the concept of reserve protein may, perhaps, not apply to hypoproteinemia produced by dietary means alone.

SUMMARY

1. A pronounced (29 per cent) fall in the concentration of the albumin fraction of the plasma was observed in 5 dogs on a protein- and fat-deficient diet for three weeks; a similar but much smaller (14 per cent) fall occurred in 10 other dogs that were fasted completely. The globulin fraction remained relatively unchanged.

2. The less pronounced hypoalbuminemia in the animals completely fasted was accompanied by an increased red blood cell volume and was, therefore, due in part at least to dehydration; in a few instances of pronounced hemoconcentration the decline was masked or even replaced by a rise.

3. The observed hypoalbuminemia began with the onset of the experiment and was progressive. This indicates the absence of any store of reserve protein for the manufacture of serum albumin during a dietary induced deficiency.

LABORATORY METHODS

GENERAL

SIMPLIFICATION OF FLUORESCENCE MICROSCOPY*

CLARENCE F. GRAHAM, M.D., ALBANY, N. Y.

THE fluorescence method of microscopy for the demonstration of *Mycobacterium tuberculosis* has recently attracted some attention in this country, but a more general testing and appraisal of the procedure is likely to be delayed because of a belief that the apparatus required is elaborate and complicated, or else expensive and difficult to obtain. Furthermore, commercial equipment already under test in some laboratories has met a most unfavorable reaction on the part of the workers who use it because the illumination is so dim that the tubercle bacilli can be seen only in an almost dark room, and at the expense of great eyestrain during protracted examination of films. This is totally unnecessary, but unless a more satisfactory form of light is devised the whole method may fall into disrepute as impractical. The principle is so simple, however, and the application so easy that the method may well be given the investigation it deserves if the technique can be reduced to a minimum no more difficult than ordinary microscopic examination.

The principle is elementary. It has been found that organisms of the acid-fast group, when stained by any one of a series of yellowish dyes, retain the stain after decolorization with acid alcohol, while bacteria not acid-fast lose the stain. The dyes used for the staining, including auramine-O, berberine sulfate, and thioflavine, are those which fluoresce when illuminated by ultraviolet light just off the end of the visible spectrum, the so-called "glass ultraviolet," which passes through ordinary glass with only moderate reduction in intensity. If a film stained and decolorized as indicated is illuminated with a powerful light which has passed through a deep blue filter of appropriate transmission band, the organisms which have retained the stain fluoresce a bright orange yellow, while the rest of the field is dazzlingly blue. An orange-yellow glass disc on the diaphragm of the ocular, selected for color so that it passes the fluorescent light of the bacilli and is opaque to the blue light of the field, will allow the stained bacteria to flare out on a dark background. The appearance is much like that seen with dark-field illumination, though the principle is totally different, and the fact that the organisms are self-luminous from their fluorescence and in sharp contrast to their surroundings makes them appear much larger than usual, so that they are easily seen with a high dry objective, as of 4 or 8 mm. focal length.

*From the Department of Pathology and Bacteriology, Albany Medical College. Aided by a grant from the Van Rensselaer Fund for Research in Tuberculosis. Received for publication, December 9, 1941.

The descriptions of the fluorescence method in the German and American literature are likely to give the impression that a rather special form of lamp is needed to give the necessary ultraviolet output.¹⁻⁶ Since, however, the light passes through the ordinary substage condenser of the microscope, perhaps fully 2 cm. in thickness, as well as through a condensing lens on the light source and through the common glass slide, the ultraviolet requirements plainly cannot be very exacting. Likewise, the insistence that a polished front-surface aluminum mirror must be used in place of the usual microscope mirror, in the belief that a silver surface absorbs the ultraviolet, is unfounded. A powerful, concentrated source of light, like a carbon arc or a 500-watt projection bulb, fitted with a condensing lens of about 7 cm. focal length with the blue filter in front of the condenser will supply an illumination bright enough to permit examination of films in a room darkened only by drawing the window shades.

Fig. 1.

A satisfactory bulb for the purpose has been found in the 500-watt G. E. projection bulb operating on 110 to 115 volts. This is mounted in a ventilated sheet metal lamp box improvised in the laboratory. A condenser can be obtained from an old arc light, but a pair of ten-cent store reading lenses in tandem has proved equally useful. The proper relation of the lamp to the condensing lens is determined by trial and error, checking the effect of changes by the appearance of the field in the microscope. It has been found that the lamp should be set with the plane of the filament coils at an angle of about 30° to the optical axis so that the images of the coils will nearly overlap, as seen in the lighted field of the microscope. The housing should be large and provided with ample air inlet and outlet to dissipate the heat rapidly. It has also been found that the filter is better placed in front of the condensing lens rather than behind it. The beam of light should practically cover the mirror of the microscope, and its location is best seen when the mirror is half covered with a card during

adjustment. This arrangement calls for only an ordinary commercial bulb of relatively low cost, plus the application of a little ingenuity in making the housing, and dispenses with all special equipment, except the blue and yellow filters.* A substitute for the blue filter can be made with an ammoniacal solution of cupric sulfate contained in a flat-sided bottle, and adjusted to the proper depth of color by watching the microscope field as the solution is diluted.

For the benefit of those who have not had the opportunity to consult the literature which outlines the fluorescence technique, the procedure is described in its simple detail.

Heat-fixed films are stained in the cold for three minutes with a solution of auramine-0 (national aniline) made up as follows: auramine-0, 0.1 Gm., phenol absolute, 3 ml., and freshly distilled water, 97 ml. This solution should be kept in the dark, and made fresh every two weeks. It forms a slight precipitate without apparent loss of staining property. The film is rinsed in running water and decolorized for two minutes, and again for five minutes, with two applications of the solution: concentrated hydrochloric acid, 4 ml., sodium chloride, 4 Gm., 70 per cent alcohol, 1 liter. Decolorization may be continued much longer if desired, even for twenty-four hours. The slide is rinsed in running water, dried, and examined with the 4 mm. objective and a 10× ocular, or with an 8 mm. objective and a 20× ocular.

In films made from concentrates of sputum by sodium hydroxide digestion, practically no fluorescent material is seen, except the auramine-stained bacilli, so that a question often asked by persons seeing such a preparation for the first time will be, "Is this from a culture?" Direct films from sputum or spinal fluid, however, may contain many fluorescent inflammatory cells which hinder the examination. In such cases the suggestion of Herrmann may be followed, to counterstain for a few seconds with 0.1 per cent potassium permanganate solution followed by Loeffler's methylene blue, to make the cells so dark a blue that they become invisible.² In this laboratory concentrate films are examined routinely, so that no difficulty has arisen, except in the case of the spinal fluid of tuberculous meningitis, in which instance the counterstain has worked perfectly. Since a properly stained preparation will show nothing fluorescing except the bacilli, if any are present, it may be difficult to focus on the plane of the slide with no reference object in view. To meet this difficulty the suggestion has been made that a dot or streak of the auramine stain be put on one end of the slide just before it is examined, to give a reference plane for focusing.

In adjusting the illumination, it has been found convenient to pick up the light from the plane mirror with the low-power objective and center it properly before the high dry lens is swung into use. If organisms are abundant, they can usually be seen with the low power directly, and if the low- and high-power lenses are parfocal, the final adjustment is much simplified. The low-power field appears dark red, greenish, or almost black with any fluorescent particles showing as bright dots of light. The condenser should be at its top position, as lowering it gives a red or light-colored background. The aluminized mirror, as stated, is not necessary, but the microscope mirror and condenser should be kept reasonably clean.

*These may be obtained from the Spencer Lens Company.

The use of the immersion lens is unnecessary in routine examination of films, but it may be employed to check on the morphology of bacilli that appear atypical. Cedar oil, mineral oil, and sandalwood oil are not satisfactory as immersion media, since they all fluoresce and cast a haze over the field, but methyl salicylate (oil of wintergreen) is an excellent immersion oil with a high refractive index, and does not fluoresce. It can also be used as a mounting medium in the examination of tissue sections by the fluorescence method.

It has been noticed that an auramine-stained film will fade in the area exposed to the ultraviolet light if left in the field for about ten minutes. The fluorescence, of course, implies absorption of energy from the activating light, and apparently photochemical changes also take place. Likewise, stained films fade after the lapse of time, and the brightest preparations are those which have just been made, but restaining is satisfactory at any time. A Ziehl-Neelsen stain can be superimposed upon an auramine stain, but not vice versa.

Examination of fluorescence films stained with auramine-O is considerably easier than similar examination of Ziehl-Neelsen films, because of the wide field covered by the dry objective and because the organisms are either seen or not seen without confusion with their surroundings, provided the illumination is bright enough to cause brilliant fluorescence. This proviso is the reason the use of such a high-power lamp is recommended. Probably at least 95 per cent of the light from the bulb is stopped in the filter, and the near ultraviolet output of a filament bulb is not great in any case, so that a large initial energy input is needed if enough active light is to reach the film to cause bright fluorescence. Fortunately economy is not an important factor in the choice of a light source, and the high-power lamp, ready to operate the moment it is plugged in, answers all practical requirements. Once the light has been put together and the adjustments of mirror and condenser completed, the system can be used indefinitely if no changes of position are made.

A photograph of the improvised light housing is shown to indicate its general manner of construction. Other designs of housing or other types of bulb may prove even more useful. It is hoped that simplification of the technique may stimulate further test of this perhaps valuable method of investigation.

PRODUCTION OF EXPERIMENTAL HYPERTENSION AND THE INDIRECT DETERMINATION OF SYSTOLIC ARTERIAL PRESSURE IN RATS*

G. F. KEMPF, M.D., AND IRVINE H. PAGE, M.D.
INDIANAPOLIS, IND.

THE assay of antipressor extracts of kidney requires the use of large numbers of hypertensive animals. Dogs have been extensively employed, but their disadvantage is the high cost of care and the resultant limitation of the number of observations. Rats are cheaper, but many investigators have had difficulty both in producing hypertension and in measuring their arterial pressure. The purpose of this communication is to record the experience we have had in the preparation and study of over 1,000 hypertensive rats.

PRODUCTION OF HYPERTENSION

Page (1939) described the use of silk and cellophane for eliciting hypertension by formation of a perinephric fibrocollagenous hull around the parenchyma of the kidneys. Thin China silk, organza silk, or even thin cotton batiste may be used. After anesthetizing the rat (males weighing 140 to 160 Gm. are most satisfactory) with seconal (sodium propyl-methyl-carbinyl allyl barbiturate, Lilly, 35 to 40 mg. per kilogram injected subcutaneously), the forelegs are tied down with the back of the animal against the operating board, while the hind legs are tied with the abdomen down, so twisting the animal in such a way as to give excellent exposure of the kidneys. The operator's hands and instruments are scrubbed, but aseptic technique is unnecessary. An incision is made parallel with the vertebral column, beginning in the costo-vertebral angle, and the kidney is delivered with the aid of chalazion forceps. The fat is stripped off, the silk is folded around the kidney and held in place by either a string around the pedicle or a purse-string ligature. The silk should be applied smoothly. The kidney is then replaced and the muscle and skin are closed with silk thread (No. A). Silk may be applied to both kidneys or only to one and its partner removed. Page, Patton, and Ogden (1941), and Williams, Harrison, and Grollman (1942) have modified this procedure by applying collodium instead of silk, but the latter investigators do not find it as satisfactory as silk.

We have also used the method employed by Drury (1938) for producing hypertension in rabbits, namely, constricting the main renal artery by a loop of silk thread. A wire approximately one-third the diameter of the normal artery

*From the Lilly Laboratory for Clinical Research, Indianapolis City Hospital, Indianapolis.

Received for publication, December 29, 1941.

(28 gauge wire is satisfactory for a 150 Gm. rat) is employed. A midline incision is made, the relative size of the renal artery is estimated with the help of a jeweler's loupe, and a wire is selected. The silk loop is placed around the wire and renal artery proximal to the suprarenal branch, and the wire is withdrawn. Since the left renal artery is the more accessible, this side is used when only one vessel is to be constricted. If the right artery is employed, the loop is placed proximal to the point at which the vessel runs dorsal to the inferior vena cava.

With either of these methods, if both kidneys are operated upon, the hypertension will usually be severe, and some will exhibit the malignant syndrome. If only one kidney has been treated, many rats develop satisfactory hypertension. If, however, arterial pressure has not risen after three weeks, the normal kidney may be removed or treated as was the other. When a silk loop has been employed in the initial operation and the pressure has not risen, it is desirable to inspect the kidney before deciding on the next procedure. If it is completely degenerated, or almost so, a second loop should be placed on the opposite renal artery. If, on the contrary, it is normal or even enlarged, but has the appearance of being congested, the partner had best be removed.

Hypertensive rats appear to need supplements to their diet in the form of brewer's yeast (2 per cent of the total diet, strain G, Anheuser-Busch) and liver extract (5 per cent of liver extract No. 343, Lilly). They seem more susceptible to lice and more frequently develop dietary deficiencies than normal rats. In our hands we consider the technique satisfactory if 50 per cent of the animals develop hypertension.

It is of interest that if a rise of arterial pressure to 200 mm. Hg or more develops within a few days of operation, death usually occurs unless a fall in pressure is induced by injection of kidney extract. Under these circumstances they may recover and again become hypertensive on discontinuing the extract, but usually less intensively than before treatment. The time of appearance of hypertension is often very variable, from several days to several months being the rule.

DETERMINATION OF SYSTOLIC ARTERIAL PRESSURE IN RATS

The method of Williams, Harrison, and Grollman (1939) has been used. We have found it very satisfactory if a few modifications are introduced. In essence the method consists in determining the pressure at which blood begins to flow into the tail after compression by a cuff, as indicated by a plethysmograph.

Apparatus.—The sphygmomanometer cuff (G) in the diagram of Williams, Harrison, and Grollman (1939) was reduced to 2.6 cm. length because a greater length of tail was left for the plethysmograph, and correspondingly the readings were sharper. The tubing should be sufficiently loose so that not more than 10 mm. Hg pressure are required to collapse it. The plethysmograph may be made more sensitive by tying off the rubber sleeve within it at the distal end instead of leaving it open as in the diagram, but we prefer the original method because

the movements of the animal are not unduly magnified. The water in the plethysmograph is warmed by means of an electric light bulb placed close to the syringe *R*. The bore of the rubber tubing leading from the plethysmograph to the water manometer may be as small as $\frac{3}{32}$ inch in diameter, and the length need not be inconveniently shortened if the wall is thick. The water manometer

Fig. 1.—Modifications of Williams, Harrison, and Grollman's method for systolic blood pressure in rats.

is easier to read if a little safranin is dissolved in the water filling it. It is important to change the fluid daily to prevent growth of mold which may clog the tubing. Cautery set double rubber bags* seem more convenient than the ordinary sphygmomanometer bulb for reduction of pressure within the system. Instead of using these bulbs for inflating the sphygmomanometer cuff (*G*), air from the laboratory line is employed.

*Double blast cautery bags may be secured from the Davol Rubber Co., Providence, R. I.

The holder (A) for the rat has been adapted (Fig. 1) from that of Chen and Rose (1939) and has been found greatly to facilitate handling of the rats. It is surrounded by a water jacket connected with a copper coil placed in a can which is insulated with asbestos and heated with a micro gas burner. Screen wire adapters (Fig. 1) are used to prevent excess movement by fitting the rat more snugly in the holder.

PROCEDURE

The rat is warmed for four to five minutes in a box kept at 55° to 58° C., placed in the holder (warmed to 40° to 42° C.), and the tail is inserted into the plethysmograph (warmed to 40° C.). Gentle pressure is exerted on the tail by pressing the plunger of the syringe down, the cuff is inflated above the probable systolic pressure, and the two-way cock is turned to connect the plethysmograph with the water manometer. Air is allowed to escape until the water in the manometer begins to rise. If the escape of air is stopped at this point, the mercury in the sphygmomanometer will return to the point at which the water in the manometer began to rise. This return is due to the elastic recoil of the blast bulb. Because of the blast bulb the escape of air can be more rapid and the readings more accurate.

The nearer one is to systolic pressure the slower will be the rise of water in the manometer. A continued rise demonstrates that the change is due to blood entering the tail rather than to the movement of the rat. When the air pressure is lowered to less than venous pressure in the tail, the water in the manometer should fall. Four or five readings are taken on each animal.

COMMENT

Comparison of the shorter sphygmomanometer cuff with the longer one shows that readings are sharper and more rapidly taken. Overheating the rats, as evidenced by red ears and paws, overactivity, and sweating, must be avoided. They may suffer a heat stroke and die. By this method of blood pressure determination more uniform and *higher* systolic pressures were obtained on properly warmed animals than on unwarmed or partly warmed ones. Preheating the rats is necessary, as Williams, Harrison, and Grollman state. We find the shorter time at a higher temperature, as suggested by them, somewhat more effective than five to ten minutes at 40° to 42° C., and we also believe that warming the rat holder is essential. The change in the design of the holder has the very considerable advantage that the rat may be introduced more easily and without excitement. Excited, frightened animals obviously give false values; it is probably not well recognized that defecation while in the holder may raise the pressure 30 mm. Hg, although occasionally a fall will occur. Unusual sounds, especially strange voices, usually affect the readings. Handling the rats by their tails should be scrupulously avoided, as well as giving intramuscular or subcutaneous injections in this region.

The average systolic pressure taken daily for five weeks in five of our normal rats was within the limits of 100 to 120 mm. Lower and much more irregular readings are obtained if the animals and the animal holders are not

warmed. Single readings with the warmed rats were found to correspond with the *average* readings in about one-half of the trials. The other half varied from 20 mm. Hg to occasionally as much as 100 mm. Hg from the average. These results caution against accepting a single reading.

For testing the antipressor potency of kidney extracts we find animals with arterial pressure about 200 mm. Hg most satisfactory. The normal fluctuations of such animals is about 20 mm. Hg; hence a satisfactory extract, when given daily, must reduce the pressure below 150 mm. Hg. After discontinuing extract, the return to the initial blood pressure level usually takes more than a day. At least three hypertensive rats are used for each assay. It is important that the personnel dealing with these animals be sympathetic toward them, and that injections of extracts not be made at or near the time blood pressure readings are taken. If the latter precaution is observed, it will be found much easier to train the animals.

SUMMARY

1. Silk perinephritis and constriction of the renal artery by a silk thread both elicit arterial hypertension in rats of a degree sufficient for assay of renal antipressor extracts. The preparation of hypertensive rats by these methods is described.

2. The method of Williams, Harrison, and Grollman for measurement of systolic blood pressure has been modified to increase its effectiveness.

A QUANTITATIVE MICROPIPETTE FOR INTRANASAL INOCULATION OF MICE WITH VIRUS SUSPENSIONS

THE UNIT PERSONNEL*
NAVAL LABORATORY RESEARCH UNIT No. 1, BERKELEY, CALIF.

IT IS standard practice in most laboratories engaged in research on viruses to employ small hypodermic syringes and needles for the intranasal inoculation of mice. When large numbers of animals are being handled, as in our current influenza investigations, we have found that this technique not only requires a very considerable outlay for syringes, but is tiring and somewhat cumbersome in practice.

Fig. 1.—Micropipette (left) and syringe fitted with adapter (right).

The apparatus shown in Figs. 1 and 2 was developed to replace the syringe-needle assembly, and has been used with satisfaction during the past several months. The micropipette (left, Fig. 1) is $3\frac{3}{4}$ inches long and is graduated to deliver five aliquots of 0.05 ml. each. The top of the pipette contains a safety bulb beyond which it tapers to fit in the adapter of the plunger unit. The latter consists of an ungraduated syringe with colored ground-in piston; it is used to generate suction for filling the micropipette and to regulate the delivery of virus suspensions from it.

*The Unit Personnel consists of Commander A. P. Krueger; Lieutenants (j.g.) W. P. Chesbro, L. E. Rosenberg, and N. S. West; Ensigns A. S. Browne, O. J. Golub, and J. R. Mathews; CPhM, I. L. Shechmeister and T. P. Sislock; PhM 1c, W. L. Axelrod; PhM 2c, E. R. Chisholm and G. B. Saviers; and PhM 3c, H. R. Burkhead and C. R. Webb, Jr.

The opinions advanced in this paper are those of the writers and do not represent the official views of the Navy Department.

Under working conditions the plunger unit is mounted rigidly in a burette clamp, and micropipettes are fitted into the adapter as needed. Usually a fairly large series of pipettes will be employed in succession, using a clean one for each

Fig. 2.—Micropipette assembly in use for conducting intranasal inoculations.

virus-containing suspension to be inoculated. The pipettes cost about one-half as much as a regulation 0.25 ml. hypodermic syringe, and since only one or two plunger units per operator are required for a day's work, the total cost for equipping a laboratory is very reasonable.

SODIUM PENTOTHAL ANESTHESIA FOR ABDOMINAL SURGERY IN EXPERIMENTAL ANIMALS*

INDUCTION BY INTRAVENOUS INJECTION AND MAINTENANCE BY INTERMITTENT INTRAPERITONEAL DRIP

A. E. PEARCE, M.D., AND L. A. TERZIAN, Sc.D.
PHILADELPHIA, PA.

SHORT duration between administration and excretion is a desirable attribute of any anesthetic because it permits more immediate control of the anesthetic level. The adage "better to repeat than to repent" has been impressed upon many surgeons and anesthetists working with various long-action anesthetic agents.

While performing certain experimental abdominal procedures in dogs and rabbits, we developed a maintenance technique with sodium pentothal† which permitted us to dispense with the services of an anesthetist for the entire procedure. If we worked in pairs, the assistant induced the anesthesia by intravenous injection while the operator remained attired in sterile gown and gloves. If we worked alone, the operator induced the anesthesia by intravenous injection while wearing an extra pair of rubber gloves, which were removed before starting the abdominal operation. The instrument tray contained a sterile syringe with a hypodermic needle into which the operator drew sodium pentothal for intraperitoneal administration during the course of the operation.

For rabbits we used 1.25 and 1 per cent solutions of sodium pentothal. The latter was more satisfactory. The animals weighed approximately 4 pounds. They were placed in a box with the head protruding, and 2 to 3 c.c. of 1 per cent solution were administered in the lateral marginal vein of the ear. With this amount, corneal reflexes still remain. Five cubic centimeters of 1 per cent solution are lethal. The animals were then strapped on the operating table and the procedure was started. If a minimal induction dose was used, the animal might be restless during the opening of the peritoneum. A few drops of 1 per cent solution administered from the syringe on the tray would stop this. After the peritoneum was opened the entire length of the incision, little difficulty was encountered. Maintenance of anesthesia was done by dropping intermittently a small amount of sodium pentothal into the open abdomen, guided by restlessness of the animal and the character of its respirations. Shallowness of respiratory exchange indicated too great depth. An average

†A product of the Abbott Laboratories.

Received for publication, February 25, 1942.

anesthesia was performed for wedge gastric resection wherein 2 c.c. of 1 per cent solution were given intravenously for induction, and 1.4 c.c. by intraperitoneal drip for maintenance. The operative procedure lasted one-half hour. More than 50 rabbits have been operated on with the above technique.

For dogs we used 2 and 2.5 per cent solutions. The animals were strapped on the operating table, and the induction dose was given into a superficial vein of the forepaw or the hind leg. The amount necessary varied with the size and vigor of the animal. Morphine and atropine preoperatively were of great advantage. Dogs weighing less than 20 pounds received morphine sulfate gr. $\frac{1}{8}$ and atropine sulfate gr. $\frac{1}{150}$; those weighing more than 20 pounds received morphine sulfate gr. $\frac{1}{4}$ and atropine sulfate gr. $\frac{1}{100}$. This preoperative sedation was given hypodermically forty-five minutes before. Little difficulty was found in opening the peritoneum. Anesthesia was maintained by intermittent intraperitoneal drip. Anesthetic level was determined by respirations and restlessness, and the status of corneal reflex was obtained by touching the cornea with a piece of gauze which was then discarded. A representative anesthesia was performed in a 60 pound dog, to which 14 c.c. of 2.5 per cent solution were given intravenously for induction and 12 c.c. were given intraperitoneally for maintenance during a procedure on the biliary ducts, lasting one hour. More than 25 dogs have been operated upon with this anesthetic technique.

2008 WALNUT STREET

THE SEDIMENTATION RATE IN HODGKIN'S DISEASE*

BOWMAN WISE, M.D., DURHAM, N. C.

IT IS generally recognized that the erythrocyte sedimentation rate usually is significantly elevated in Hodgkin's disease, but that it is of no aid in the differential diagnosis of this disease. However, the relationship of the sedimentation rate to phases of activity, or relative quiescence, of the disease has not been studied. The present study was undertaken to determine whether the sedimentation rate might be of aid in determining the state of activity of the Hodgkin's disease process, thereby furnishing indications for treatment, especially during intervals in which the patient is symptom free and has no objective evidence of activity of the disease.

MATERIAL AND METHOD OF STUDY

The sedimentation rate of the red blood corpuscles has been determined by the Wintrobe method.¹

The data reported here have been accumulated from patients in Duke Hospital in whom the diagnosis of Hodgkin's disease has been established histo-

*From the Department of Medicine and the Department of Bacteriology, Duke University School of Medicine, Durham.

Received for publication, January 16, 1942.

pathologically. Sedimentation rates have been determined at the time of the initial visit and, whenever possible, at intervals throughout the period of observation. Because patients frequently leave the hospital or out-patient clinic promptly upon the completion of roentgen therapy, it has not been possible to make observations of the immediate effect of such therapy on the sedimentation rate.

RESULTS

Single determinations of the sedimentation rate were made on 17 patients suffering from Hodgkin's disease, the results of which are given in Table I. They show a significant elevation of the sedimentation rate in Hodgkin's disease and an absence of any correlation with the duration of the disease or therapy. In all these patients, because of the existence of fever, obvious progressive lymph node enlargement, or evidence of progressive visceral or osseous involvement, the disease process was considered to be active at the time the sedimentation rates were determined.

Thirteen patients afforded an opportunity to make repeated determinations of the sedimentation rate during the course of the disease. The case histories of the majority of these patients have been reported in detail elsewhere² and are summarized briefly here in the numerical sequence in which the patients came under observation.

TABLE I
BLOOD SEDIMENTATION RATES OF 17 PATIENTS SUFFERING FROM HODGKIN'S DISEASE

PATIENT	RACE	SEX	AGE	CORRECTED SEDIMENTA- TION RATE (MM./HR.)	DURATION OF DISEASE BY HISTORY	PREVIOUS THERAPY
J. O.	W	M	20	43	2½ years	Roentgen therapy
L. S.	W	F	44	44	2 years	Roentgen therapy
V. W.	W	F	26	40	8 to 9 years	Roentgen therapy
M. H.	W	F	24	29	20 months	None
S. S.	W	M	38	34	21 months	Roentgen therapy
E. W.	W	M	28	39	8 years	Roentgen therapy
V. H.	W	F	21	42	6 months	None
P. T.	W	F	29	39	22 months	Sulfapyridine and roent- gen therapy
C. S.	W	M	38	37	4 years	Roentgen therapy
J. C.	W	M	30	32	13 months	Roentgen therapy
S. M.	W	F	43	38	3 months	Roentgen therapy
E. M.	W	M	26	32	9 months	None
P. C.	W	F	25	46	8 months	None
K. G.	W	M	17	40	5 years	Roentgen therapy
F. T.	W	M	30	40	2 months	None
S. G.	W	M	38	32	8 months	Roentgen therapy
W. D.	W	M	31	25	2 years	Roentgen therapy

Case 1 is of particular interest because of the demonstration of normal or nearly normal sedimentation rates during periods in which there was no evidence of activity of the disease. In this patient elevation of the sedimentation rate from a previous normal level preceded by six weeks any definite evidence of recurrent activity of the disease process.

CASE REPORTS

CASE 1.—R. P., a 24-year-old white man, entered the hospital on Oct. 26, 1938, complaining of right cervical lymph node enlargement of one year's duration, which had been treated by excision and superficial radium therapy. At the time of admission a lymph node, 3 to 4 cm. in diameter, and several smaller nodes were palpable in the right cervical region. *Brucella suis* was isolated from a right cervical lymph node which had the characteristic histopathologic appearance of Hodgkin's disease.

DATE	CORRECTED SEDI- MENTATION RATE MM./HR.	SUBSEQUENT COURSE
10/27/38	5	Regression of right cervical lymph node enlargement under treatment with sulfanilamide and serum from a person considered immune to brucella infection
7/31/39	4	No evidence of activity of the Hodgkin's disease process
9/23/39	8	Questionable slight recurrent enlargement of right cervical lymph nodes following acute pharyngitis two weeks previously
11/27/39	20	No evidence of activity
1/29/40	34	Recurrent right cervical lymph node enlargement regressing slightly under sulfanilamide and roentgen therapy
4/15/40	34	Condition unchanged
6/10/40	25	Cough of two weeks' duration; mediastinal mass demonstrable in chest roentgenogram; marked diminution of cough during treatment with sulfathiazole, but size of mass unchanged; roentgen therapy instituted to mediastinum
8/ 6/40	34	Chills and fever of three weeks' duration; complete atelectasis of left lung from pressure of mediastinal mass; roentgen therapy
10/ 8/40	36	Fever; weight loss; persistent atelectasis of left lung; liver and spleen palpable
10/ 8/40	34	Condition unchanged under further roentgen therapy
12/ 2/40	15	Fever, marked weight loss and anemia; reexpansion of lung; liver and spleen increase in size; questionable infiltration of lumbar spine; no improvement under roentgen therapy; death on Feb. 7, 1941

Cases 2, 7, and 11 show a tendency of the elevated sedimentation rate to remain at a constant level during a period of months, even though temporary improvement in the patient's condition or relative inactivity of the disease may be apparent.

CASE 2.—M. W., a 5-year-old negro boy, was brought to the hospital on Nov. 16, 1938, with an enlargement of his neck of ten months' duration. It was not possible to admit the patient to the hospital until Jan. 26, 1939, at which time examination revealed marked enlargement of the left cervical and left axillary and inguinal nodes. A chest roentgenogram showed a mediastinal mass. Lymph node biopsy confirmed the clinical diagnosis of Hodgkin's disease. Under treatment with sulfapyridine there was a marked decrease in the size of the enlarged superficial lymph nodes, and roentgenographic examination showed diminution in the size of the mediastinal mass. The patient was discharged from the hospital on March 3, 1939. In May, 1939, he was readmitted to the hospital with an enlargement of the left inguinal and femoral lymph nodes, but there was no recurrent enlargement of other superficial lymph nodes, and a chest roentgenogram showed complete absence of the mediastinal

mass noted before. His temperature reached 39° C. *Brucella melitensis* was isolated from a blood culture. Following treatment with sulfapyridine and bovine antimelitensis serum, the patient became afebrile, and the enlarged lymph nodes had decreased in size by the time of discharge on June 1, 1939. The patient's subsequent course is tabulated below:

DATE	CORRECTED SEDI- MENTATION RATE MM./HR.	SUBSEQUENT COURSE
9/ 8/39	28	Fever and recurrent left cervical, axillary and inguinal lymph node enlargement of one week's duration, subsiding under treatment with sulfapyridine
2/ 5/40	28	History of intermittent brief episodes of fever; transient left cervical enlargement one week previously
6/24/40	30	Condition unchanged; no demonstrable recurrence of lymph node enlargement
12/12/40	21	Intermittent enlargement of superficial lymph nodes accompanied by fever of one month's duration; spleen palpable
6/13/41	22	Marked enlargement of cervical, axillary, and inguinal lymph nodes; fever of one week's duration; spleen and liver palpable; prompt regression of lymph node enlargement under sulfathiazole
6/23/41	26	
6/27/41	15	

CASE 7.—M. T., a 31-year-old white woman, experienced the onset of per-sistent generalized itching in November, 1936, along with enlargement of left cervical and left axillary nodes which fluctuated in size, but there had been recurrent enlargement of these nodes for two months before admission to the hospital on March 8, 1939. Lymph node biopsy confirmed the diagnosis of Hodgkin's disease. Her subsequent course is given below:

DATE	CORRECTED SEDI- MENTATION RATE MM./HR.	SUBSEQUENT COURSE
3/ 8/39	38	Left cervical and axillary lymph node enlargement; severe pruritus; lessened pruritus and decrease in the size of the enlarged lymph nodes under treatment with sulfapyridine
5/ 7/39	38	Recurrence of lymph node enlargement with enlargement of right cervical and axillary nodes, and small areas of density shown in the right lung by roentgenogram; stomatitis; fever; improvement under sulfapyridine
7/18/39	28	Recurrent superficial lymph node enlargement; cough and extensive mediastinal and hilar enlargement demonstrable roentgenographically; intensified pruritus; improvement under roentgen therapy
9/11/39	44	Further roentgen therapy; cough relieved; pruritus unchanged
10/18/39	43	Slight enlargement of left cervical lymph nodes; increasing weakness
11/23/39	44	Fever; extension of pulmonary parenchymal involvement; progressive weakness, weight loss, and anemia; further roentgen therapy
2/12/40	37	Afebrile; further superficial lymph node enlargement, including inguinal nodes; decrease in size of pulmonary lesions by roentgen examination
3/14/40	42	Fever and progressive cachexia; vague abdominal discomfort; further roentgen therapy
9/12/40	18	Continued fever and progressive cachexia terminating in death on Sept. 20, 1940

CASE 11.—A. A., a 40-year-old woman, entered the hospital on June 27, 1939, complaining of weakness, loss of weight, and enlargement of the neck of seven months' duration. Above the suprasternal notch and in the right cervical region were numerous enlarged lymph nodes constituting a mass 5 by 4 cm. The spleen was palpable. A chest roentgenogram showed a large mediastinal mass. Lymph node biopsy confirmed the clinical impression of Hodgkin's disease, and from the biopsied node and from the blood *Brucella suis* was isolated. Her subsequent history is summarized below:

DATE	CORRECTED SEDI- MENTATION RATE MM./HR.	SUBSEQUENT COURSE
6/27/39	34	Moderate decrease in cervical and mediastinal lymph node enlargement under roentgen therapy
9/ 8/39	34	Weight gain of 11 pounds in interval; no recurrent lymph node enlargement; marked fatigability
12/22/39	34	Slight recurrent enlargement of cervical nodes; enlargement of left inguinal nodes; roentgen therapy

Cases 6, 17, and 18 show a definite fall in the sedimentation rate following sulfonamide and/or roentgen therapy.

CASE 6.—C. I., a 40-year-old white woman, in June, 1938, noted gradual enlargement of the superficial lymph nodes accompanied by fever and marked fatigability. In January, 1939, mediastinal enlargement was demonstrable, and the liver and spleen were palpable. Lymph node biopsy established the diagnosis of Hodgkin's disease. Under roentgen therapy her fever subsided, the lymph node enlargement disappeared, and the liver and spleen were no longer palpable. Her subsequent course as is known is given below:

DATE	CORRECTED SEDI- MENTATION RATE MM./HR.	SUBSEQUENT COURSE
3/ 1/39	26	Initial visit two weeks after completion of roentgen therapy
6/ 6/39	36	Fever and slight enlargement of a right cervical node; spleen palpable; <i>Brucella melitensis</i> isolated from blood cultures. Prompt subsidence of symptoms and splenic enlargement under treatment with sulfapyridine and bovine antimelitis serum
7/20/39	19	Entirely symptom free

CASE 17.—G. R., a 16-year-old white boy, entered the hospital on March 8, 1940, complaining of superficial lymph node enlargement of two years' duration. Lymph node biopsy in August, 1939, established the diagnosis of Hodgkin's disease, and he was subsequently given roentgen therapy, with reduction in the size of the enlarged nodes. At the time of admission to the hospital there were daily elevations of temperature to 39° C., a few small firm lymph nodes were generally palpable, and the spleen, which was firm and nontender, extended 10 cm. below the costal margin. A chest roentgenogram was not remarkable.

DATE	CORRECTED SEDI- MENTATION RATE MM./HR.	SUBSEQUENT COURSE
3/4/40	18	Initial visit
3/8/40	18	Temperature fell under sulfathiazole therapy, but the patient did not become afebrile until roentgen therapy was instituted to splenic area; spleen ceased to be palpable
4/5/40	7	

CASE 18.—J. Q., a 23-year-old white man, was referred to the hospital on April 20, 1940, for study. His illness began in December, 1934, with generalized pruritus, which persisted until the summer of 1937. In May, 1937, a slight enlargement of the cervical and axillary lymph nodes was noted, and the histopathologic findings in an excised node were typical of Hodgkin's disease. A chest roentgenogram taken at this time showed hilar enlargement. Roentgen therapy was instituted in August, 1937, since which time the patient had been almost symptom free. In September, 1939, a few small nodes were noted in the axillae. At the time of his visit to the hospital he felt entirely well, but he had noted an elevation of temperature to 99.1° F. each evening of the preceding week. Physical examination revealed two very small palpable right axillary nodes. His subsequent course during the period of observation is given below:

DATE	CORRECTED SEDI- MENTATION RATE MM./HR.	SUBSEQUENT COURSE
4/20/40	47	Initial visit
6/ 7/40	20	Condition unchanged. Slight daily elevation of temperature continued
6/17/40	14	Patient received sulfathiazole from 6/11/40 to 6/26/40
6/19/40	11	

DISCUSSION

The finding of a normal or low erythrocyte sedimentation rate during a period of apparent quiescence of the Hodgkin's disease, suggests that this procedure may have a distinct usefulness in following the course of the Hodgkin's disease process. In particular, the finding of an elevated sedimentation rate may aid in deciding when further therapy is advisable.

It has not been possible as yet in this study to determine the immediate effect of roentgen therapy upon the sedimentation rate in Hodgkin's disease. Patients in whom the progress of the disease process has been relatively constant and rapid, and who from time to time have received roentgen therapy, have maintained elevated sedimentation rates. However, these determinations of the sedimentation rate have not been made at sufficiently close intervals to furnish information regarding the effect of roentgen therapy during the period when its effect is clinically most obvious.

In patients suffering from Hodgkin's disease, treatment with sulfonamide drugs has frequently been followed by regression of lymph node enlargement, disappearance of fever, and improvement in the patient's general condition. Although the number of observations is few, a fall in the sedimentation rate has attended the good results of sulfonamide therapy. Only further investigation and experience can determine the proper place of the sulfonamide drugs in the treatment of Hodgkin's disease, but repetition of the sedimentation rate at frequent intervals during the treatment period, regardless of the type of therapy employed, may be expected to aid in the decision as to the amount and extent of treatment advisable.

Attention should be called to a fall in the sedimentation rate exhibited by two patients of this group, Cases 1 and 7, during the terminal stage of the disease. Wintrobe has stated that the sedimentation rate may be normal, or fall toward normal, in the markedly cachectic stage of tuberculosis, and that corrections of

the sedimentation rate in the presence of severe anemia may be misleading.³ Both patients, mentioned above, exhibited severe anemia and cachexia, to which the fall of the sedimentation rates seems attributable.

SUMMARY

The sedimentation rate has been studied during the course of Hodgkin's disease. Although usually elevated in this disease, the sedimentation rate may be normal during periods of relative inactivity of the disease process. The usefulness of the sedimentation rate in following the course of Hodgkin's disease and as a guide in therapy is suggested.

A MERCURY VACUUM RELEASE*

FOR ULTRAFILTRATION AND OTHER EVACUATED SYSTEMS

PETER S. ERHARD, B.A., AND GEORGE M. DECHERD, JR., M.D.
GALVESTON, TEXAS

IN CONNECTION with many laboratory experiments it is desirable to maintain a vacuum of a given level. While a simple mercury trap is adequate when the vacuum desired is only a few millimeters of mercury, for a higher vacuum, bubbling and loss of mercury is troublesome unless a large diameter tube is used, in which event a great deal of mercury is required. The device we describe is easily constructed, and is capable of maintaining the vacuum in a given system with a variation of only a few millimeters.

A 120 mm. T-tube is connected to the upper end of a 50 c.c. burette; through this, held by a piece of pressure tubing, is run a length of 5 mm. glass tubing, of such dimensions that when bent the upper end extends about 2 inches below the mouth of the burette, and the lower end about 1 inch above the tip. By a heavy clamp, not shown in the diagram, placed near the upper end of the burette, the whole device is suspended in a bottle containing mercury. When connected to the system to be held at a given vacuum, the mercury rises in both tubes. When the level of the mercury drops below the tip of the glass tube, the mercury in this tube is drawn over, returning through the burette to the bottle,

*From the Department of Medicine, University of Texas, School of Medicine, Galveston.

and allowing air to enter the system. By adjusting the depth which the tubes penetrate into the mercury, in conjunction with a manometer, the device may be set so that air enters the system at any given vacuum level, and is by-passed to the pump, making certain that the vacuum does not exceed the desired level.

Fig. 1.

Variation in the internal pressure in the evacuated system may be minimized by drawing out the lower end of the tube to a small tip.

We have used this for maintaining vacua of from 15 to 360 mm. of mercury and have found it satisfactory for ultrafiltration and for holding animals at varying fractions of atmospheric pressure.

CHEMICAL

EFFECT OF STANDING ON CHOLESTEROL AND CHOLESTEROL ESTER VALUES IN HUMAN BLOOD*

IDA KRAUS, PH.D., AND EVELYN KALAL, B.A., CHICAGO, ILL.

STUDIES on cholesterolysis, cholesterogenesis,† cholesterol ester hydrolysis, and esterification of the different parts of human blood (blood serum, blood plasma, whole blood) have presented varied and conflicting results.

Schultz,¹ Thannhauser,² Bloor and Knudson,³ found no change in the cholesterol values on incubation of human blood while Cytronberg⁴ and Sperry⁵ report marked hydrolysis and marked esterification. Schube⁶ states that blood cholesterol may change in vivo from week to week from 0 to 73 mg. He made a study⁷ of 21 normal bloods and showed that after different time intervals and at different temperatures, there was a variation from 15 points above to 49 points below the original cholesterol values.

Inasmuch as the per cent of cholesterol esters in the total blood cholesterol is of diagnostic significance in cases of liver damage and jaundice,^{3, 8-12} the question arose in our laboratory as to whether it was safe to allow the blood to stand any length of time before analyzing it for cholesterol and cholesterol esters, or whether these determinations should be made immediately after the blood was drawn.

To answer these questions, a comparative study of cholesterolysis, cholesterogenesis, and cholesterol ester hydrolysis and esterification on (a) oxalated blood, (b) plasma from oxalated blood, and (c) blood serum was made.

PROCEDURE

The bloods were selected at random from those of patients and blood donors‡ in the Cook County Hospital. Duplicate determinations for both total cholesterol and cholesterol esters were made immediately after the blood was drawn and after the specimens had stood for twenty-four hours.

The plasma and serum were separated from the cells by centrifugation and placed in cork-stoppered containers. The whole oxalated blood was kept in stoppered tubes. For the "immediate" analyses, aliquots were taken soon after the bloods were drawn, and alcohol ether filtrates were made at once (as directed below) and set aside in glass-stoppered bottles until the twenty-four-hour filtrates were ready. For the "twenty-four-hour" analyses the specimens were tightly stoppered and allowed to stand for twenty-four hours at room temperature or in the incubator at 37° C.; aliquots were then taken and alcohol-

†"Cholesterolysis, cholesterogenesis" used in the same sense as the terms "glycolysis and glycogenesis."

‡Blood from normal donors was obtained through the courtesy of Dr. E. H. Schirmer, Director, Blood Bank, Cook County Hospital.

ether filtrates were made. Total cholesterol and cholesterol ester determinations were made simultaneously to rule out additional time factors.

Total Cholesterol (Bloor,¹³ Sachett¹⁴ method slightly modified).—Three cubic centimeters of oxalated blood, plasma, or serum are transferred into a 100 c.c. volumetric flask, using an Oswald-Folin pipette;* 3:1 alcohol-ether mixture is added through a funnel while agitating the flask.† Make up to volume, mix well, and filter. If the filtrate is tinted yellow (icteric blood), shake with Lloyd's reagent and refilter. Use aliquots of the clear filtrate for duplicate determinations‡ of cholesterol or cholesterol esters.

Cholesterol Esters.—Cholesterol is precipitated from the filtrate with digitonin. A quantitative separation of the cholesterol esters from the cholesterol digitonide is made by extraction with petroleum ether (b.p. 60° C.) as follows:

Add 15 c.c. of petroleum ether to the residue from 25 c.c. of evaporated filtrate. The mixture is thoroughly scraped from the sides and bottom of the beaker and triturated. Cover the beaker with a watch glass and boil on a water bath over an electric plate, rotating constantly to avoid bumping, until about one-half of the liquid has evaporated. Dry the beaker on the outside, and when boiling ceases, decant the solution with the aid of a stirring rod through a small funnel plugged with a small piece of cotton. The treatment with petroleum ether is repeated three or four times in order to insure quantitative extraction of the cholesterol esters. *The filtrate must be absolutely clear.* Any trace of turbidity will give high results. Evaporate the combined extracts to dryness, and proceed as under cholesterol with chloroform extraction.

*Twenty milligrams of potassium oxalate for 10 c.c. of blood.

†A fine granular precipitate is obtained, no lumps.

‡Not more than two or three sets of duplicates were set up at any one time.

Using the foregoing technique, we were always able to get like results with duplicate and triplicate samples.

Table I shows the difference between the cholesterol values of whole blood, serum, or plasma tested immediately after drawing, and again in twenty-four hours. This difference is so slight that it is of the same magnitude as the limits of experimental error. This indicates, contrary to the contention of Schube,⁷ that the total cholesterol does not change significantly, if at all, when oxalated whole blood, plasma, or serum is allowed to stand at room temperature for twenty-four hours. It appears, therefore, that a specimen for total cholesterol determination may safely be analyzed within twenty-four hours.

On the other hand, Table II shows that the values of cholesterol esters definitely change as the specimens stand. Of the 58 specimens studied, 25 showed a significant increase in esters or an esterification on standing, ranging from 11 to 74 mg. per 100 c.c.; 9 showed a significant decrease, or a hydrolysis, on standing, ranging from -5.5 to -19 mg. per 100 c.c.; the remaining 24 specimens showed little change.

163	79	90.5	+11.5
164	92	93.5	+ 1.5

*Complete protocols available on request.

†Similar results were obtained with plasma and with serum.

These results confirm the presence of esterase activity in human bloods.⁵ The presence and extent of that activity are unpredictable and varied and, therefore, must be evaluated for each specimen.

Since the percentage of cholesterol esters in the total cholesterol is used clinically as a diagnostic aid in liver damage, the determination, to be of value, must be made on freshly drawn blood.

The original value for cholesterol or cholesterol esters does not indicate the degree or direction of the possible changes on standing.

To establish whether the "enzymatic" activity present in some bloods and absent in others is transitory or is relatively constant, second determinations were made on the same patients a week later. The presence of the activity was shown to be relatively constant.

CONCLUSIONS

1. The total cholesterol content of human blood, plasma, or serum does not change on standing.
2. The value of cholesterol esters in human blood, plasma, or serum may or may not change on standing.
3. Cholesterol determinations on whole blood, plasma, or serum need not be performed immediately after the blood is drawn. Cholesterol ester determinations must be made immediately.
4. The presence of an "esterase activity" producing an hydrolysis of cholesterol esters in some specimens and an esterification of cholesterol in others is confirmed. The nature of this activity, and why it is found in some bloods and not in others, is being investigated.

THE QUANTITATIVE DETERMINATION OF BLOOD IN HUMAN FECES*

JOHN S. ANDREWS,† D.Sc., AND JOSÉ OLIVER-GONZÁLEZ, Ph.D.
SAN JUAN, PUERTO RICO

INTRODUCTION

ALTHOUGH there are many references in medical literature dealing with problems associated with the detection and clinical significance of occult blood in the stomach and intestinal contents of patients suffering from hemorrhage within the gastrointestinal tract, there are very few papers approaching the subject from the standpoint of quantitative measurement. Abrahams¹ and Bramkamp⁵ reported experiments designed to ascertain the smallest quantity of blood which after ingestion would produce a stool giving a positive reaction to the benzidine test for occult blood. Later Daniel and Egan,⁶ working with larger quantities of blood, found that 50 to 80 c.c. of blood must be ingested by adults on a milk and cream diet in order to produce a so-called "tarry" stool. Although van Eck⁷ published a method for the quantitative determination of blood in human feces, careful search of the literature has failed to produce any evidence of its practical application in clinical medicine. In a recent paper² Andrews and Brooks outlined a procedure for the quantitative determination of blood in the feces of sheep by means of the Evelyn Photoelectric Colorimeter, incorporating the technique of Bing and Baker⁴ for the hemoglobin determination. Since we were of the opinion that one of the more important uses of this method lies in its application to the quantitative study of hemorrhage within the human gastrointestinal tract, we carried out the following experiments.

MATERIALS AND METHODS

The materials and reagents necessary for the work, as outlined in the experiments are as follows:

1. Blood-free human feces.
2. 50 c.c. round-bottomed heavy glass centrifuge tubes.
3. Blood of known hemoglobin content.
4. Accurately calibrated pipettes of 1, 2, 4, 5, 10, 15, and 20 c.c. capacity.
5. Glacial acetic acid.
6. 50 c.c. volumetric flasks.
7. 10 c.c. volumetric flasks.

Received for publication, February 7, 1942.

8. Purified benzidine reagent of Bing.¹⁰
9. Test tubes for the Evelyn photoelectric colorimeter.
10. 3 per cent hydrogen peroxide.
11. Paraffined corks to fit the colorimeter tubes.
12. No. 660 red filter for the colorimeter.

Fig. 1.—Curve showing the corrected galvanometer readings obtained from the analysis of 1 Gm. portions of human feces to which had been added the indicated volumes of calf blood containing 9 Gm. of hemoglobin per 100 c.c.

PROCEDURE

We first placed ourselves on a meat-free diet in order that the feces we passed would not contain ingested blood pigment. To 1 Gm. portions of blood-free human feces collected on the third day, artificial mixtures of known amounts of calf blood, containing 9 Gm. of hemoglobin per 100 c.c. were added, and a graph (Fig. 1) relating the quantity of blood to the colorimetric measurement

*Dissolve the benzidine reagent in 200 c.c. of 95 per cent ethyl alcohol with the aid of gentle heat. Add 1 Gm. of blood charcoal (extracted with hydrochloric acid and washed with water) to the filtrate, stir, and maintain at a temperature of $50^{\circ} \pm 10^{\circ}$ C. for fifteen minutes. Filter while warm and wash charcoal with 10 c.c. of warm ethyl alcohol. Repeat treatment with charcoal until filtrate is almost colorless. To filtrate add 135 c.c. of distilled water, or sufficient water to make alcohol 50 to 60 per cent by volume, and warm if necessary to obtain a clear solution. Allow solution to stand in the refrigerator for twenty-four to forty-eight hours to crystallize the benzidine. Filter on a Buchner funnel with suction, wash with cold 50 per cent alcohol, and continue suction until crystals are dry. Preserve in a bottle protected from light.

Prepare the reagent by dissolving with the aid of heat 1 Gm. of purified benzidine in 20 c.c. of glacial acetic acid. Add 30 c.c. of distilled water and 50 c.c. of 95 per cent ethyl alcohol.

Test by placing 2 c.c. of the reagent in a test tube, add 1 c.c. of distilled water and 1 c.c. of 0.6 per cent hydrogen peroxide, and mix. No color, or only a very slight yellow color, should develop in two hours. If the mixture is then diluted to 25 c.c. with 20 per cent acetic acid and viewed through a thickness of about 1 cm., it should be practically indistinguishable from distilled water.

was plotted, as was done in the original paper.² The operations necessary for obtaining the data for the curve are as follows:

1. Weigh thirty-two 1 Gm. portions of blood-free human feces on an analytical balance and place each portion in a clean, dry, 50 c.c. centrifuge tube.

2. Make a 1:10 dilution of a blood sample of known hemoglobin content with distilled water and mix thoroughly.

3. Number each centrifuge tube and carefully add the required amounts of diluted blood to each of the 1 Gm. portions of feces, setting up the tubes in triplicate for each point on the curve to be determined. Mix the blood solution thoroughly with the feces, using individual glass stirring rods, and leave the rods in the tubes. Use the remaining two samples as duplicate blanks with blood omitted.

4. Add 10 c.c. of distilled water to the blanks and proportionately less to the remaining tubes, so that the total volume of fluid added will be 10 c.c. Mix thoroughly.

5. Add 15 c.c. of glacial acetic acid to each tube and mix. Heat and remove each tube as soon as the contents begin to boil vigorously. Care must be taken to prevent the contents from boiling over. (The heating was facilitated by putting tubes in wire baskets and placing them on an electric hot plate.)

6. Push particles adhering to the walls of the tubes back into the solution, remove the stirring rods, and arrange them according to number on the edge of a table with the acid-covered ends projecting so that none of the material on the rods may be lost. Centrifuge the tubes at approximately 2,700 r.p.m. for five minutes.

7. Decant the supernatant fluid into properly numbered 50 c.c. volumetric flasks. After transferring the contents of each tube, wash off the decanting rod with a small amount of glacial acetic acid.

8. Make three similar extractions, each with 10 c.c. of glacial acetic acid, and bring the contents of the 50 c.c. volumetric flasks to volume with glacial acetic acid and mix thoroughly.

9. Put 1 c.c. aliquots from the 50 c.c. volumetric flasks into 10 c.c. volumetric flasks, and bring the contents of the 10 c.c. volumetric flasks to volume with glacial acetic acid and mix.

10. Put 2 c.c. of the purified benzidine reagent into the bottom of each colorimeter tube, and add 1 c.c. aliquots from the 10 c.c. volumetric flasks and mix.

11. Add 1 c.c. of a 0.6 per cent hydrogen peroxide solution (3 per cent commercial solution freshly diluted with 4 parts of distilled water) and mix. Close with paraffined corks and allow the tubes to stand for two hours.

12. Dilute with 20 c.c. of a 20 per cent solution of glacial acetic acid in distilled water, insert corks, and invert the tubes several times to mix the contents. Allow to stand for at least eight minutes.

13. Adjust the colorimeter so that the blank reads 100 on the galvanometer scale when a No. 660 red filter is used. With this adjustment make the colorimetric readings on solutions derived from the feces-blood mixtures, and plot the average readings of the triplicates against the volumes of blood employed.

After we had been on a meat-free diet for at least three days, the volumes of blood (indicated in Table I) from the same calf that furnished the specimens for making the reference curve were diluted with 50 c.c. of distilled water and ingested. Each stool was then collected, weighed, thoroughly mixed by means of a spatula, and analyzed quantitatively for blood pigment according to the procedure outlined. Additional blood, however, was not added to the feces, 10 c.c. of distilled water were added to the blank and also to the feces containing blood, and one blank and triplicate samples of the unknown were sufficient for the analysis. The galvanometer readings obtained from the fecal extract containing the unknown quantity of blood were then translated into cubic centimeters of blood by means of the reference curve.

RESULTS

The results of the analysis of the fecal specimens passed subsequent to the ingestion of calf's blood containing 9 Gm. of hemoglobin per 100 c.c. are shown in Table I.

			6	-----	8:30 A.M.	110.5	95	100	0.00	0	20	33

The data in Table I show that 33 to 85 per cent of the ingested blood was recovered from the feces. All the specimens containing any appreciable quantity of blood were noticeably darker in color than the blood-free feces, but none of them in our opinion could be called "tarry." In Experiment 1 the blood either acted as a purgative or was accompanied by some substance which had a similar action. The rapid removal of the blood in this instance resulted in the recovery of 85 per cent within eighteen hours after ingestion. The re-

maining experiments show a progressively smaller percentage of recovery, and in general, indicate a negative correlation between the length of time the blood was retained in the digestive tract and the quantity recovered from the feces. Bramkamp⁵ reported that pancreatic digestion in vitro reduced the strength of the color reaction between hemoglobin and benzidine by 50 per cent. This prolonged action of digestive juices plus the increased absorption of the blood from the intestine in those instances where the blood was retained in the digestive system for several days would explain the decrease in the apparent quantity of hemoglobin recovered.

A practical test of the method was made on the feces of a patient in the hospital of the School of Tropical Medicine who was suffering from profuse hemorrhage resulting from a condition diagnosed as ulcerative colitis. The results of these tests which were made during the time the patient was hospitalized and placed on a bland ulcer diet with rest in bed are shown in Table II. Because of the large amount of blood pigment in the first two fecal specimens obtained from this patient, four additional extractions with glacial acetic acid were necessary before all the hemoglobin was removed. In this instance the acid extracts were decanted into a 100 c.c. volumetric flask. The blood pigment was so highly concentrated in the extract that it was necessary to use a fraction of a cubic centimeter of the diluted extract in order to obtain a color intensity that could be measured in the colorimeter; hence the multiplying factors shown in column 5.

TABLE II
QUANTITY OF BLOOD RECOVERED FROM THE FECES OF A PATIENT SUFFERING
FROM ULCERATIVE COLITIS

DATE	WEIGHT OF STOOL	AVERAGE GALVAN- OMETER READINGS	BLOOD INDI- CATED	MULTI- PLYING FACTOR	BLOOD* INDICATED IN ONE GM. OF FECES	TOTAL BLOOD* RECOVERED
10/10/40	Gm. 150	53	c.c. 0.275	16	c.c. 4.40	c.c. 660
10/11/40	No specimen					
10/12/40	107	93	0.050	8	0.40	43
10/13/40	135	89	0.070	0	0.07	9
10/14/40	90	108	0.000	0	0.00	0

*Volume of blood computed on the basis of 9 Gm. of hemoglobin per 100 c.c.

The data in Table II show clearly the severity of the hemorrhage at the beginning of treatment and the gradual cessation of the bleeding under proper care.

DISCUSSION

At first glance the time and technical difficulties involved might make the method outlined appear to be impractical. However, we found that once the reference curve was made, the routine was so well known that tests on specimens containing unknown quantities of blood were easily and quickly carried out. One and one-half hours would probably be a conservative estimate of the time consumed in running a test consisting of one blank and triplicate unknowns. This period does not include the time required for color development.

Five points were emphasized as being important in the successful carrying out of the procedure for the quantitative determination of blood in the feces of sheep. These points are:

1. Use the same lot of purified benzidine reagent for plotting the reference curve and for making the determinations on the unknown in any one experimental series.
2. Always make determinations on fresh fecal specimens.
3. Use meticulous care in weighing, pipetting, and diluting operations.
4. Use fresh glacial acetic acid fecal extracts in making colorimetric comparisons.
5. Do not use blanks for reference points for any other similar sample containing blood unless the two tubes have been diluted at the same time.

In the application of the method to human feces the observance of these measures is just as important as it was in the previous work. The reader is referred to the original paper for further discussion.

SUMMARY AND CONCLUSIONS

A modification of a method for the quantitative determination of blood in the feces of sheep is described for use with human feces. By its use 33 to 85 per cent of ingested blood was recovered from the feces. A negative correlation was observed between the percentage recovered and the length of time the blood remained in the digestive tract. This decrease in the amount of blood recovered was considered to be due to the action of digestive juices and to absorption within the digestive tract.

The method was tested on the feces of a patient bleeding profusely from a condition diagnosed as ulcerative colitis. During the period the patient was under treatment, the tests demonstrated the severity of the hemorrhage at the beginning of treatment and the gradual cessation of bleeding during the days that followed until no more fecal blood was demonstrable.

The results of the tests indicate that the method described can be used for the purpose of estimating the amount of blood passed in the feces of human patients suffering from gastrointestinal hemorrhage.

THE ADAPTATION OF MARSHALL'S MICRO SULFONAMIDE METHOD TO THE PHOTOELECTRIC COLORIMETER*

JOHN F. HALL, JR., M.A., DAYTON, OHIO

THE increasing importance of the sulfonamides in the treatment of various bacterial infections has resulted in the development and extensive use of several methods for determining these substances in the blood, urine, and body tissues. Of these methods those of Marshall,⁶ and Bratton and Marshall,² are perhaps the most extensively used in this country. In this report Marshall's improved method⁶ has been adapted for use in the determination of sulfanilamide, sulfapyridine, sulfathiazole, sulfadiazine, and sulfaguanidine† with the Evelyn photoelectric colorimeter⁴ which is a stabilized direct reading single-photocell type instrument.

The introduction by Bratton and Marshall of N-(1-naphthyl) ethylenediamine dihydrochloride as the coupling reagent to replace the dimethyl alpha-naphthylamine, which had been previously employed, has eliminated some of the objections to the Marshall method advanced by Andrews and Straus.¹ Sunderman and Pepper⁷ reported a diminution in recovery of sulfathiazole from whole blood when using the coupling agent (dimethyl-alpha-naphthylamine) of Marshall's original procedure. It is now easily possible to complete a determination by Marshall's method in approximately fifteen minutes, and the color produced remains stable for a period of two or more hours. The method recently proposed by Churg and Lehr,³ while equally rapid for the free sulfonamide, is somewhat slower for the total determination than the procedure presented here.

The method to be described has proved rapid, simple, and accurate, as evidenced by high percentage recoveries of the various sulfonamides which have been added to whole blood (dog and human), and may be used with either 0.2 or 0.1 c.c. of blood. Certain previous objections or uncertainties of the method, such as the length of time required for analysis, instability of color, or incomplete recoveries, are eliminated by the use of Marshall's more recent coupling agent N-(1-naphthyl) ethylenediamine dihydrochloride and by the use of the photoelectric colorimeter.

Reagents.—1. A solution of trichloroacetic acid containing 15 Gm. dissolved in water and diluted to 100 c.c.

2. A 0.1 per cent aqueous solution of sodium nitrite—this reagent should preferably be made up at weekly intervals.

*From the Aero Medical Unit, Army Air Forces, Materiel Center, Wright Field, Dayton.

†Supplies of these sulfonamides were obtained from Merck & Co., Inc., and the Lederle Laboratories, Inc.

Received for publication, March 2, 1942.

3. An aqueous solution of N-(1-naphthyl) ethylenediamine dihydrochloride containing 100 mg. per 100 c.c. This solution should be kept in a dark-colored bottle.

4. 4 N hydrochloric acid.

5. A solution containing 0.5 Gm. of ammonium sulfamate per 100 c.c. This solution should be freshly prepared each week and discarded at the first sign of contamination with molds.

6. Stock solutions of the various sulfonamides in water containing 200 mg. per liter. From this solution a series of dilutions were prepared for use in determining the respective calibration curves.

PROCEDURE

Blood for 0.2 c.c. Samples.—Two-tenths cubic centimeter of blood (oxalated or heparinized) is delivered into a colorimeter tube* containing 7.8 c.c. of distilled water. Proteins are precipitated by adding 2.0 c.c. of trichloroacetic acid, and removed by filtering. (Whatman No. 12 has proved suitable.)

Blood for 0.1 c.c. Samples.—One-tenth cubic centimeter of blood is added to 3.9 c.c. of distilled water in a graduated centrifuge tube and 1.0 c.c. of trichloroacetic acid is added for protein precipitation. Centrifuge for four to five minutes. Two cubic centimeter samples of supernatant fluid are then treated as outlined for the free and total sulfonamide determination.

Free Sulfonamide.—Two cubic centimeter samples of the blood filtrate are delivered into a colorimeter tube. One-half cubic centimeter of sodium nitrite is added. After two minutes 0.5 c.c. of the ammonium sulfamate is added. After another two minutes, 0.5 c.c. of N-(1-naphthyl) ethylenediamine dihydrochloride is added. The solution is then diluted to 10 c.c. by adding 6.5 c.c. of distilled water, and the color density is determined in the photoelectric colorimeter with a green filter (Corning) No. 540.

Total Sulfonamide.—After the sample for determination of the free sulfonamide is removed, the remainder of the blood filtrate is placed in a graduated centrifuge tube, the volume is observed and 0.4 c.c. of 4N HCl is added. It is heated in boiling water for twenty minutes, cooled, and adjusted to original volume with distilled water. This dilution precaution must be observed to avoid considerable error. Subsequent procedure is identical to that outlined above for free determination.

Calibration Curves.—Dilutions of a stock solution (200 mg. per liter) were prepared in concentrations ranging from 0.5 to 15.0 mg. per 100 c.c. and containing 18 c.c. of trichloroacetic acid per 100 c.c. A 0.2 c.c. sample of these respective stock dilutions was added to 8.1 c.c. of distilled water to which 0.2 c.c. of trichloroacetic acid has been added. One-half cubic centimeter of each reagent was then added at two-minute intervals. The calibration curves of the respective sulfonamides were then determined from the colorimeter readings of samples prepared in duplicate as above.

*These tubes are of especially selected glass and are furnished by the Rubicon Company, Philadelphia, Pa. from whom the Evelyn photoelectric colorimeter and filters may also be obtained.

Reagent Blank.—A stock blank is prepared by adding 2.0 c.c. of trichloroacetic acid to 8.0 c.c. of distilled water. A 2.0 c.c. sample is then delivered into a colorimeter tube, and 0.5 c.c. of each of the reagents is added at two-minute intervals. Six and one-half cubic centimeters of distilled water are added, the tube is placed in a colorimeter and the galvanometer is adjusted to 100, the reagent blank thus serving as the 0.0 mg. per 100 c.c. standard.

RESULTS

Calibration curves relating concentration (milligrams) to photoelectric density ($2 - \log G$) of these sulfonamides were found to be linear from a concentration of 0.5 mg. per 100 c.c. to 10 mg. per 100 c.c. for all the sulfonamides tested. Concentrations in excess of 10.0 mg. per 100 c.c. deviate somewhat from a straight line, particularly in the case of sulfanilamide. The calibration factors (K) derived from the respective curves were used in the calculation of the per cent recoveries of the various sulfonamides from whole blood. These factors were 50.6 for sulfanilamide, 33.5 for sulfapyridine, 36.0 for sulfathiazole, 36.9 for sulfadiazine, and 39.3 for sulfaguanidine. Standard deviations of these factors were 1.2, 1.2, 0.2, 0.2, and 0.2, respectively.

The percentage error for the 0.2 c.c. procedure in the recoveries from whole blood concentrations of 10 mg. per 100 c.c. varied from 0.2 to 2 per cent, and from 1 to 2 per cent in recoveries from concentrations of 1 mg. per 100 c.c. This probably represents the limit of accuracy for the 0.2 c.c. method as described here. The accuracy of the 0.1 c.c. procedure is somewhat less.

Results reported here were calculated by use of the formula:

$$\text{Mg. per 100 c.c.} = \frac{(2 - \log G)}{K} \times \frac{\text{dilution used}}{\text{c.c. of filtrate used}} \times 100$$

G is the galvanometer reading and K the calibration factor for the respective sulfonamide. For a 1:50 blood dilution the use of 2 c.c. blood filtrates and the twenty-minute hydrolysis period have been found to give satisfactory results. Color developed in the blood blank is negligible, since in the 1:50 dilution of blood the correction due to this was found to be about 0.08 mg. per 100 c.c. The reagent blank shows no measurable color development subsequent to its exposure to ordinary indoor room lighting conditions over a period of three to four hours. If analyses continue beyond this period of time, a fresh blank should be prepared if precise results are desired. The color developed as a result of the coupling reaction is stable for a period of two or three hours, after which its density slowly alters, and readings made after longer periods of time may be considerably in error.

DISCUSSION

The use of calibration curves for the respective sulfonamides seems desirable, since they are linear over the range of 0.5 to 10 mg. per 100 c.c. and quite reproducible. Their use avoids any uncertainty that arises from the employment of a standard whose color density, as mentioned above, is slowly altering. The green filter recommended (Corning No. 540) may be used for all the sulfonamides reported, since the wave length of the maximum absorption for

the respective compounds has been found by Feinstein and associates⁵ to be practically identical. As pointed out by Bratton and Marshall² the method is extremely sensitive, and concentrations of 1 μ g can be easily detected.

Diazotization with the nitrite and destruction of the excess nitrite by the ammonium sulfamate are rapid reactions, both being complete within thirty to sixty seconds. Formation of the azo dye by the coupling reaction is slower and the two-minute interval recommended must be observed for reproducible results. Complete analyses for the free drug require twelve to fifteen minutes, while the total sulfonamide determination may be completed in thirty-five to forty minutes.

N-(1-naphthyl) ethylenediamine dihydrochloride as the coupling agent possesses several distinct advantages, some of which have previously been pointed out by Bratton and Marshall. One of these is its speed, the method reported here being equally as rapid as that suggested by Andrews and Straus,¹ or Churg and Lehr.³ The procedure proposed by the latter workers requires also the undesirable use of an empirical factor to correct for a decrease in the color intensity due to the additions of hydrochloric acid in the total sulfonamide determination. No difficulty in securing satisfactory recoveries of sulfathiazole added to whole blood has been experienced. The necessity, therefore, for centrifuging the protein precipitate as Sunderman and Pepper⁷ reported, has been removed.

It is important in all procedures to observe the time interval between the addition of the various reagents and also to agitate slightly the solution during the various steps. Unless these precautions are observed in the preparation of blanks or samples, turbidities may result, or improper unstable colors may develop.

SUMMARY

1. An adaptation of Bratton and Marshall's method for the determination of sulfonamides in 0.2 and 0.1 c.c. blood samples is described for use with the photoelectric colorimeter.

2. Calibration curves obtained with the Evelyn photoelectric colorimeter over a 0.5 to 15 mg. per 100 c.c. range of concentration has been determined for sulfanilamide, sulfapyridine, sulfathiazole, sulfadiazine, and sulfaguanidine. The calibration factors (K) and standard deviations of these curves are presented.

3. The per cent error in the recoveries of these various sulfonamides as determined in concentrations of 1 and 10 mg. per 100 c.c. varied from 0.2 to 2.0 per cent.

4. The method as presented here is simple, sensitive, relatively rapid, and gives precise reproducible results over a range of concentrations varying from 0.5 to 15.0 mg. per 100 c.c.

I wish to express my appreciation to Dr. J. W. Heim for helpful criticism and suggestion.

A CLINICAL MICROMETHOD FOR THE DETERMINATION OF BLOOD UREA*

JOSEPH C. BOCK, CH.E., PH.D., MILWAUKEE, WIS.

THE diagnostician realizes that functional disturbances may be the first indication of anatomic changes. A deviation from normal nonprotein nitrogen of the blood is often a sign of a metabolic disturbance, if not an indication of a change to a definite pathologic stage. The study of the total nonprotein nitrogen or of urea nitrogen in the blood, although of diagnostic value in a number of disturbances, is most important when confronted with the problems of renal dysfunction.

The determination of the total nonprotein nitrogen of the blood, while most frequently employed, has several disadvantages. The method requires a well-equipped laboratory and a technician with good training. The nonprotein nitrogen fraction of the blood contains about 25 per cent of undetermined or rest nitrogen, made up of nitrogenous substances of practically unknown metabolic significance, especially under pathologic conditions. The relative increase in urea nitrogen is greater than the nonprotein nitrogen rise when dealing with certain renal disturbances. It must be kept in mind that urea is largely a waste product, whereas the undetermined nitrogen is anabolic. We believe, therefore, that the variations in urea alone serve as a better diagnostic guide than the nonprotein nitrogen.

A recently published procedure¹ for the determination of urea nitrogen has been modified to give the physician a method which does not require a laboratory, and at the same time is accurate enough to satisfy his diagnostic needs.

The enzyme urease converts urea into ammonium carbonate. The addition of the alkali sodium carbonate liberates ammonia, which is absorbed in the present method through "passive distillation" in hydrochloric acid.

The apparatus consists of a cylindrical vessel and a small glass cup fused to a rod. The cup and rod are attached to a cork which is inserted into the cylinder (Fig. 1).

*From the Department of Biochemistry, Marquette University School of Medicine, Milwaukee.

Received for publication, March 26, 1942.

The procedure is as follows: 0.1 ml. of blood from the ear lobe or finger tip is measured into the cup. One urease tablet, containing both urease and the necessary buffer salts, is crushed, and one-third to one-half of this powder is added to the blood contained in the cup. Blood and urease are mixed by gentle agitation, care being taken to avoid any liquid spilling over the rim of the cup. The stopper with the cup is inserted into the vessel and is allowed to stand for about one hour at room temperature. The cup assembly is then

Fig. 1.

Fig. 2.

removed, and 1 ml. of approximately tenth-normal hydrochloric acid is carefully measured into the cylinder. Three drops of a concentrated solution of sodium carbonate are added to the blood in the cup, and the stopper is *quickly* inserted, to avoid any possible loss of ammonia. The vessel is gently agitated by a rotary motion, to mix the contents of the cup. The apparatus is allowed to stand (at room temperature) for about eight hours, or still better overnight. The stopper with the cup is then removed, 3 ml. of water are added to the fluid in the cylinder and the contents are mixed by rotation. One milliliter of Nessler reagent (Bock-Benedict modification¹) is added, the solutions are mixed again and allowed to stand for eight to ten minutes. This is necessary for full development of the color. The liquid is transferred to a small tube, which in

turn is inserted into the holder of a Taylor* slide comparator (Fig. 2). The movable slide of the instrument has a set of tubes containing permanent standards, the colored tubes being interspersed by tubes containing water. The slide is moved back and forth until the unknown is flanked by those two standard tubes which match the closest. The standards are permanent, consisting of a mixture of ferric and cobaltous chloride in acid solution and arranged to give a direct reading in milligrams per 100 c.c. of blood, ranging from 10 mg. to 100 mg. of nitrogen.

The color standards are made as follows:

$\text{FeCl}_2 \cdot 6\text{H}_2\text{O}$: 100 Gm. in 1,000 c.c., using 1 per cent (by weight) hydrochloric acid as solvent.

$\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$: 100 Gm. in 1,000 c.c., using 1 per cent (by weight) hydrochloric acid as solvent.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

ALCOHOL, The Perchlorate Method for Determining Concentration of, in Expired Air, Jetter, W. W., and Forrester, G. C. *Arch. Path.* 32: 829, 1941.

A critical evaluation of the perchlorate method for the determination of breath alcohol has been made, and the following data have been presented: When the test is properly made, there is no loss of alcohol or of carbon dioxide before the breath reaches the absorption tubes; reducing substances in the breath other than alcohol are negligible in their effect; the presence of acidosis or alkalosis in the test subject materially affects results, but these conditions may be controlled or eliminated by proper precautionary measures.

In a series of 79 cases in which breath and direct blood analyses were made, the deviation did not exceed 16 per cent in any instance.

In view of the simplicity of operation and the ease with which the instrument can be transported, this method is well adapted for use by law enforcement agencies.

AMYLOIDOSIS, Standardization of the Congo Red Test for, Taran, A., and Eckstein, A. *Am. J. M. Sc.* 203: 246, 1942.

A standardized method for the Congo red test for amyloidosis is presented.

The dye is administered according to body weight. It was found that 1 c.c. of a 1 per cent aqueous solution of the dye per 10 pounds of body weight yielded more accurate tests than the fixed amount customarily used.

Tests were performed on amyloid and nonamyloid patients, using both the usual technique of injecting 10 c.c. of dye regardless of body weight and the standardized method.

In one nonamyloid group patients were selected whose body weights were nearly the same (range between 95 and 105 pounds) and in the other those whose body weights varied considerably (range between 50 and 175 pounds). The former group showed consistently reliable four-minute specimens, while the latter gave four-minute specimens which differed as much as 75 per cent. In some cases the per cent absorption could not be computed because of insufficient dye in the four-minute specimens.

In the amyloid group 90 to 100 per cent absorption was a consistent finding. This is in so close correlation with previous work that such results must be obtained to indicate amyloidosis. In all but 11 cases the four-minute specimens contained sufficient dye to be considered as appropriate standards.

These 11 cases were investigated further along with 24 of the other amyloid cases, and it was found expedient to draw a two-minute specimen in addition to the four-minute and one-hour specimens. A group of 60 nonamyloid cases was chosen as controls. In all of the amyloid cases, the two-minute specimens showed good color intensity and the differences in color between them and the four-minute specimens were marked (as high as 75 per cent). There were only slight differences in color intensity between the two-minute and four-minute specimens in the nonamyloid group, the highest per cent variation being 15.

The two-minute specimen was adopted as the colorimetric standard in place of the four-minute specimen.

Since the inception of this study 21 of the 42 amyloid patients have come to autopsy and each revealed amyloidosis of greater or lesser degree. Twenty of the nonamyloid patients have come to autopsy and only one case revealed a moderate degree of amyloidosis.

The standardized method has improved the accuracy and reliability of the test as a diagnostic aid.

The authors' method follows:

Inject 1 c.c. of a 1 per cent aqueous solution of Congo red per 10 pounds of body weight intravenously. At the end of exactly four minutes, and then one hour, after the injection, obtain blood specimens of 10 c.c. each and place them into clean, dry test tubes. Allow the bloods to clot and retract and then centrifuge them at a moderate speed for ten minutes. Aspirate off the clear sera and place them into graduated centrifuge tubes. Add acetone equal to the volume of serum in each tube and shake them well. Centrifuge tubes for ten minutes at a moderate speed. Pour off the supernatant fluids and place them into micro cups of a colorimeter to be compared. Set the four-minute specimen at 20 mm. and read the one-hour specimen.

Calculation:

$$100 - \frac{\text{Reading of four-minute specimen}}{\text{Reading of one-hour specimen}} \times 100 = \text{Per cent absorption.}$$

For example: The four-minute specimen is set at 20 mm. in the colorimeter. The one-hour specimen reads 25. Therefore, the per cent absorption of the dye is 20.

COAGULATION, Blood, Simple Method of Timing, Knauer, C. H. J. Med. Soc. New Jersey 39: 75, 1942.

An ordinary hypodermic syringe with a slightly larger-sized needle than ordinary is used. If necessary, the small diameter needle will serve. Blood is withdrawn from the median basilic or some other prominent vein. A few bubbles of air are drawn into syringe, and it is allowed to rest on its side for three minutes, after which time it is tilted slowly from end to end so as to permit the bubbles with their interspaces of blood to travel slowly from one end of the barrel to the other at one-quarter minute intervals. It is soon found that the rapidity with which these bubbles travel the length of the syringe becomes diminished with the formation of the clot and that one-half to three-quarters minute transpires between the onset of the clot formation and the actual completion of the process which is noted by the almost immobility of the bubbles.

RHEUMATIC FEVER, Formol-Gel Test in, Butterworth, J. S., and Poindexter, C. A. Am. J. M. Sc. 203: 278, 1942.

The formol-gel test is essentially a test for hyperglobulinemia and has no correlation with the erythrocyte sedimentation rate.

It is of little or no value in the diagnosis of acute rheumatic fever with or without carditis.

HYPOPROTHROMBINEMIA in Pernicious Anemia, Warner, E. D., and Owen, C. A. Am. J. M. Sc. 203: 187, 1942.

Patients with Addisonian pernicious anemia in relapse usually show considerable decrease in plasma prothrombin. In the majority of such cases the prothrombin level is found to be between 40 per cent and 65 per cent of the normal. The hypoprothrombinemia is not rectified by large doses of vitamin K. When specific liver therapy is instituted, the plasma prothrombin level promptly shows a marked rise.

PROTHROMBIN DEFICIENCY, Effect of Vitamin K Therapy on the Plasma Prothrombin Level of Patients With, Rhoads, J. E., and Norris, R. F. Bull. Ayer Clin. Lab., Pennsylvania Hosp. 3: 359, 1941.

The administration of an excess of 2 methyl-1,4-naphthoquinone to surgical patients without hypoprothrombinemia resulted in a slight shortening of the prothrombin time, as determined by the Quick method and a modification thereof.

This difference is not regarded as significant in the number of cases studied, in view of the variations observed among the controls; it is less than the difference between normal controls and the plasma of parturient mothers, observed by Norris and Rush, and much less than was observed in some of their patients.

It is also of interest that six days of therapy yielded no better result than did two days of therapy.

The results indicate, therefore, that the supply of vitamin K is not an important limiting factor in determining the prothrombin level under normal conditions.

There is nothing in the results of the study to suggest that the administration of vitamin K would be valuable in the prevention of hemorrhage in patients who do not have hypoprothrombinemia, nor that it would be dangerous to give the vitamin in considerable excess to patients whose prothrombin levels were already normal.

The method of study is not sufficiently accurate to establish satisfactorily or to exclude a mass action effect of vitamin K on the production of prothrombin.

PROTHROMBIN, Comparison of Bilirubin Values and, in the Umbilical Artery and Vein at Delivery, Norris, R. F., and Bennett, M. C. Bull. Ayer Clin. Lab., Pennsylvania Hosp. 3: 353, 1941.

The average bilirubin content of fetal blood exceeds that of maternal blood at delivery. In individual infants there is a marked variation in the degree of hyperbilirubinemia, which is independent of the amount of bilirubinemia in their respective mothers.

There is no evidence that bilirubin diffuses in either direction through the placenta.

No relationship is demonstrated between the amount of serum bilirubin and the plasma prothrombin in individual infants.

SHOCK, The Vascular and Cellular Dynamics of, Moon, V. H. Am. J. M. Sc. 203: 1, 1942.

An analysis of the sources for disagreement concerning the dynamics of shock indicates that four major causes have operated to confuse interpretations of its phenomena and of their interrelationships.

The first of these was deficient knowledge of capillary reactions and of circulatory disturbances originating in them. A comprehension of these has contributed immeasurably to an understanding of shock resulting from trauma, burns, and other types of tissue damage. It clarifies also the disturbances of fluid balance and of chemical concentrations which are associated regularly with this condition.

Failure to distinguish between shock and hemorrhage has caused much confusion. Hemorrhage, when present, is a potent contributory factor, but the effects of uncomplicated hemorrhages present numerous features opposite in character from those which constitute the syndrome of shock.

Variations in blood pressure used as a criterion, and failure to consider the depressor effects of both anesthesia and losses of blood, have led to undependable conclusions concerning the effects of absorption. Varied forms of experimentation have shown that products derived from normal tissues, independent of narcosis and hemorrhage, will produce the syndrome of shock accompanied by its characteristic physiologic and morphologic features.

Hemoconcentration during life, and the presence of engorged capillaries, stasis, petechiae, and edema after death, indicate endothelial damage as a major factor. The occurrence of these conditions in extensive visceral areas remote from the injury indicates systemic, not local, endothelial damage. Shock, like other conditions of disease, is accompanied by a pattern of morphologic changes which are related etiologically to its mechanism of origin and which corroborate the interpretation of shock as due to endothelial damage.

The major causes for disagreement concerning shock have been discussed. In view of the character and magnitude of these, it is not strange that final clarification of the problem has been delayed.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

Lymphatics, Lymph, and Lymphoid Tissue*

A COMPREHENSIVE authoritative volume, this book covers the origin, nature, and function of the elements indicated in the title.

As the writers bring out, study of the physiology of lymph carries us nearer to a study of the life processes of the tissue cells. Lymph circulates from the blood vessels into the tissue spaces surrounding the cells and out again through the lymphatics into the blood vessels. It is this fluid that is of utmost importance in the maintenance of vital cellular equilibrium. Considerable space is necessarily given to the phenomena of capillary permeability, and there is an associated discussion of water balance and electrolyte metabolism. Clinical implications are adequately discussed.

This volume should be of interest to physiologists and, on the clinical side, especially to surgeons, internists, allergists, and dermatologists.

Photomicrography†

A HANDBOOK which adequately covers the entire field of photomicrography, the first portion of *Photomicrography* deals with the physics of photography, especially as applied to the use of the microscope with photographic cameras. The major portion of the book deals with equipment and its use. This extends from simple homemade equipment, through the use of candid camera attachments, such as the Leica and Contax, up to complicated apparatus of highest precision, including the electron microscope. Fifty pages are given to darkroom technique, developing and printing, and there is an abundance of formulas for developing solutions. In this way the book is complete, requiring little or no reference to other volumes. It is abundantly and very well illustrated.

Biological Symposia‡

THIS volume is devoted entirely to the structure and experimental physiology of muscle. It contains sixteen essays by various authors. One is likely to find the answer to whatever one would wish to know concerning muscle physiology, somewhere in this volume. Unfortunately there is no index. Also, the binding does not indicate the subject matter. Although the book is devoted to one subject, muscle, one must look inside to discover this.

Subjects discussed include muscle excitability, action, potentials and conduction, activity around the neuromuscular junction, regulation of energy exchange, changes during muscle contraction, the significance of oxidation, efferent innervation, electrolyte equilibrium in muscle, and electric potential changes accompanying neuromuscular transmission. Both smooth and striated muscle are covered.

*Lymphatics, Lymph, and Lymphoid Tissue. Their Physiological and Clinical Significance (Harvard University Monograph in Medicine and Public Health, No. 2). By Cecil Kent Drinker, M.D., D.Sc., Professor of Physiology, School of Public Health, Harvard University; and Joseph Mendel Yoffey, M.Sc., M.D., F.R.C.S. (Eng.), Senior Lecturer in Anatomy, University College of South Wales and Monmouthshire, Cardiff, Wales. Cloth, 406 pages, \$4.00. Harvard University Press, Cambridge, Mass., 1941.

†Photomicrography. By R. M. Allen. Cloth, 365 pages, \$5.50. D. Van Nostrand Company, New York, 1941.

‡Biological Symposia—A Series of Volumes Devoted to Current Symposia in the Field of Biology. Edited by Jaques Cattell, Editor of The American Naturalist and American Men of Science. Volume III. Muscle. Cloth, 370 pages. The Jaques Cattell Press, Lancaster, Pa., 1941.

A Manual of Neurohistologic Technique*

THIS small volume presents methods of preparation and staining of nerve tissue for microscopic study. In it the author has collected the best techniques from scattered places in the literature and gives his own critical experiences with them. This should make a handy reference volume for pathologists and neuroanatomists.

An Introduction to Dermatology†

PRIMARILY a condensation of the larger book *Diseases of the Skin* by the same authors, the fourth edition of the book is based on the tenth edition of the larger volume. Even the introduction is large enough, covering 900 pages. It is abundantly and well illustrated, and constitutes an adequate dermatologic reference book for all who are not primarily dermatologists.

Chemical Solutions‡

IN THIS book the author has collected in one place the methods for the preparation of the solutions most commonly used in the average chemical laboratory, such as organic, biochemistry, food chemistry, metallurgy and metallography, bacteriology, gas and fuel analysis, general testing, and water analysis. The solutions are listed alphabetically according to their most common name; when a reagent is known by several names, these names are also included in their proper place in the alphabetical tabulation with proper cross references. Additional valuable information is also given, such as, (a) the uses of each solution; (b) the procedure for use where this is practicable; (c) interfering substances; (d) sensitivity of the test reagent; and (e) general keeping qualities. One or more reference is included for each solution, wherever advisable. A valuable feature is an index in which the various reagents are classified according to their use. All descriptions are concise and to the point, and unnecessary detail is eliminated. It is the opinion of the reviewers that this book should prove a most valuable adjunct to any chemical library.

Chromatographic Adsorption Analysis§

A GOOD technique sometimes renders more service to science than the elaboration of highly theoretical speculations." With this introduction from the writings of Claude Bernard, Dr. Strain in this book, Volume II of the series of monographs on Chemical Analysis by the same publishers, has compiled in a single volume practical information on chromatography from widely scattered sources. The remarkable influence of this technique on the progress of many chemical investigations of varied nature, particularly in the field of biological compounds, makes such a book highly desirable. The technique of separation of many types of compounds, organic and inorganic, colorless as well as colored, by adsorption on Tswett columns is described. Many diagrams of apparatus are presented. Various absorbents, their applications, limitations, availability, and choice for certain types of compounds, as well as various methods for filling the columns, are discussed. Selection of solvents and eluents and the many factors influencing their usefulness are presented in detail. The usefulness of the volume is greatly enhanced by the inclusion of an extensive bibliography, with titles from which one can readily find literature pertaining to particular problems, as well as a very good author and subject index which indexes bibliography as well as text. It is a useful

practical book for the chemical investigator, and its readable style also makes it valuable for others who would like to know more about the technique involved in chromatographic adsorption analysis.

Analytical Chemistry of Industrial Poisons, Hazards and Solvents*

THIS is an exhaustive text dealing with the detection of substances important from the standpoint of industrial health. Thorough discussion is made of air sampling, measurement of gas volume and quantity, absorbers and absorbents, the chemical and microscopic estimation of dust. Then follows specific and detailed description of the detection of silica, the dangerous metals, poisonous compounds of sulfur, and the halogens. The gases, carbon monoxide, carbon dioxide, hydrocyanic, and cyanogen, are subsequently taken up and then a consideration of the various solvents, including the alcohols and glycols. The author closes his text on the very timely topic of the chemical warfare agents. Brief mention is made in each instance on the toxicity and physiologic activity of the materials under consideration. This is an outstanding text which will prove most beneficial to all interested in industrial health. *It is most heartily recommended.*

CLINICAL AND EXPERIMENTAL

HEMATOLOGIC VALUES FOR NORMAL HEALTHY MEN 16 TO 25 YEARS OF AGE*

CHRISTOPHER J. HAMRE, PH.D., AND MAN HING AU, M.S.
HONOLULU, T. H.

NUMEROUS investigations have been made in this country and in other countries during the past few years in an effort to determine the reliability of long-accepted blood values and to establish standard normal blood values for particular geographical areas. The greater number of studies have been concerned with the normal or mean values for the quantity of hemoglobin and the number of red blood cells for healthy persons. Only a relatively small number of studies have been made on the normal values for other blood elements. The present report is concerned with the results of complete hematologic examinations of healthy men. Reports in the literature of similar complete hematologic studies for men have not come to our attention.

Reviews, including normal values for all blood elements for adult men, are lacking, though reviews of the studies of normal values of some individual blood elements are found in the literature. Myers and Eddy,¹ and Nelson and Stoker,² have reviewed the literature on normal values for hemoglobin of men, while the latter, Andresen and Mugrage,³ and Mugrage and Andresen⁴ have reviewed the literature on normal numbers of red blood cells. The last-named authors have also presented a consideration of the values for the various corpuscular constants. Garrey and Bryan,⁵ Osgood,⁶ and Osgood and co-workers⁷ have reviewed the literature on leucocyte values, while Olef⁸ has reviewed

*From the Department of Zoology, University of Hawaii, and the Nutrition Laboratory of the Hawaii Agricultural Experiment Station, Honolulu.

Published with the permission of the Director, as Technical Publication No. 58, of the Hawaii Agricultural Experiment Station.

This work was supported in part by grants made by the Honolulu County Medical Society and the Hawaiian Academy of Science.

Received for publication, May 26, 1941.

studies of normal values for platelets. The results of studies of normal values for the various blood elements for men in the literature available to us are summarized in Tables I and II for the purpose of comparison with the results of investigations of mean blood values presented here.

SUBJECTS EXAMINED

The 137 men examined in this study were all university students, ranging in age from 16 to 25 years. All had resided in the Hawaiian Islands for at least two years, and the greater number of them were born there and had lived continuously in the Islands. The individuals were all of average good health, and none had had recent illness. They were of different racial groups, the number of persons in each age group, and as well the number in each racial group, are indicated in Tables III and IV. Honolulu is situated on the seashore, and the homes of its residents range from sea level to an altitude of approximately 1,000 feet.

METHODS OF STUDY

All blood samples of the subjects examined were of capillary blood, obtained from a deep puncture of the finger made with a sharp spring lancet, only the freely flowing blood being used. The hemoglobin estimations for 31 men were made by the acid hematin method, employing a Bausch & Lomb colorimeter equipped with a standard hemoglobin color disk. The color disk was checked for accuracy during the course of the study. The remaining hemoglobin estimations were made with a Klett-Summerson photoelectric colorimeter employing the acid hematin method, the colorimeter being checked and standardized against the Van Slyke oxygen capacity method of hemoglobin determination.

Enumerations of erythrocytes, leucocytes, and platelets were made by the use of Thoma pipettes and Levy counting chambers, certified for accuracy by the United States Bureau of Standards. Hayem's solution and Tuerk's solution were used in diluting the blood samples for red and white blood cell counts made in the usual manner. The solution of Rees and Ecker was used for dilution of blood samples for platelets, the counts being made by the direct method. The volume of packed red blood cells was determined by the use of capillary hematocrit pipettes according to the method described by one of us (C. J. H.),¹⁰ and calculations of the corpuscular constants were made by the use of the formulas suggested by Wintrobe.¹¹ Differential leucocyte counts were made from blood smears stained with Wright's stain and counterstained with Giemsa. Counts were made from three smears for each person, the average for the three counts being taken as the differential count for the person.

The data obtained in this study were submitted to statistical analysis, and mean values were determined for each blood element for each age group and racial group. Statistical constants were calculated in all instances. The results and conclusions presented in this paper are based on the statistical studies of these data.

OBSERVATIONS AND RESULTS

It has frequently been suggested that values for the different blood elements may vary for different racial groups. It has also been suggested that

*Indirect method of platelet enumeration.

†Direct method of platelet enumeration.

values for different geographical regions may vary due to operation of factors of climate and altitude. Age differences for adult men, however, are thought not to occur, and if they do they may be so slight as to be insignificant. The extensive data collected in this investigation were analyzed to determine whether age or racial differences occurred for this series of persons. If age and racial differences were found not to occur, mean values could be calculated for all the blood elements for the entire group, these values to serve as standard blood values for the Hawaiian Islands for comparison with blood values reported for other geographical regions of the world.

The persons examined in this study ranged in age from 16 to 25 years, but the number in each age group was great enough to permit critical analysis only for the ages from 18 to 22 inclusive. General observations of the blood values for these age groups, supported by statistical analysis, showed that significant differences in the blood values did not occur. The values for the various blood elements for the different ages are summarized in Table III.

In the study of racial differences in blood values, sufficiently large numbers of persons to permit statistical analysis occurred only for the Caucasian, Chinese, and Japanese racial groups. The number of persons of other racial groups attending the University of Hawaii is so small that many years would be required for critical studies. For the three larger racial groups, statistically significant differences for none of the blood elements occurred. The values for the various blood elements for the different racial groups are summarized in Table IV.

Since significant age and racial differences for the various blood elements did not occur, all these data were combined for determination of normal blood values for young men residing in the Hawaiian Islands. The mean values, statistical constants, and the range of the values for the different blood elements are presented in Table V. The frequency of occurrence of the various blood values is graphically presented in histograms in Chart 1.

The mean values for the various blood elements obtained in this study for healthy young men of the Hawaiian Islands may be compared to those for men of other geographical regions summarized in Tables I and II. Such a comparison indicates that the values obtained in this study are closely similar to those given by the greater number of investigators. It is evident that particular or peculiar types of normal blood values do not exist for adult men of the Hawaiian Islands.

DISCUSSION.

It is generally agreed that blood values for healthy adult males are constant. This feature of blood values has been pointed out by Osgood,⁶ Andresen and Mugrage,³ Wintrobe,¹² and many others. Our conclusion that age differences did not occur for the blood values of the series of healthy persons examined in this study was, therefore, anticipated, particularly in view of the narrow age limits of the group examined. Also, it has been pointed out by Osgood,⁶ Mugrage and Andresen,⁴ Sachs, Levine, and Griffith,¹³ Goldhamer and Fritzell,¹⁴ and many others that adult blood values are attained by males between the ages of 15 and 17 years. Our data tend to support these observations.

†Platelets determined for 137 subjects.

It has frequently been suggested that racial differences for blood values may occur and that these variations may account for differences in mean blood values reported by different authors. It is, however, a problem on which very little direct work has been undertaken. Hamre and Wong,¹⁵ in a study of normal blood values for pre-school age children of different races, particularly Chinese, Japanese, and Caucasian, found the blood values to be similar, with

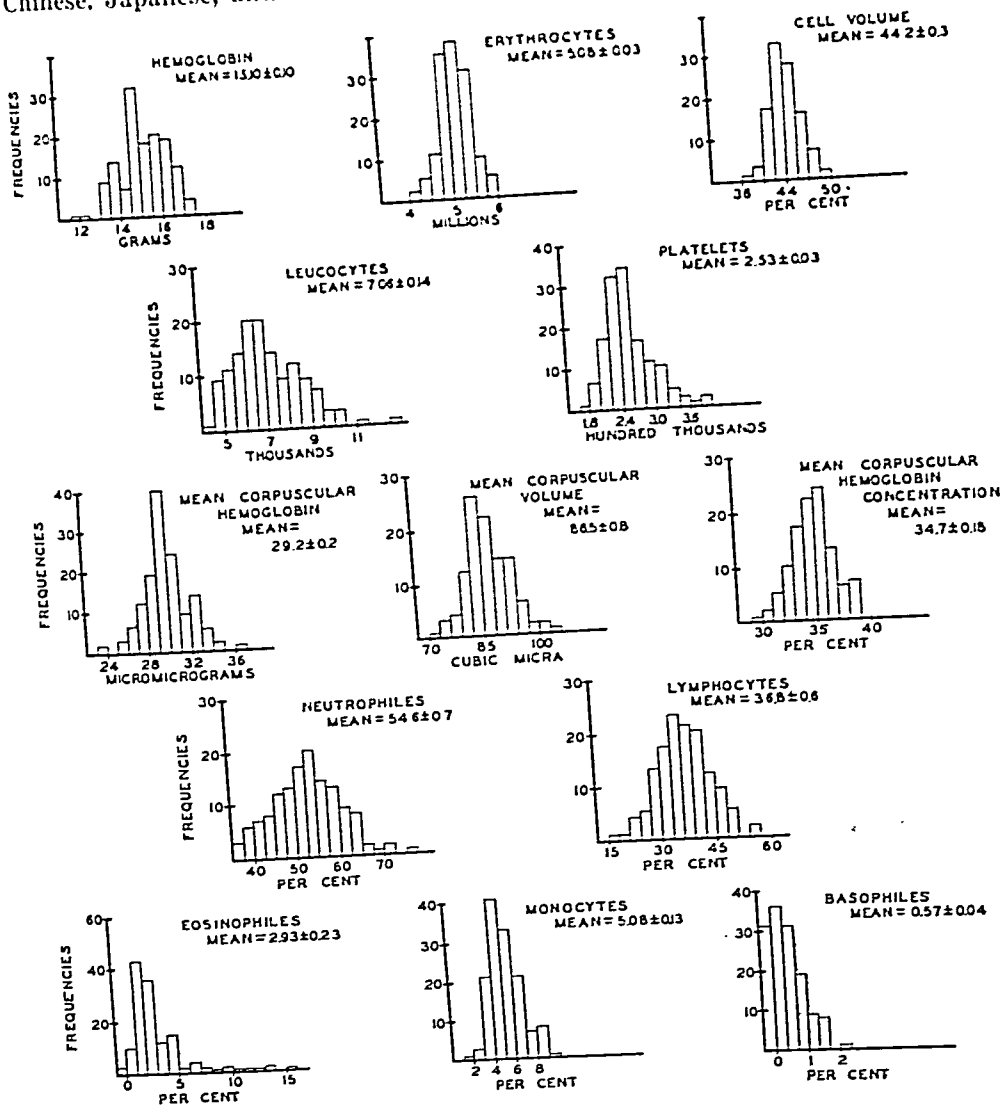

Chart 1.

no significant differences. Nelson and Stoker,² in studies of hemoglobin and red blood cell values of white and negro adult men, found no racial differences to exist. Myers and Eddy,¹ after a study of hemoglobin values reported in the literature for different races, came to the conclusion that racial differences did not occur. A study of Tables I and II, which include blood values for several races, indicates that, when due consideration is given to variations in technique

employed in the studies, racial differences in blood values do not exist, or if they exist, they are very small. The present study supports these conclusions, since it shows that for Chinese, Japanese, and Caucasian men of similar ages and environment, statistically significant differences for the mean values of none of the blood elements occur.

It has also frequently been suggested that the differences in mean blood values reported by different investigators may be due to geographical factors other than that of altitude. Walters,^{16, 17} Wintrobe,¹² and Myers and Eddy¹ have concluded that significant differences of blood values for different geographical regions do not exist, and that blood values are generally the same for all regions of the world. The mean values reported by various investigators from various sections of the world, presented in Tables I and II, indicate that this conclusion must be accepted, and that the normal blood values for men residing in the Hawaiian Islands cannot be considered to differ from the blood values of men residing in other regions of the world.

Mean blood values for normal persons, as Nelson¹³ and others have pointed out, represent only the central values of normal, the normal values ranging above and below these means. Mean values, however, may be employed in making comparisons for the degree of similarity and agreement of the results of different investigations. The mean values for hemoglobin, obtained by different investigators and presented in Table I, vary greatly though the greater number fall in the region of 14.5 to 15.5 Gm. per 100 c.c. of blood. Since various methods were used in making the hemoglobin determinations, it is possible that the variation in mean values obtained may be due to a great extent to the differences in methods employed. Where the technique and apparatus employed have been quite uniform, as for instance in the enumeration of red blood cells, the results of the different investigations are more nearly alike. The greater number of red blood cell values summarized in Table I fall into the interval of 5 to 5.5 millions per cubic millimeter of blood. Our mean hemoglobin value of 15.10 Gm. and mean number of red blood cells of 5.08 millions, therefore, fall in the regions which include the greater number of mean values reported for these blood elements.

The mean values for the volume of packed red blood cells of healthy adult men reported in the literature vary markedly. This is undoubtedly due to a great extent to differences in technique employed in the determinations. Other factors may also contribute to this difference in reported values. A number of recent workers (Walters,¹⁷ Andresen and Mugrage,² and Mugrage and Andresen⁴) have reported mean values of 48 and 49 per cent for cell volume. These values are exceptional, the greater number of investigators having reported values ranging from 44 to 46 per cent. Our mean values of 44.2 per cent for the volume of packed red blood cells, therefore, fall in the group of more frequently reported values.

The corpuscular constants have received only little consideration except in recent investigations. The mean values for mean corpuscular hemoglobin concentration tend to be nearly alike and fall in the interval 32 to 35 per cent. Values for mean corpuscular hemoglobin are also in general agreement, and the greater number of mean values vary from 29 to 31 micromicrograms. Greater differences for mean corpuscular volume reported in the literature

occur and vary from 84 to 96 cubic microns. The same investigators who report high mean values for packed red blood cell volume have also reported high values for mean corpuscular volume. Our values of 34.7 per cent for mean corpuscular hemoglobin concentration, 29.2 micromicrograms for mean corpuscular hemoglobin, and 86.5 cubic microns for mean corpuscular volume agree with the values reported by the greater number of investigators and with the values of 35 per cent, 29.5 micromicrograms, and 87 cubic microns originally suggested by Wintrobe.¹¹

TABLE V

MEAN VALUES, STATISTICAL CONSTANTS, AND RANGE OF VALUES FOR ENTIRE GROUP*

BLOOD ELEMENT	MEAN VALUE	STANDARD ERROR OF THE MEAN	STANDARD DEVIATION	RANGE
Hemoglobin in grams per 100 c.c. of blood	15.10	0.10	1.11	11.83 to 17.20
Erythrocytes in millions per cubic millimeter of blood	5.08	0.03	0.35	4.23 to 5.97
Volume of packed red blood cells in cubic centimeters per 100 c.c. of blood	44.2	0.3	2.8	37.5 to 51.6
Mean corpuscular volume in cubic microns	86.5	0.8	7.9	71.2 to 103.2
Mean corpuscular hemoglobin in micromicrograms	29.2	0.2	2.2	23.1 to 36.1
Mean corpuscular hemoglobin concentration in per cent	34.7	0.18	1.7	29.9 to 38.9
Platelets in ten thousands per cubic millimeter of blood	25.3	0.03	0.40	17.8 to 39.8
Leucocytes in thousands per cubic millimeter of blood	7.06	0.14	1.56	4.4 to 12.6
Differential leucocyte count in per cent				
Neutrophiles	54.6	0.70	8.0	38.6 to 78.3
Eosinophiles	2.93	0.23	2.7	0.0 to 15.6
Basophiles	0.57	0.04	0.48	0.0 to 2.3
Lymphocytes	36.81	0.6	6.9	16.3 to 55.6
Monocytes	5.08	0.13	1.47	1.6 to 9.3

*All mean values determined for 127 persons, except for leucocytes and differential leucocyte counts, which are for 136 persons, and cell volume and corpuscular constants for 107 persons.

The mean values reported for platelets may be divided into two groups, those obtained by the direct method and those obtained by the indirect method of enumeration. The mean values obtained by the two methods have been reviewed by Olef.⁹ In general, the values obtained by the first method are about half as great as those obtained by the second method, and range from 250,000 to 300,000 per cubic millimeter of blood. We chose the direct method of enumerating platelets, and our mean value of 253,000 per cubic millimeter of blood compares well with the mean values obtained by this method by other investigators.

The mean values for the normal number of white blood cells reported in the literature available to us, and summarized in Table II, vary from 5,618 to 8,350 per cubic millimeter of blood. Our mean value of 7,067 falls well within the limits of these observed values. The mean values of 54.6 per cent for neutrophiles, 2.93 per cent for eosinophiles, 0.57 per cent for basophiles, 36.81 per cent for lymphocytes, and 5.08 per cent for monocytes obtained in this study compare closely to the mean values obtained by Osgood,⁶ and Osgood

and co-workers.^{7, 8} They, however, differ from the values usually given in textbooks in that the mean values for neutrophils are lower while the mean values for lymphocytes are higher than values commonly considered to be normal.

SUMMARY

Data are presented for the blood values of 137 healthy young men residing in the Hawaiian Islands, and ranging in age from 16 to 25 years. They were of several different races, the larger number being Caucasians, Chinese, and Japanese. In this study, age or race differences were not found to occur for values for any of the various blood elements. The mean blood values obtained compared closely with those given by investigators in other parts of the world, and we have concluded that blood values for men in the Hawaiian Islands do not differ significantly from those of men residing elsewhere. The mean values, statistical constants, and range of observed values for the various blood elements are summarized in Table V.

THE AGGLUTININ RESPONSE OF NORMAL PERSONS TO SKIN TESTS WITH BRUCELLERGEN AND BRUCELLA VACCINE*

WILLIAM M. M. KIRBY, M.D., AND LOWELL A. RANTZ, M.D.
SAN FRANCISCO, CALIF.

TWO types of antigens are commonly employed in skin testing for brucellosis. One, Huddleson's brucellergen, contains the purified protein nucleate fraction of *Brucella* cells. The other, *Brucella* vaccine, is a suspension of heat-killed organisms in physiologic saline, and is also used for therapy.

There is evidence that the intradermal injection of these substances stimulates the production of agglutinins. Giordano,¹ Goldstein,² Heathman,³ and Meyer and Eddie,⁴ have noted positive agglutination tests following skin tests with heat-killed organisms. Wide variations are reported, however, in the maximum titers obtained. For example, Goldstein recorded titers as high as 1:5,120, while the highest titer noted by Meyer was 1:80. Similar differences have occurred with brucellergen. Evans⁵ found titers as high as 1:320, while Huddleson⁶ states that "one skin injection of brucellergen may give rise to *Brucella* agglutinins in a low titer in a small percentage of individuals. The agglutinins disappear in about sixty days."

Among the factors contributing to these variations are (1) individual differences in agglutinin response, (2) the size of the skin test dose, (3) the nature of the antigen used for the agglutination tests, and (4) the technique of reading the agglutination tests. Since no single observer has studied both brucellergen and vaccine at the same time, it is difficult to draw conclusions as to their relative ability to stimulate agglutinin production.

Since this development of agglutinins may cause difficulty in interpreting agglutination tests, it is the routine procedure in some clinics to take blood for the agglutination test before the skin test is performed. However, since the results have been variable, as described, and since there is considerable difference of opinion concerning the relative merits of the skin and agglutination tests,

*From the Department of Medicine, Stanford University School of Medicine, San Francisco.

there is no general agreement on this point. For example, physicians using Huddleson's brucellergen are advised that "the first procedure to follow in arriving at a diagnosis is the performing of an intradermal test with brucellergen." Thus, in a clinic where patients are usually seen after consulting one or more other physicians, we are constantly faced with the problem of interpreting agglutination tests performed at intervals of several days to several weeks following skin tests, and it is of considerable importance to know as accurately as possible the effect of the skin test itself.

Due to marked local and systemic reactions in sensitive individuals, the size of the skin test dose has been reduced in the past few years, both for brucellergen and for the heat-killed organisms. Keller⁷ has shown that the smaller doses of heat-killed organisms are equally as reliable as brucellergen for skin testing, and that reducing the size of the dose has abolished the more severe reactions previously noted.

Our purpose in undertaking this study was to determine the agglutinin response to commercial products commonly used at the present time, hoping we might, with these smaller doses, obtain information of value in interpreting agglutination tests performed on patients at varying intervals following skin tests. It also seemed of interest to compare the effects of vaccine and brucellergen, using the same antigen and the same technique in interpreting the tests.

METHOD AND MATERIALS

Fifty apparently normal, healthy adults, most of them members of the house staff of Stanford University Hospitals, volunteered for the study. All had negative *Brucella* agglutinations before being skin tested. One-half were given 0.1 c.c. of Huddleson's brucellergen 1:12,000, obtained from the Department of Bacteriology of the Michigan State College, and the other one-half were given 0.1 c.c. of the commercial *Brucella* vaccine, prepared by the Lederle Laboratories, diluted so that 0.1 c.c. contained forty million heat-killed organisms. The skin tests were read after forty-eight hours, an area of induration and edema of 5 mm. or more being considered positive. Agglutination tests were performed during the second and fourth weeks following the skin tests.

The antigen was prepared from *Br. abortus* strain 19, from which contaminants and rough variants were carefully excluded. A forty-eight-hour growth of the organisms was suspended in 0.5 per cent phenolized saline, and diluted to a density corresponding to approximately 4 cm. on the Gates apparatus. In performing the tube agglutination tests, serial dilutions of the serum, from 1:10 to 1:160, were added to constant amounts of the antigen. The tests were read after twelve hours' incubation at 37° C., and again after standing at room temperature for twenty-four hours. Tubes not showing a perfectly clear supernatant solution, with good clumping in the bottom, were regarded as negative. Tube agglutination tests were also performed on many sera with the stock antigen, prepared by the United States Department of Agriculture, as a check on the sensitivity of our own antigen. Finally, rapid slide agglutination tests were performed, using commercial *Br. abortus* febrile antigen, prepared by the Lederle Laboratories. The dilutions ranged from 1:20 to 1:160. These were read after standing ten minutes.

RESULTS

The results are presented in the accompanying tables. Individual skin and agglutination tests are recorded in Tables I and II, while Table III is a comparison of the results obtained with the two antigens. For convenience, Tables I and II are arranged in the following order: positive skin and agglutination tests, negative skin and positive agglutination tests, positive skin and negative agglutination tests, and negative skin and negative agglutination tests.

TABLE I
RESULTS IN PERSONS SKIN TESTED WITH BRUCELLERGEN

NUMBER	SKIN TEST	AGGLUTINATION TEST SECOND WEEK AFTER SKIN TEST		AGGLUTINATION TEST FOURTH WEEK AFTER SKIN TEST	
		SLIDE	TUBE	SLIDE	TUBE
1	+	0	1:10	0	1:10
2	+	1:40	1:40	1:20	1:20

13	+	0	0	0	0
14-25	-	0	0	0	0

Eleven of the group tested with brucellergen and 7 of the vaccine group developed positive intradermal reactions. Five of the former and three of the latter developed red streaks up the arm, with swollen, painful axillary nodes. General malaise, chills, and fever occurred in two instances. In spite of these strongly positive reactions no local tissue necrosis resulted. A mild secondary infection of the skin developed in one instance. The local induration and edema

tended to be firmer and deeper following vaccine than following brucellergen, and persisted almost a month in two cases.

In each group about one-half of the persons failed to develop agglutinins. In the others the titers were uniformly low. The maximum of 1:80 was attained in only four instances. All but three with positive skin tests developed agglutinins. Of those with negative intradermal reactions, four in the brucellergen and six in the vaccine group also developed agglutinins, and the titers were equally as high as in those in whom the skin test was positive. From Table III it is apparent that there was very little, if any, difference in the response to the two skin test antigens.

TABLE III
RESULTS GROUPED ACCORDING TO THE MAXIMUM TITERS ATTAINED

SKIN TEST ANTIGEN	NUMBER OF POSITIVE SKIN TESTS	0	1:10	1:20	1:40	1:80
Brucellergen	11	11	2	5	4	3
Brucella Vaccine	7	13	3	5	3	1

DISCUSSION

The high incidence (36 per cent) of positive intradermal reactions found in this study cannot, of course, be considered representative of the population as a whole, since only 50 persons were skin tested. However, it does serve to emphasize the point that healthy, active adults, who have never had symptoms of brucellosis, may have strongly positive skin tests. It does not seem presumptuous to state that several of these persons, if possessed with mild neurasthenic symptoms, would be regarded in certain circles as cases of chronic brucellosis. With the present enthusiasm for this disease, there is a tendency to forget that more than a positive skin test is necessary to make a diagnosis of active *Brucella* infection.

The agglutinin titers were consistently low. In one-half of the group none developed, and only a few were as high as 1:80. There was no apparent correlation between positive skin tests and agglutinin production, for a significant number developed agglutinins following negative skin tests, and the titers were as high as in those in whom the intradermal reaction was positive. From a comparative standpoint it can be said that the response to the two skin test antigens is almost identical.

From these results it would appear that titers above 1:80 can be regarded as due to contact with *Brucella* other than that of the skin test. Since only titers above 1:80 are usually regarded as indicative of active infection, the effect of the skin test can be disregarded entirely. Using a carefully prepared antigen and a standardized technique for reading the agglutination tests, we feel considerable confidence in this point of view.

As has been reported by others,⁶ the titers obtained with the rapid slide test and with the macroscopic tube test were in close agreement. For many purposes the slide test, which is very simple to perform, would seem a satisfactory

diagnostic method. The possibility that our own tube antigen is relatively insensitive is precluded by the close agreement in agglutination titers obtained with the rapid slide method and with the stock antigen of the United States Department of Agriculture.

Several patients with low-grade fevers have reacted similarly to the "normal" persons described above. However, in two patients with acute febrile illnesses, both of whom had temperatures of above 40° C., agglutinin titers of 1:320 developed two weeks following skin tests. The intradermal reaction was positive in one and negative in the other. This excess rise in agglutinin titers, associated with fever, is well known and must be borne in mind in the interpretation of all agglutination tests.

The patients that present the greatest diagnostic problems are those with little or no fever, but with symptoms suggestive of chronic brucellosis. We can say with considerable assurance that in them the skin test will not influence the interpretation of the agglutination test. Where the blood culture is negative, and a careful correlation of the other laboratory procedures with the clinical picture is essential, it is of considerable practical aid to have such a criterion in dealing with patients who have been previously skin tested.

SUMMARY AND CONCLUSIONS

1. The agglutinin response of apparently healthy adults to the two commonly used types of *Brucella* skin-testing antigens has been studied, since this is a possible source of confusion in the clinical interpretation of the agglutination test. Commercial products, Lederle's *Brucella* vaccine and Huddleson's brucellergen, were used for the skin tests, to make the results of more practical value.

2. Positive intradermal reactions were present in 36 per cent of the 50 persons studied.

3. Approximately one-half of those skin tested failed to develop agglutinins, and in the others the titers were low, the maximum being 1:80.

4. There was little, if any, difference in response to the two antigens, and there was no correlation between positive skin tests and agglutinin production.

5. The practical significance of these results is discussed, and it is suggested that, except when high fevers are present, the agglutinin response to *Brucella* skin tests need not cause confusion in the interpretation of the agglutination tests.

OBSERVATIONS ON THE ELECTROCARDIOGRAM IN EPILEPSY AND COMPARISON WITH ELECTROCARDIOGRAM IN SEIZURES FOLLOWING CONVULSANT DRUG THERAPY*

THOMAS ZISKIN, M.D., AND ALEXANDER G. DUMAS, M.D.
MINNEAPOLIS, MINN.

THE introduction of convulsive drugs into the treatment of mental disease has stimulated interest in the study of the physiologic changes associated with the seizures resulting from the use of these drugs, and also in the study of changes associated with convulsive seizures in general.

Bellet, Freed, and Dwyer¹ noted the electrocardiographic alterations during 58 shock treatments on 40 different patients during the hypoglycemic shock treatment of schizophrenia. In two-thirds of the shock treatments noteworthy electrocardiographic changes were obtained. These consisted of depression of the S-T segments, diminution of the height of the T wave, prolongation of the Q-T interval, auricular fibrillation, extrasystoles, shifting pacemaker, sinus arrhythmia, and sinoauricular heart block.

Orenstein² observed 15 schizophrenic patients treated with metrazol convulsions. Electrocardiographic changes varying according to the severity of the convulsions were noted following the convulsions. After a mild seizure there were a rapid rate, T-wave elevation, depression of S-T segment, and arrhythmia. After a severe convulsion he found in addition, sinus arrest, shifting of the pacemaker, auricular and ventricular premature contractions, coupling of beats, nodal escape, and rarely a marked bradycardia.

Messinger and Moros³ studied the electrocardiographic findings in patients before and immediately after metrazol convulsions. In no instance did they find any significant deflection of the S-T interval. In 3 of 10 cases they found a slightly diminished amplitude of the T waves, and in 7 others a slightly increased amplitude of the T waves.

Levine, Piltz, and Reznikoff⁴ also studied the effects on the electrocardiogram of metrazol shock therapy and found no significant changes. In one patient they found inversion of the T wave in Leads II and III after the seizures. Since they believed this to be due to anoxemia, they gave the patient 100 per cent oxygen by inhalation for fifteen minutes. Thirty minutes later an electrocardiogram was taken; it recorded that most of the T waves in Leads II and III were upright.

*From the Veterans Administration Facility, Minneapolis.

Received for publication, July 21, 1941.

Lennox and Cobb⁵ obtained electrocardiographic records of patients during petit mal and myoclonic seizures, and in these instances neither the rhythm nor the amplitude of the waves was appreciably affected.

Erickson,⁶ in a clinical study of changes in the circulatory system during or immediately preceding an attack of epilepsy, observed the electrocardiographic picture also. In most cases only one lead of the electrocardiogram was taken in order to avoid picking up too many electrical effects from the muscles during the convulsion. He used a direct chest lead, one electrode being placed over the manubrium sterni just below the sternal notch and the other just below the point at which the apex beat of the heart was palpated. He obtained satisfactory electrocardiographic tracings during 54 epileptic seizures of various types in 17 different patients. In none of the 54 attacks observed was there any dropping out of the QRS interval of the electrocardiogram. The T wave was unchanged in all but 4 patients. In 4 the T wave became biphasic or flattened at the end of the attacks.

Winternitz⁷ observed a patient in status epilepticus, and for several days after the occurrence he noted changes in the electrocardiogram, a long R-T segment.

NEW DATA

The present study concerns mainly the electrocardiographic findings in a group of 20 epileptics observed at the Minnesota State Colony for Epileptics at Cambridge, Minn. Electrocardiograms were taken before seizures, during seizures, and at various intervals after seizures. Three standard leads and Lead IVF, as adopted by the American Heart Association, were taken on each patient. Thirty-eight electrocardiograms were taken in this series. The age of the patients varied from 13 years to 45 years. There was neither history nor clinical signs of heart disease in any of them.

Diminished amplitude of the T waves and increased depth of the T wave, where the T wave was normally inverted, were noted in practically every instance after the seizures. Other significant changes were observed in 5 of 12 patients in whom comparative electrocardiograms were made during seizures and in the period of remission. These changes consisted of variations of the electrical axis, changes in rhythm, various degrees of auriculoventricular block, dislocation of the pacemaker, and inversion of the T waves. Some of these changes were noted immediately after the seizures, and others for periods as long as four and one-half hours after a seizure. In one patient a tracing taken immediately after the termination of a convulsive seizure showed a negative T wave, whereas a positive T wave was noted immediately preceding the seizure. Another patient showed a change of electrical axis to right axis deviation, ventricular extrasystoles, and negative T waves in Leads I and IV after the seizure, and a normal electrocardiogram during the period of remission. A detailed description of the significant electrocardiographic findings is given in Table I.

A comparison of the electrocardiographic findings we observed following epileptic seizures, with those noted by other workers following convulsive seizures

induced by insulin shock and metrazol therapy of schizophrenia, reveals the fact that the changes are similar in character in each instance. This would lead us to believe that the physiologic changes preceding the convulsion and during the convulsive seizures are the same whether the convulsions are the result of insulin shock, metrazol, or epilepsy. Also in epileptic seizures there is an intrinsic factor which acts on the cerebral circulation and the cardiovascular circulation in general, in a manner similar to the extrinsic factors, insulin, and metrazol in their respective convulsive seizures.

TABLE I

NAME	AGE	SEX	TIME OF SEIZURE	DATE	TIME OF EKG	INTER-VAL	EKG FINDINGS

			None	5/25/39			Negative

POSSIBLE CAUSES OF EKG CHANGES

Clinical observation and experimental research by many observers have shown that electrocardiographic changes similar to those observed following convulsive seizures are an indication of myocardial ischemia or anoxemia of the heart muscle.

Kountz and Gruber⁸ produced anoxemia in animals, and when the oxygen saturation fell below 50 per cent, electrocardiographic changes similar to those observed clinically in coronary occlusion were found. Release of the animals from the anoxic state caused the electrocardiogram to return to normal. They

also produced pictures similar to anoxemia by the injection of pitressin, the primary action of which is vasoconstriction. The electrocardiographic changes in these instances could be made to disappear by the use of vasodilators, such as sodium nitrite. Milles and Smith² produced similar changes by the intravenous injection of epinephrine. It may be assumed, therefore, that the electrocardiographic changes seen following convulsive seizures from insulin shock, metrazol, and epilepsy are due to myocardial ischemia or anoxemia of the heart muscle.

Bellet, Freed, and Dwyer³ believe that in insulin shock therapy the lack of available carbohydrates and the increased work of the heart during hypoglycemic shock of long duration suggest that anoxemia may be a factor in producing the cardiac effects. They base their conclusions on previous investigations which have shown that lowering of the blood sugar reduces the oxygen consumption of the brain; also that the profound changes which occur in cerebral metabolism during hypoglycemia and the resultant coma may indirectly affect the heart.

Messinger and Moros³ formulate an hypothesis to account for the diverse cardiovascular changes they noted in their study of the effects of insulin and metrazol in these cases. They are of the opinion that persons differ in their response to various types of stimuli, and particularly in the degree of their response to drugs of the sympathetic-adrenal type. It is now recognized that the prolonged administration of insulin (as in shock treatment) may induce an altered state of reactivity of the sympathetic system primarily in the direction of an increased sensitivity of response to adrenalin and sympathetic-mimetic

drugs. Also metrazol may produce transitory effects which are typical of a mild hyperadrenalemia. That adrenalin may cause heart changes has been shown by the work of Milles and Smith⁹ and others. These observers showed that electrocardiographic changes similar to those occurring in convulsive seizures could be produced by the intravenous injection of adrenalin.

Levine, Piltz, and Reznikoff,⁴ contending that anoxemia might account for the electrocardiographic changes seen after metrazol therapy, gave their patient, who showed an inverted T_2 and T_3 after metrazol convulsions, 100 per cent

oxygen by inhalation for fifteen minutes. Thirty minutes later the electrocardiogram revealed that most of the T waves in Leads II and III were upright.

In the study of chemical and physiologic conditions, which may be contributing factors to epileptic seizures, four major conditions are usually given; namely, acid-base balance, fluid balance, oxygenation, and circulation. That these factors may be interrelated and responsible for cardiovascular changes in epilepsy, as depicted by the electrocardiogram, may be assumed from our observations on this group of patients which we studied.

Reduction of alkalinity and induction of acidosis, either by fasting, physical exercise, or the ketogenic diet, is known to precipitate seizures.

McBroom,¹⁰ in collaboration with Hirschfelder and Haury,¹¹ made a study of blood potassium in epilepsy. They found a gradual increase in the potassium up to the time of seizure, followed by a drop immediately after the seizure.

Moglia¹² studied the effects of adrenalin on the potassium in the plasma. He injected adrenalin intravenously into chloralosed dogs at a constant rate for fifteen minutes. A dose of 5 gamma per kilogram per minute produced an initial increase of plasma potassium, lasting from five to ten minutes, followed by a prolonged decrease. A dose of 0.5 and 0.25 gamma produced a prolonged decrease without the initial increase. The larger doses were similar to the amounts secreted by the adrenals in states of emergency; the smaller ones were similar to the physiologic amounts of adrenalin and sympathin.

Thomson¹³ studied the effect of potassium on the heart by giving potassium chloride and citrate in doses varying from 3 to 30 Gm. daily to 24 patients with various diseases, and observed the effects on the electrocardiogram. In 14 patients there was an increased height in the T waves in one or more leads after giving the potassium. The average increase in the level of the serum potassium was 8.3 mg. per 100 c.c., as compared with 2.6 mg. per 100 c.c. in the patients who showed no such change. In one patient the T wave became more diphasic. In two patients definite degrees of heart block were produced. In one there was prolongation of the P-R interval. Other changes also were noted. Thomson advances the hypothesis that these changes may be mediated through the action of the potassium ion on the myocardium because of the similarity of these changes to those produced by vagal stimulation, by acetylcholine, and by pitresin.

Changes in the cerebral circulation and also in the general circulation, probably resulting from this vasoconstrictor effect, have been shown by many observers. Penfield¹⁴ reported the cessation of cerebral pulsations during convulsions occurring when the brain was exposed by craniotomy.

Olkon¹⁵ studied the microscopic vascular changes in the brain, internal viscera, and skin of living animals in relation to convulsions. Following convulsions induced by the injection of excitant drugs, capillary changes were invariably found in the pia-arachnoid, skin, and internal organs. These consisted of twisting, irregularity, and deformity, and a sluggishness in the circulating cells within their lumen.

Denyssen and Watterson¹⁶ also are of the opinion that a vasoconstrictor effect is responsible for the convulsions. They gave vasodepressor drugs, such as amyl nitrite, sodium nitrite, and histamin, prior to the administration of convulsive doses of metrazol. No fits occurred.

CONCLUSIONS

The electrocardiographic findings which we have observed during and after epileptic seizures tend to show that cardiovascular changes occur following epileptic seizures, and that these changes are part of circulatory changes throughout the body. As a result of this, and from the experimental and clinical observations of other workers, the supposition is made that the epileptic seizures are due to a cerebral anoxemia resulting from an ischemia of the brain following vasoconstriction. This is probably the result of an electrochemical change and adrenalin-like action on the cerebral vessels.

After comparing our findings with those of other workers who studied the electrocardiographic changes following seizures after convulsant drug therapy, we conclude that the physiologic changes during and after convulsive seizures from excitant drugs are the same as those due to epilepsy; also that the extrinsic factors, such as insulin shock and metrazol, probably produce a similar adrenalin-like reaction as the intrinsic factor which brings on the cerebral ischemia and anoxemia in epileptic seizures.

We wish to thank Dr. D. E. McBroom, Superintendent, Minnesota Colony for Epileptics, and his associates for the opportunity to observe the patients at the institution and for their valuable cooperation and assistance in making this study possible.

PERIPHERAL NERVES IN CHRONIC ATROPHIC ARTHRITIS*

HUGO A. FREUND, A.B., M.D., GABRIEL STEINER, M.D.,
BRUNO LEICHTENTRITT, M.D., AND ALVIN E. PRICE, A.B., M.D.
DETROIT, MICH.

THE obvious fact that chronic atrophic arthritis is not solely a joint disease, but one in which many systems of the body are involved, has caused us to undertake a more detailed investigation of the entire organism. We have begun with a re-examination of all the pathologic changes. Recently, the muscles and valves of the heart have been examined and noteworthy findings have been reported. Because of the nature of the pains, trophic conditions, vasomotor alterations, and heightened reflexes, a more detailed study of the peripheral nerves and sympathetic chains were undertaken. In earlier studies only the brains and spinal cords were examined; no specific or characteristic lesions were found.

Fig. 1.—A longitudinally cut section through a femoral nerve of a patient with severe chronic atrophic arthritis, $\times 9$. The arrows indicate the perineural or interfascicular location of the nodules.

In our present study, covering the past two and one-half years, hitherto undescribed pathologic changes involving the peripheral nervous system have been found. These are recorded here briefly; a more detailed report will follow.

The brains of 11 patients with definite chronic atrophic (rheumatoid) arthritis and the peripheral nerves in five of the patients were examined. There were no specific changes in the central nervous system; however, in two of five cases of chronic atrophic arthritis characteristic and severe pathologic lesions

Fig. 2.—A and B represent the same nodule in two different magnifications, $\times 150$ and $\times 550$, respectively. Three distinct zones, the inner necrotic zone, the intermediate zone of proliferating mesenchymal cells, and the peripheral lymphocytic zone, are clearly shown. The intermediate zone in this nodule is somewhat smaller than usual.

were found in peripheral nerve trunks (sciatic, femoral, brachial plexus). In one case the lesion in the peripheral nerves was somewhat milder, and in the last two cases the changes were only slight. The characteristic findings were represented by sharply circumscribed nodules of round or oval shape. The nodules are not seen grossly in unstained specimens. However, they can be seen with the naked eye in stained slides. Fig. 1 represents a longitudinally cut part of a peripheral nerve magnified nine times to show the distribution of the nodules in a peripheral nerve. The nodules are located in the perineurium and are less common in the epineurium; they are never found in the endoneurium of the peripheral nerves. The size of a single nodule varies. Serial sections through a single nodule show an involvement 0.14 to 0.2 mm. in diameter. The nodules are often found in groups of three or four in the same longitudinally cut section. Histologically, each nodule consists of two or three zones: a central zone of necrosis which may or may not be present, an intermediate zone of proliferating mesenchymal cells, and a peripheral ringlike zone of inflammation with lymphocytes and plasma cells. The cells in the intermediate zone are of the so-called epithelioid type. They are polyhedral and have large elongated irregular nuclei, poor in chromatin. Clear cell outlines are usually not demonstrable. Fig. 2 *A* and *B* are photomicrographs, $\times 175$ and $\times 550$, respectively. The three zones of the nodule are clearly seen. Conglomeration into larger areas is never found. This finding has to be classified as "rheumathritic nodulous perineuritis." The specificity of this change has been confirmed by examination of peripheral nerves from 86 control cases which were examined without knowledge of the clinical history or the findings at autopsy. Six cases showed pathologic changes in the peripheral nerves. In one case with the finding of perineuritic nodules the clinical history revealed that the patient had chronic atrophic arthritis for many years. Recently in continuing our control examination, a new case with perineuritic nodules in peripheral nerves was found. This was an 80-year-old female with old rheumatic heart disease (clinically diagnosed as rheumatoid arthritis). The pathologic changes in the five nonarthritic control cases (one of Buerger's disease, two of dermatomyositis, one of postencephalitic parkinsonism, one of carcinomatous infiltrations of the epineurium) differed distinctly from the perineuritic changes in chronic atrophic arthritis. We consider rheumathritic nodulous perineuritis a specific active inflammatory process concomitant and parallel with other rheumatic pathologic features in chronic atrophic arthritis, such as rheumatic heart disease, subcutaneous nodules, and synovial inflammation and proliferation.

BRUCELLOSIS: STUDIES EMPHASIZING STRAIN VARIATION IN SEROLOGIC TESTING*

FRED E. ANGLE, M.D., WILLIAM H. ALGIE, M.D., AND
DOROTHY MORGAN, A.B., KANSAS CITY, KAN.

THE purpose of this study is to explain the wide variation in agglutination titer and opsonocytophagic activity which we have observed from various laboratories. In many cases the difference in results were too great to be accounted for as technical variations. To illustrate, a state laboratory reported a negative *Brucella* agglutination titer on the same serum which we were able to demonstrate a positive titer of 1:640 with three commercial antigens. In another instance, the laboratory using a single strain of the *Brucella* reported 69 per cent of polymorphonuclear neutrophils showing marked phagocytosis. One week later we did not find marked phagocytosis in any of the cells. Therefore, we outlined a plan to investigate the agglutination titer and cytophagic activity when the tests were performed by the same technician with 20 different strains.

In this study we selected 34 patients from private practice. From all, blood serum had yielded positive agglutination tests either in our laboratory or in other laboratories. The antigens were prepared from 20 smooth strains of the *Brucella* obtained from the universities of Michigan, Minnesota, Illinois, Wisconsin, and the Public Health Laboratory in Washington. All strains were negative to thermoagglutination and dye agglutination before and after the experiment. All strains were injected into guinea pigs. Fourteen strains produced death, 8 of which showed gross *Brucella* lesions and 6 of which produced microscopic changes only. The other 6 showed evidence of disease by loss of weight, roughening of hair, comparatively low white blood cell counts and maintenance of high agglutinin titers. All strains were determined to react with known positive and negative bloods.

Opsonocytophagic Tests.—Suspensions were prepared from forty-eight-hour cultures of *Brucella* organisms in saline with pH 7.02 to 7.1. Turbidity was adjusted to McFarland nephelometer No. 25. Five cubic centimeters of blood were collected in sterile tubes that had been filled with the proper amount of citrate to give a final concentration of 0.8 per cent and marked to the level to which the blood should be added. All tests were completed within four hours after the blood was collected. Performance of the test was that described by Huddleson,¹ except that smears were made by the cover slip method since this method, in our opinion, is superior to the slide method in that less mechanical injury to the cells is induced when blood spreads by capillarity rather than by

*From the Hixon Laboratory for Medical Research, University of Kansas, by the Boylan Foundation.

Received for publication, September 8, 1941.

actual smearing. Smears were stained with Hasting's stain. One hundred cells were counted; the findings are, therefore, expressed as percentage of cells which showed marked, moderate, weak, and negative cytophagic activity.

Agglutination Test.—Strain antigens were prepared by washing a seventy-two-hour culture of *Brucella* from liver infusion slants with saline containing 0.5 per cent phenol. The suspensions were strained, centrifuged, and resuspended. The stock antigens were stored as concentrated suspensions. The dilution was adjusted to McFarland nephelometer No. 1.5 for each antigen, recorded, and made up as needed. Twenty cubic centimeters of patient's blood were collected in a chemically clean tube, rimmed, and centrifuged. The serum was removed and stored at 7° C. until the agglutination series could be run within the next two days.

Tube	1	2	3	4	5	6	etc.
Antigen	1.8 cc.	1 cc.	1 cc.	1 cc.	1 cc.	1 cc.	etc.
Serum	.2 cc.	1 cc.	1 cc.	1 cc.	1 cc.	1 cc.	etc.
Dilution	1:10	1:20	1:40	1:80	1:160	1:320	etc.

Fig. 1.

Chart 1.—Range of variation of opsonocytophagic index numbers, as determined by Foshay-LeBlanc method, in 34 patients with brucellosis when tested with 20 strains of *Brucella*.

To prevent numerous pipettings, the agglutination test was performed as shown in Fig. 1. The method is more accurate by reason of fewer operations in pipetting small amounts, and is a timesaver as well. The tests were incubated at 37° C. in a hot-air incubator for twelve hours and allowed to stand at refrigerator temperatures for twenty-four hours, after which readings were made. The titer was read from the last serum dilution showing complete agglutination, that is, the supernatant fluid completely clear with the bacteria completely sedimented in clumps.

EXPERIMENTAL RESULTS

Charts 1 and 2 record our results. Chart 1 represents the correlation of results of the opsonocytophagic tests calculated by the Foshay-LeBlanc method,² the final results being obtained by subtracting the minimum index from the maximum index to determine the variation when each serum was set up against 20 strains of *Brucella* simultaneously.

Chart 2 shows the correlation of agglutination titers demonstrating the variation in agglutinins by subtracting the minimum titer from the maximum titer in terms of number of tubes apart in the test set-up.

Chart 2.—Variation in agglutinin titers of patients with brucellosis tested with antigens from 20 strains of Brucella.

Chart 3.—Agglutination series on a single patient (EM-26), showing marked variation of agglutination titers when tested with 20 strains of Brucella.

It is observed from the studies that there is wide fluctuation in the majority of instances. When there was little variation, as in the patients 17, 31, 32 in Chart 1, their actual opsonocytophagic activity was almost negative; similarly, when the records of patients 3, 9, 17, 18, 25, 31, 32 in Chart 2 are examined, their agglutination titers were negative throughout. When there was only a difference of one tube, probably not outside the range of individual variation, the titers were either very low (1:10) or very high (1:2,560 to 1:5,120 and 1:1,280 to 1:2,560). In the analysis of Chart 2 a variation is noted in the study of the

agglutination reaction, the widest being from no agglutination to complete agglutination in a dilution of 640 in the case of EM-26. This is shown graphically in Chart 3. The range of agglutination is from 0 to 1:640. Ten strains were agglutinated in a dilution of 1:160 or above. Eight strains were not agglutinated.

DISCUSSION

It will be noted from the foregoing results that there is wide variation between the agglutination and opsonocytophagic activity of the same blood taken at the same time and tested under the same conditions with the 20 strains employed.

A like observation was made in 1937 by Campbell and Greenfield,³ employing four strains of *Brucella* in agglutination tests on patients with pyrexia in whom typhoid, paratyphoid, influenza, pyogenic and tubercular infections had been excluded. They found in one case agglutination tests varied from no complete agglutination with a *melitensis* strain to 1:1,600 complete with one *abortus* strain and 1:100 with another. The organism isolated from the patient's blood was *Brucella abortus*. Previously, in 1932, Plastringe and McAlpine,⁴ who employed agglutination absorption technique on 116 strains of *abortus*, indicated close agreement of antigenicity of strains, 85 per cent of which completely absorbed agglutinins from antisera of bovine and porcine types and from one *melitensis* antiserum. In their own words, "No serologic differences were observed between bovine and porcine types of *Brucella abortus*, regardless of origin." Feusier and Meyer,⁵ as early as 1920, concluded, "Strains within the same group do not necessarily act in a uniform manner when absorbed from the same antiserum. This constitutes the basis for individual differentiation. In several *melitensis* strains, for example, the range of variability was so great that certain strains appeared to have little in common." Giordano,⁶ Keefer,⁷ Carpenter, Boak, and Chapman,⁸ and Foshay⁹ mention specifically that in routine testing variations in agglutination titers of patients were marked when separate strains were used to check. Agglutination absorption test and standard agglutination test apparently are not comparable, since from our results with *abortus*, *suis*, and *melitensis* strains we concluded that infecting *Brucella* strains must vary tremendously in antigenicity.

Huddleson¹ states that in routine testing an antigen containing one smooth strain of *abortus* is sufficient. To determine the smoothness of the strain, the method of choice is the phagocytosis of the strain with known negative and positive bloods as an index. Our strains were neither thermoagglutinable nor dye agglutinable and yet variation in phagocytic system was marked. We feel that variation in the phagocytic system was a strain difference, not necessarily associated with its smoothness or roughness.

CONCLUSIONS

1. A series of 34 patients diagnosed as having chronic undulant fever has been examined, employing agglutination and opsonocytophagic tests.
2. Marked variation in both agglutinin titers and opsonocytophagic indices has been found. This indicates the necessity for standardization of *Brucella* polyvalent antigens for agglutination tests.

3. Testing with five to ten smooth strains for cytophagic activity is necessary to obtain reliable results.

4. From our studies it would appear that the diagnosis of acute or chronic brucellosis is dependent upon clinical opinion with some positive immunologic test.

RECOVERY OF RABIES VIRUS FROM THE BRAIN OF AN UNDIAGNOSED CASE*

MORRIS SCHAEFFER, PH.D., AND ANN G. LEIDER, M.Sc.
NEW YORK, N. Y.

THE symptoms of rabies are usually so typical that when accompanied by a history of a dog bite, the case will appear to follow the classical description closely, and the diagnosis is rarely missed. When, however, a history of a bite is not previously established, and a case presents itself during a late stage of the disease, a correct diagnosis may then become exceedingly difficult. It is possible, therefore, that an occasional death which follows a symptomatology obscured by the lack of an incriminating history of contact with a rabid animal, may actually be the result of infection with rabies virus.

The belief has been expressed that this may occur much more frequently than may be supposed.¹⁻³ An excellent illustration of such an occurrence is described in the following report, which deals with the isolation and identification of rabies virus from a case that came to the Medical Examiner for autopsy because the symptomatology and cause of death were obscure.

In the afternoon of Feb. 15, 1940, S. G., white, 49 years old, residing on the lower East Side of New York, walked into the Columbus Hospital and asked to be admitted for observation. He complained of difficulty in swallowing, which he stated was "because of poison in

*From the Bureau of Laboratories, Department of Health, New York City.
Received for publication, September 26, 1941.

throat placed there by someone." After admission the patient became unmanageable, wildly delirious, and induced emesis which resulted in the vomiting of black fluid mixed with blood. The diagnosis was "psychoneurosis" and "acute state of anxiety." He was about to be transferred to the psychopathic ward at Bellevue Hospital, when he died at 10:00 A.M. on February 16. The body was submitted to the Medical Examiner, and a post-mortem examination was made by Dr. Eugene Clark on February 17.

There was no evidence of injury, except for abrasions on the dorsum of the hands, on the middle finger of the right hand, and a healing wound, irregularly shaped and $1\frac{1}{2}$ inches long, on the right index finger. The meninges were normal. There was a slight subarachnoid hemorrhage at the posterior pole of the cerebrum. No macroscopic lesions were found in the pons, medulla, or elsewhere in the brain. Aside from a general visceral congestion, no special pathology could be observed. Opinion as to the cause of death was, therefore, reserved, pending chemical and microscopic examination.

On the day of autopsy portions of the brain in glycerin and in 10 per cent formalin were submitted to us for investigation of a possible central nervous system virus infection.

For aid in the pathologic examination of the fixed tissues, we secured the assistance of Dr. Vera B. Dolgopel, of the Willard Parker Hospital. Her opinion was: "Sections from medulla show a number of veins with several rows of lymphocytes within the walls. The perivascular space is free from exudate, but is markedly dilated. Some of the veins with cellular exudate are situated near the ventricular surface, while others are present on the lateral aspect of the medulla and near the olives. No glial nodules are observed. The ganglion cells show no remarkable degeneration. The section from the brain shows marked congestion of veins but no vascular infiltration. Microscopic diagnosis: bulbar myelitis."

Because it was inconvenient to do animal inoculations at the time the glycerinated brain material was received, it was washed several times in saline solution to remove the glycerin, then frozen and stored in a dry-ice cabinet at -76° C. for forty-eight hours. The portions of brain were then thawed rapidly in the incubator at 37° C., titrated in a mortar to a fine pastelike consistency, and suspended in broth to a concentration of about 20 per cent. The suspension was centrifuged at about 2,000 r.p.m. for ten minutes, and the supernatant fluid was inoculated intracerebrally into animals. Each of six mice received 0.03 c.c., each of two guinea pigs 0.25 c.c., and each of two rabbits 0.5 c.c. Cultures in broth were made simultaneously to determine the bacterial content of the suspension. The results of these inoculations and all successive passages made thereafter are indicated in Fig. 1.

All material for subsequent inoculations consisted of a 10 per cent suspension of a pool of several mouse brains or, as in the one case indicated, of a single guinea pig brain. The volumes inoculated throughout were the same as those stated above.

The two inoculated guinea pigs were found dead the following morning. Smears and cultures from the brains of these animals showed heavy bacterial growth, with predominance of a gram-positive bacillus and fewer gram-positive cocci. These were also present in cultures of the original brain material.

Fortunately, the mice resisted these contaminants, and on the ninth day after inoculation two mice became inactive and showed a weakness of the hind legs. Several hours later they became moribund and were thereupon promptly killed. Their brains were removed with aseptic precautions, a portion of each was inoculated into culture media and the remainder was frozen at -76° C. As

Fig. 1.—Animal passages and tests with virus isolated from a case of human rabies.

no growth was observed in the cultures, a 10 per cent suspension of these brains was prepared and inoculated into a group of ten mice. On the thirteenth day a third mouse of the originally injected group of six showed symptoms similar to those observed in the first two, and a suspension of its brain proving bacteriologically sterile was inoculated into a group of six mice.

The two rabbits were found dead in their cages on the eleventh and fourteenth day, respectively. Bacteriologic examination of the brains of both these animals yielded negative results, and they were stored at -76°C ., pending the outcome of the mouse passages.

Beginning with the second passage, the mice began to show more definite symptoms, usually starting with paresis, rapidly developing paralysis, and terminating in prostration and death. Since serial passage of the brains of animals thus affected resulted in a clear-cut, reproducible clinical syndrome, we inferred that an infectious agent, probably a neurotropic virus, was involved.

Judging from the case history, incubation period, and clinical symptoms in mice, the viruses first to be considered logically appeared to be those of rabies, herpes, or encephalitis.

Accordingly, the brain of one mouse in the second passage was examined for Negri bodies by direct smear, and two brains were sectioned for histopathologic study. No Negri bodies were found on direct smear. The histologic sections showed mononuclear cuffing around small veins in the subcortical structures and the cortex. There was no diffuse meningitis, although occasionally groups of lymphocytes were present in limited areas of the meninges. A large number of intracellular and extracellular Negri bodies were seen in one of the sections of the hippocampus.

In subsequent passages, namely, the third, fourth, and fifth, Negri bodies were easily demonstrated by direct smear. These were seen also in the brains of a rabbit and a guinea pig* inoculated with third passage mouse brain and in the brain of another guinea pig receiving a further guinea pig brain passage. None of the brains obtained in the remainder of passages was examined for Negri bodies.

The finding of Negri bodies made it fairly obvious that rabies virus had been isolated. It was nevertheless deemed necessary to conduct neutralization tests in order to demonstrate the serologic specificity of this virus. The virus was, therefore, tested against an antirabic serum prepared by the injection of rabbits with a Department of Health strain of fixed rabies virus. The serum definitely neutralized the isolated virus in this test, but because of the low infectivity of the virus in its third passage, further passages were resorted to so that the potency of the virus might increase sufficiently and a repetition of the neutralization test could be made under more suitable conditions.

The chart of the virus passages shows quite clearly that a gradual rise in the infectivity titer took place, starting at 10^{-2} in the third passage to 10^{-5} in the eleventh passage. It will also be noted that correspondingly there was a decrease in the incubation period from nine days or more at the beginning to a uniform six-day incubation period in the last passage made.

*This animal exhibited symptoms characteristic of furious rabies. It became excitable, ran wildly about in its cage, frothed at the mouth, and repeatedly attacked and bit its cage mate. Finally, after repeated convulsive seizures, it became prostrate and died.

A virus preparation obtained from a pool of eleventh passage mouse brains was again tested against the antirabic serum. The results of the second test fully confirmed the findings of those in the first in a clear-cut and satisfactory manner.

As soon as sufficient evidence was obtained to be certain that we had uncovered a case of undiagnosed rabies, further investigation was made by the Bureau of Preventable Diseases, and the following facts were elicited:

From an interview with the son of S. G. it was learned that S. G., while at play with his dog on December 25, was bitten on the index finger of the right hand. He applied tincture of iodine and a bandage to the bleeding wound, but sought no medical advice. The son, P. G., was bitten on the left leg on the same day. He also applied tincture of iodine with no further treatment. The dog subsequently vanished and was not seen thereafter, but P. G. added the further information that the dog had been ill for two days prior to December 25 with vomiting and "fits," and had tried to bite people on the street. He also stated that the dog showed scars on its face as a result of having been bitten by another dog two weeks previously.

S. G. felt well and worked as a laborer until February 13 when he developed fever. On February 14 he could not drink or swallow, had dryness of the mouth, and feared the sight of water. A local physician examining him that day diagnosed his condition as that of grippe.

On February 15 a Hospital ambulance interne refused to remove him to the hospital, stating he was not sick enough for hospitalization. The same day S. G. went to Columbus Hospital where he was admitted. Death ensued the following day.

This information, furnished by the Bureau of Preventable Diseases, served to complete the history of a perfectly typical case of rabies which, baffling as it appeared in the beginning, might have remained undetermined and unrecorded were it not for the first clues obtained in the laboratory.

To the physician and public health officer this report may be of significance, since it indicates the need to be more watchful for cases of unsuspected rabies in areas where this disease is endemic.

SUMMARY

With the utilization of laboratory procedures, rabies virus was recovered from a person, the cause of whose death was obscure. The presence of virus in the brain of this undiagnosed case was established by animal passages, by the demonstration of Negri bodies in the brains of inoculated animals, and by immunologic methods.

Following the recovery of virus, further investigation revealed that the history of a dog bite and other data pertinent to a typical case of rabies also existed.

The need to be ever mindful that such cases may occur in communities where rabies is endemic is indicated by this report.

SULFONAMIDE THERAPY OF STREPTOCOCCUS INFECTIONS BY THE INTRAVENOUS DRIP METHOD*

WITH A NOTE ON THE TOXICITY OF NEOPRONTOSIL BY INTRAVENOUS ADMINISTRATION

JOHN A. KOLMER, M.D., AND HERMAN BROWN, B.Sc.
PHILADELPHIA, PA.

WITH THE TECHNICAL ASSISTANCE OF ANNA M. RULE AND LORAINÉ GROSKIN

THE massive arsenotherapy of early syphilis by the intravenous drip injection of solutions of neoarsphenamine or mapharsen over a period of five days, proposed by Chargin, Leifer, and Hyman,^{1, 2} has suggested that this method of administration of the soluble sulfonamide compounds may be useful in the treatment of streptococcal and other septicemias.

However, since therapeutically effective concentrations of free sulfonamide compounds in the blood may be maintained in the majority of persons by oral or parenteral administration of adequate doses at suitable intervals, the indications for their administration by the continuous intravenous drip method are not apparent, although worthy of investigation in relation to the chemotherapy of severe septicemia with special reference to the treatment of subacute bacterial endocarditis due to infection with *Streptococcus viridans*.

In this connection it may be stated that the massive arsenotherapy of acute testicular syphilis of rabbits by Kolmer and Rule,³ consisting of the intravenous drip method of administration of neoarsphenamine and mapharsen once a day for five days in succession, did not prove any more effective than the daily intravenous injection of single doses by syringe for five days in succession, or single intravenous injections of the compounds, as the *total* minimal curative doses in relation to biologic cure were practically the same by all three methods of administration, being approximately 0.020 Gm. of neoarsphenamine or 0.005 Gm. of mapharsen per kilogram of weight.

EXPERIMENTAL

Rabbits were chosen for the experimental part of this investigation because of their susceptibility to infection with virulent beta hemolytic streptococci of group A by intradermal or intravenous inoculation⁴ and the ease with which solutions of sulfanilamide and neoprontosil could be injected intravenously by the drip method at daily intervals.

*From the Research Institute of Cutaneous Medicine, Philadelphia.
Received for publication, December 11, 1941.

On the other hand, it was realized that rabbits are not as suitable as mice for chemotherapeutic investigations in experimental streptococcus infections with the sulfonamide compounds largely because sulfanilamide and other sulfonamide compounds are more rapidly acetylated into compounds of reduced or doubtful therapeutic properties.^{5, 6} Thus Kolmer, Brown, and Rule⁷ have observed that about 83 per cent of untreated rabbits inoculated intradermally and intravenously at the same time with virulent beta hemolytic streptococci developed suppurative arthritis, which progressed to a fatal outcome with positive blood and joint cultures. In a series treated with sulfanilamide by intravenous administration about 75 per cent developed suppurative arthritis with positive blood and joint cultures, all of which terminated fatally. Better results, however, were observed in the treatment of rabbits with neoprontosil inoculated only intradermally, which produces a severe local lesion without an associated septicemia.⁵

The strain of beta hemolytic streptococcus (group A) employed in this investigation was of such virulence that the intravenous injection of adult rabbits, weighing from 2,000 to 2,800 Gm., with 0.8 c.c. of 18-hour broth culture, regularly produced infections fatal within fourteen days with the development of suppurative arthritis with positive joint cultures in about 75 per cent of animals. Heart blood cultures were usually positive at daily intervals during the first four or five days following inoculation after which they were usually sterile.

TABLE I

RESULTS OF TREATMENT OF RABBITS WITH SULFANILAMIDE AND NEOPRONTOSIL ADMINISTERED BY THE INTRAVENOUS DRIP METHOD*

COMPOUNDS	NUMBER RABBITS†	DOSE PER KG. (GM.)	SURVIVALS: DAYS						NUMBER SCR- VIVALS
			2	4	6	8	10	14	
Sulfanilamide	3	0.020	3	3	3	2	2	0	0
Sulfanilamide	3	0.050	3	3	2	1	1	0	0
Sulfanilamide	3	0.100	3	3	3	2	2	0	0
Sulfanilamide	3	0.200	3	3	3	2	1	0	0
Neoprontosil	3	0.020	3	2	2	1	0	0	0
Neoprontosil	3	0.050	3	3	2	2	1	0	0
Neoprontosil	3	0.100	3	3	3	2	1	0	0
Neoprontosil	3	0.200	3	2	2	1	0	0	0
Untreated controls	8	-	8	8	8	6	4	0	0

*Administered once daily for five days in succession. Each dose of both compounds was given in 80 c.c. of 5 per cent solutions of glucose. Time required for injections varied from three hours and forty-seven minutes to four hours and two minutes. First dose of each compound was given twenty-four hours after inoculation.

†Weights 2,400 to 2,800 Gm. Inoculated intravenously with 0.8 c.c. of eighteen-hour broth culture of virulent beta hemolytic streptococcus.

In one experiment 32 rabbits were inoculated in this manner with 8 being kept as untreated controls. Of the remaining 24 animals 12 were given sulfanilamide and 12 neoprontosil intravenously by the drip method at daily intervals for five days in succession, the first dose of each compound being given twenty-four hours after inoculation, at which time positive heart blood cultures were observed. The daily doses of each compound varied from 0.020 to 0.200 Gm. per kilogram of weight, equivalent to 1.4 to 14.0 Gm. per 70 kg. of weight. Each dose was dissolved in 80 c.c. of a 5 per cent solution of glucose and given intravenously by the drip method, each treatment requiring about four hours. No difficulties were encountered in giving the injections by the gravity method

through the veins of the ears, the animals being confined in a special box in a comfortable position without the need of employing anesthesia. The results are summarized in Table I.

A second series of 32 rabbits was inoculated in the same manner, 8 being kept as untreated controls, and the remaining 24 treated with sulfanilamide and neoprontosil in the same dosage per kilogram of weight except that each compound was administered daily by intravenous injection by the syringe method at the rate of 5 c.c. per minute. Sulfanilamide was employed in an 0.8 per cent solution which required the injection of from 6 to about 48 c.c. in order to administer doses of 0.020 to 0.200 Gm. per kilogram of weight. In the case of neoprontosil a stock 5 per cent solution was employed so diluted with sterile water that each dose was administered in a volume of 15 c.c. The results are summarized in Table II.

TABLE II

RESULTS OF TREATMENT OF RABBITS WITH SULFANILAMIDE AND NEOPRONTOSIL ADMINISTERED BY THE SYRINGE METHOD*

COMPOUNDS	NUMBER RABBITS†	DOSE PER KG. (GM.)	SURVIVALS: DAYS						NUMBER SURVIVALS
			2	4	6	8	10	14	
Sulfanilamide	3	0.020	3	3	2	1	0	0	0
Sulfanilamide	3	0.050	3	3	3	2	0	0	0
Sulfanilamide	3	0.100	3	3	3	3	3	0	0
Sulfanilamide	3	0.200	3	3	3	2	1	0	0
Neoprontosil	3	0.020	3	3	3	2	0	0	0
Neoprontosil	3	0.050	3	3	3	2	0	0	0
Neoprontosil	3	0.100	3	3	3	2	1	0	0
Neoprontosil	3	0.200	3	3	3	3	2	0	0
Untreated controls	8	-	8	8	7	6	3	0	0

*Administered once daily for five days in succession. Each dose of sulfanilamide was dissolved in 6 to 48 c.c. of 5 per cent solutions of glucose. Each dose of neoprontosil was prepared of a stock 5 per cent solution diluted with sterile distilled water to a total volume of 15 c.c. First dose of each compound was given twenty-four hours after inoculation.

†Weights 2,000 to 2,400 Gm. Inoculated intravenously with 0.8 c.c. of eighteen-hour broth culture of virulent beta hemolytic streptococcus.

Determinations of free sulfanilamide in the blood were made about one hour after the completion of the second treatment by both the drip and syringe methods of administration, and about two hours after the fourth treatment by both methods. The average results are summarized in Table III. It will be noted that the concentrations after the syringe method of administration were frequently higher than after the continuous drip method of administration, probably because of greater elimination of both compounds during the four hours required for their administration by the latter method.

TOXICITY OF SULFANILAMIDE AND NEOPRONTOSIL BY INTRAVENOUS ADMINISTRATION

Toxicity of Sulfanilamide.—Sulfanilamide was well borne by both methods of administration. All of four normal rabbits given the compound in doses of 0.020, 0.050, 0.100, and 0.200 Gm. per kilogram, respectively, at daily intervals for five days in succession by the intravenous drip method in the same manner as employed in the therapeutic experiments, survived indefinitely, with no clinical evidences of toxicity. The same was true of four normal controls given the

compound in similar dosage daily for five days in succession by the syringe method of intravenous injection with no evidences of the "speed shock" observed by Hirschfeld, Hyman, and Wanger⁹ in relation to the intravenous injection of the organic arsenical and other compounds, probably because the sulfanilamide was administered in an 0.8 per cent solution.

TABLE III
CONCENTRATIONS OF FREE SULFANILAMIDE IN THE BLOOD*

COMPOUNDS	DOSE PER KG. (GM.)	METHOD OF AD- MINISTRATION	AVERAGE BLOOD CONCENTRA- TION AFTER	
			2ND DOSE	4TH DOSE
Sulfanilamide	0.020	Drip	1.1	3.1
Sulfanilamide	0.020	Syringe	2.2	1.2
Sulfanilamide	0.050	Drip	3.5	3.1
Sulfanilamide	0.050	Syringe	1.6	1.2
Sulfanilamide	0.100	Drip	4.0	3.7
Sulfanilamide	0.100	Syringe	1.5	1.6
Sulfanilamide	0.200	Drip	12.05	5.3
Sulfanilamide	0.200	Syringe	7.1	5.6
Neoprontosil	0.020	Drip	0.5	0
Neoprontosil	0.020	Syringe	1.5	0.8
Neoprontosil	0.050	Drip	0.5	0.5
Neoprontosil	0.050	Syringe	0.5	0.5
Neoprontosil	0.100	Drip	0	0.5
Neoprontosil	0.100	Syringe	0.5	0.8
Neoprontosil	0.200	Drip	0.8	Negative
Neoprontosil	0.200	Syringe	3.6	1.8

*Milligrams per 100 c.c. Determinations were made about one hour after the completion of injections by the drip method and about two hours after injections by the syringe method.

Toxicity of Neoprontosil.—Of particular interest, however, was the fact that neoprontosil was likewise well borne by intravenous injection. All of four normal rabbits given 0.020, 0.050, 0.100, and 0.200 Gm. per kilogram, respectively, at daily intervals for five days in succession by the intravenous drip method in the same manner as employed in the therapeutic tests, survived indefinitely with no clinical evidences of toxicity. The same was true of four additional animals given the compound in the same dosage daily for five days in succession by the syringe method of administration, each dose being diluted with sterile water to a total volume of 15 c.c.

However, since neoprontosil is not customarily administered to human beings by intravenous injection, we have thought it advisable to conduct additional toxicity tests by this route of parenteral administration.

For this purpose normal rabbits were given neoprontosil* intravenously in 5 per cent solution twice daily (10 A.M. and 3 P.M.) for eight days in succession in doses of 0.1, 0.2, 0.5, and 1.0 Gm. per kilogram by syringe injection, two animals being used for each dose. The total daily dosage varied, therefore, from 0.2 to 2.0 Gm. per kilogram or from 1.6 to 16.0 Gm. per kilogram over the eight days of administration and equivalent to from 14.0 to 140.0 Gm. per day for a human adult weighing 70 kg. As shown in Table IV, all animals survived indefinitely except one which died after six doses of 1.0 Gm. each or a total of 6.0 Gm. per kilogram over three days of administration.

*We are indebted to the Department of Medical Research, Winthrop Chemical Company, for kindly supplying the compound.

All surviving animals were killed one week after the last dose and microscopic examinations were made of the liver, spleen, kidneys, and sternal bone marrow of each. No pathologic tissue changes were found in the sections of the spleens or bone marrow. The livers of two animals showed slight cloudy swelling with perilobular congestion, but no fatty degeneration or necrosis of the peripheral lobular cells. The kidneys of only one animal showed some dilatation of the convoluted or collecting tubules associated with tubular necrosis of minor degree. The histopathologic changes, therefore, were much less marked than observed by Rake, VanDyke, and Corwin¹⁰ following the oral administration of sulfathiazole and sulfapyridine to mice, rats, and monkeys and also less than observed by Kolmer, Rule, and Groskin¹¹ following the oral administration of sulfathiazole and sulfathiazoline to rabbits.

TABLE IV
TOXICITY OF NEOPRONTOSIL FOR RABBITS BY INTRAVENOUS ADMINISTRATION

WEIGHT (GM.)	GM. PER KG. TWICE DAILY*	TOTAL PER KG. (GM.)	RESULTS	BLOOD CONCENTRATIONS (MG. PER 100 C.C.)†				
				1ST DOSE	3RD DOSE	5TH DOSE	9TH DOSE	15TH DOSE
2,000	0.1	1.6	Survived	0.16	0.12	0.16	0.16	0.14
1,950	0.1	1.6	Survived	Negative	Negative	0.08	0.08	0.04
1,850	0.2	3.2	Survived	0.16	0.16	0.24	0.24	0.14
1,900	0.2	3.2	Survived	Negative	0.12	0.16	0.16	0.14
1,750	0.5	8.0	Survived	0.28	0.32	0.36	0.40	0.32
1,800	0.5	8.0	Survived	0.28	0.28	0.36	0.38	0.32
1,700	1.0	6.0	Died 4th day	0.40	0.72	0.60	0	0
1,700	1.0	16.0	Survived	0.50	0.56	0.56	0.60	0.64

*At 10 A.M. and 3 P.M. for eight days in succession; 5 per cent solution of neoprontosil was employed.

†Determinations were made four hours after administration.

Total erythrocyte and leucocyte counts were made just before and four hours after the second, sixth, tenth, and sixteenth doses in each rabbit. Allowing for physiologic variations in different animals, the results have shown no effect upon the erythrocytes and leucocytes of those given 0.2 and 0.4 Gm. per kilogram per day. In those animals given 1.0 and 2.0 Gm. per kilogram per day a slight but definite decrease of the total erythrocytes per cubic millimeter of blood was noted, especially in the case of the animal that died after six doses of 1.0 Gm. each per kilogram, in which the total erythrocytes had dropped from 6,070,000 per cubic millimeter before the first dose to 4,200,000 four hours after the sixth dose. None of the animals, including that which died, showed a leucopenia; on the contrary, most of them showed a tendency to slight leucocytosis.

Blood examinations for the determination of free sulfanilamide were made four hours after the first, third, fifth, and fifteenth injections of the compounds in each rabbit. As shown in Table IV, the concentrations were quite low, evidently due in part to rapid acetylation, and usually much less than those observed one hour after administration, shown in Table III.

Agglutination tests *in vitro*, employing 1 c.c. of a 1 per cent suspension of washed human erythrocytes with amounts of 5 per cent solution of neoprontosil, varying from 0.1 to 1.0 c.c., and the addition of physiologic saline solution to a total volume of 2 c.c. showed some agglutination (+ to +++) upon microscopic examination of each mixture after incubation in a water bath for two hours at

37° C., but in spite of this evidence of the agglutination of washed erythrocytes *in vitro* no clinical evidences of intravascular agglutination or hemolysis were apparent *in vivo* in the case of rabbits, probably because of the protection afforded by the plasma proteins.

THERAPEUTIC RESULTS IN THE TREATMENT OF RABBITS

As shown in Tables I and II, both sulfanilamide and neoprontosil administered once daily for five days in succession by the intravenous drip and syringe methods of administration proved ineffective in the treatment of rabbits inoculated intravenously with virulent beta hemolytic streptococcus. All treated animals, including 16 untreated controls, died within a period of fourteen days. All developed suppurative arthritis with positive joint cultures at the time of death.

These results were not unexpected in the case of those animals given the compounds intravenously once a day by syringe injection in view of the unfavorable results previously observed following the oral administration of sulfanilamide to rabbits developing this type of streptococcus infection.⁷ The main purpose of the investigation was to determine whether or not better results could be secured by the intravenous drip method of administration, but such has not been observed in these experiments. It is likely that failure of treatment by both methods of administration was largely due to the lack of maintenance of therapeutically effective concentrations of free sulfanilamide in the blood because of rapid acetylation of sulfonamide compounds by rabbits, along with the fact that only single doses were given once daily for five days in succession. It was hoped, however, that the intravenous drip method of administration, covering a period of about four hours for the injection of each dose, might prove superior, but such has not been observed.

THERAPEUTIC RESULTS IN THE TREATMENT OF HUMAN BEINGS

Both sulfanilamide and neoprontosil, however, may be safely administered to human beings by the intravenous drip method. The same is true of the soluble sodium salt of sulfapyridine. At least one of us (J. A. K.) has administered sulfanilamide by this method to five adult patients with severe surgical hemolytic streptococcus septicemia in whom oral administration was unsatisfactory because of nausea and vomiting. There were no apparent ill effects. Each treatment consisted in the intravenous injection of a mixture of 600 c.c. of 0.8 per cent solution of sulfanilamide in sterile saline solution diluted with 600 c.c. of 5 per cent solution of glucose at the rate of about 200 c.c. per hour, covering a period of about six hours. This administered 4.8 Gm. and the injections were repeated at intervals of six hours (two per twenty-four hours, totaling 9.6 Gm.) for five days in succession. The therapeutic effects were very prompt and all recovered.

Three additional cases of postabortal hemolytic streptococcus septicemia were treated in the same manner with neoprontosil with no apparent ill effects and with complete recoveries. Each treatment consisted of the intravenous drip administration of 100 c.c. of a 5 per cent solution of neoprontosil diluted with 1,100 c.c. of 5 per cent glucose solution given at the rate of about 200 c.c. per

hour over a period of about six hours (5 Gm.). The injections were repeated at intervals of six hours (two per twenty-four hours, totaling 10 Gm.) for five days in succession. It is true that neoprontosil has not been customarily administered by intravenous injection, since it is stated that this frequently produces nausea, vomiting, and immediate bowel movements,¹² but such were not observed following the intravenous drip administration of the compound in our three cases by the method employed.

Sodium sulfapyridine has been given to two adult patients with subacute bacterial endocarditis due to infection with *Streptococcus viridans* with two to four positive blood cultures, respectively, before the institution of treatment. Each treatment consisted of the intravenous drip administration of 4 Gm. of the compound dissolved in 1,200 c.c. of sterile saline solution at the rate of about 200 c.c. per hour over a period of about six hours. The injections were repeated at intervals of six hours (two per twenty-four hours, totaling 8 Gm.) for eight days in succession. There were no ill effects, although one patient developed a very mild hematuria on the sixth day of treatment which may have been due to the compound. At the completion of the course treatment was continued for twenty-four days by oral administration of sulfapyridine combined with the intravenous injection of typhoid-paratyphoid vaccine every three days for eight doses, for the production of fever. In spite of temporarily negative blood cultures, both patients ultimately died of the disease.

SUMMARY

1. The intravenous drip administration of sulfanilamide and neoprontosil in doses of 0.020 to 0.200 Gm. per kilogram once a day for five days in succession was well borne by rabbits with no evidences of toxicity.
2. The intravenous injection of neoprontosil to rabbits by syringe in doses of 0.1 to 1.0 Gm. per kilogram twice daily for eight days in succession was well borne with no clinical evidences of toxicity.
3. The intravenous drip administration of *sulfanilamide* in dose of 4.8 Gm. (600 c.c. of 0.8 per cent solution diluted with 600 c.c. of 5 per cent glucose solution) at the rate of 200 c.c. per hour for six hours, repeated every six hours (two injections per twenty-four hours) for five days in succession, was well tolerated by human beings with hemolytic streptococcus septicemia and gave excellent therapeutic results.
4. The intravenous drip administration of neoprontosil in dose of 5 Gm. (100 c.c. of 5 per cent solution diluted with 1,100 c.c. of 5 per cent glucose solution) at the rate of 200 c.c. per hour for six hours, repeated every six hours (two injections per twenty-four hours) for five days in succession, was well tolerated by human beings with hemolytic streptococcus septicemia and gave excellent therapeutic results.
5. The intravenous administration of *sodium sulfapyridine* in dose of 4 Gm. dissolved in 1,200 c.c. of physiologic saline solution at the rate of 200 c.c. per hour for six hours (two injections per twenty-four hours) for eight days in succession was well tolerated by two cases of subacute bacterial endocarditis due to infection with *Streptococcus viridans* but with unsatisfactory therapeutic results.

6. The intravenous drip and syringe methods of administration of sulfanilamide and neoprontosil in doses of 0.020 to 0.200 Gm. per kilogram of weight once a day for five days in succession proved ineffective in the treatment of rabbits inoculated intravenously with virulent beta hemolytic streptococcus and developing suppurative arthritis with septicemia. Failure was largely ascribed to rapid acetylation of the compounds resulting in therapeutically ineffective concentrations of free sulfanilamide in the blood.

THE CHEMOTHERAPEUTIC STUDIES OF 2-SULFANILYL-3-5-DIHYDROTHIAZOLE (SULFATHIAZOLINE)^a

GEORGE W. RAIZISS, PH.D., M. SEVERAC, M.D., AND J. C. MOETSCH

SULFATHIAZOLINE,¹ chemically 2-(p-aminobenzenesulfonyl)aminothiazoline,

differs from sulfathiazole in that the double bond in the latter, between carbon atoms 4 and 5, is saturated by the addition of an hydrogen atom to each of these carbon atoms. It is a colorless, crystalline compound, sparingly soluble in water, soluble in dilute mineral acids and alkalis. It has a melting point of 207 to 209° C.

TOXICITY

Mice tolerate more than 20 Gm. per kg. of body weight of sulfathiazoline given orally (Table I).

TABLE I

TOXICITY OF SULFATHIAZOLINE AND SULFATHIAZOLE ADMINISTERED TO MICE PER OS
Drugs Given in a 10 Per Cent Gum Acacia Suspension

DRUG	DOSE PER KG. (GM.)	NO. OF ANIMALS	SURVIVALS	
			NO.	PER CENT
Sulfathiazoline	10.0	20	20	100
	15.0	25	25	100
	20.0	50	49	98
Sulfathiazole	10.0	20	16	80
	15.0	24	17	71
	20.0	20	15	75

TABLE II

TOXICITY OF SULFATHIAZOLINE AND SULFATHIAZOLE ADMINISTERED TO RABBITS PER OS
Drugs Given in Water Suspension

DRUG	DOSE PER KG. (GM.)	NO. OF ANIMALS	SURVIVALS	
			NO.	PER CENT
Sulfathiazoline	3.0	12	12	100
	4.0	22	19	86
Sulfathiazole	4.0	9	5	66

According to Table II, sulfathiazoline was tolerated by 86 per cent of rabbits which received 4.0 Gm. per kilogram. Sulfathiazole, on the other hand, was tolerated by 66 per cent of rabbits which received 4.0 Gm. per kilogram.

^aFrom the Dermatological Research Laboratories, Philadelphia, Division of Abbott Laboratories, North Chicago.

Received for publication, December 11, 1941.

Five dogs were given sulfathiazoline by mouth in a dose of 1.0 Gm. each daily for fifty days, and no diarrhea or vomiting was observed in any case. The dogs survived the fifty-day observation period and did not lose any weight (Table III).

TABLE III
TOXICITY OF SULFATHIAZOLINE IN DOGS GIVEN ORALLY

5	20 $\frac{1}{4}$	21 $\frac{1}{2}$	1.0	50

*Daily dose of 1.0 Gm. for 50 consecutive days.

†No diarrhea or vomiting was observed in any of the animals.

Kolmer¹ found that sulfathiazoline, in doses of 0.05, 0.1, and 0.2 Gm. per kilogram twice daily for ten days in succession (20 doses) by oral administration, was well tolerated by rabbits.

No macroscopic or microscopic injury of the meninges, brain, or spinal cord of any of the animals, including those receiving the largest amount of the compound, was found.

No gross or microscopic injury of the kidneys, liver, or spleen in a dose of 0.05 Gm. per kilogram twice daily for 20 doses was observed.

There was evidence of slight injury of the kidneys, liver, and spleen in the case of some animals given a dose of 0.1 Gm. per kilogram orally twice daily for 20 doses.

We made comparative studies of sulfathiazoline and sulfathiazole in reference to blood concentrations. The perusal of figures in test A shows a figure of 2.59 to 1.11 mg. per cent for sulfathiazoline. For sulfathiazole we found the blood concentration ranging from 3.2 to 1.19 mg. per cent. When a higher dose, namely, 0.5 Gm. per kilogram was given, the blood levels, two hours after injection, were considerably higher (Table IV).

Therapeutic Effect in Pneumococcus Types II and III.—In these experiments mice were infected intraperitoneally with 10 to 200 M.L.D. of types II or III pneumococcus, of which the average minimum lethal dose was 0.5 c.c. of 1:1,000,000 to 1:10,000,000 dilution of broth culture.

The drugs were given by mouth in a dose of 10 mg. three times daily at 9 A.M., 5 P.M., and 12 P.M. for five days; at 9 A.M. and 5 P.M. on the sixth day; and at 9 A.M. on the seventh day, a maximum of 18 treatments. From Table V, which presents a summary of the results obtained in several experiments, one should note that at the end of four days the percentage of survivals was higher for sulfathiazoline, 78 per cent against 73 per cent for sulfathiazole. At the end of the seventh day, however, the percentage of survivals is higher for sulfathiazole than for sulfathiazoline. The former shows 19 per cent survivals, and the latter, 14 per cent. At the end of twenty-eight days, 5 per cent of sulfathiazole-treated mice survived against 2 per cent for sulfathiazoline. In type III pneumococcal infections the percentage of survivals is highest for sulfa-

*Each mouse received only one dose of 0.002 Gm., which is approximately 0.1 Gm. per kilogram of body weight, in 10 per cent gum acacia solution.

†Each dose administered was of 0.010 Gm. per os in a 10 per cent gum acacia solution.

1st dose given at 10 A.M.

2nd dose given at 4 P.M.

3rd dose given at 10 A.M. next day.

‡Each mouse received one dose of 0.010 Gm. per os in a 10 per cent gum acacia solution.

TABLE V
THERAPEUTIC EFFECT IN TYPES II AND III PNEUMOCOCCIC INFECTION IN MICE

TYPE OF PNEUMOCOCCUS	DRUG	NO. MICE USED	PERCENTAGE OF SURVIVALS IN DAYS											
			1	2	3	4	5	6	7	14	21	28		
II	Sulfathiazoline	170	100	100	90	78	48	24	14	2	2	2		
	Sulfathiazole	105	100	95	85	73	54	33	19	6	5	5		
	Controls	101	15	0										
III	Sulfathiazoline	31	100	86	65	35	26	13	3	3	3	3		
	Sulfathiazole	33	94	82	58	27	18	15	6	3	3	3		
	Controls	25	48	48	8	0								

thiazoline at the end of five days; i.e., 26 per cent for sulfathiazoline and 18 per cent for sulfathiazole. At the end of the twenty-eighth day the percentage of survivals is equal for both drugs.

THERAPEUTIC EFFECT IN STAPHYLOCOCCUS AUREUS INFECTIONS IN MICE

Mice were infected intravenously (saphenous vein) with 0.2 c.c. of a dilute saline suspension of F.D.A. strain No. 209 *Staphylococcus aureus*. Prior to the experiment the strain was passed through mice four times, the abscessed kidneys of the infected animals being removed at the time of death and recultured on plain agar. This increased the virulence of the strain so that 100 per cent of a series of at least 25 mice were killed within one to five days as a result of infection.

The mice were treated one and one-half, seven, twenty-four, and thirty-two hours after infection, then once daily for fourteen days, a total of 18 treatments per os. From Table VI one can see that the percentage of survivals for sulfathiazoline at the end of four days was 100; for sulfathiazole, 84. At the end of fourteen days the percentage of survivals for sulfathiazoline is higher than that for sulfathiazole—48 per cent as compared with 28 per cent. At the end of twenty-eight days 4 per cent of sulfathiazoline-treated mice survived as compared with 8 per cent of sulfathiazole.

TABLE VI
THERAPEUTIC EFFECT IN STAPHYLOCOCCUS AUREUS INFECTIONS IN MICE

DRUG	NO. OF MICE USED	PERCENTAGE OF SURVIVALS, DAYS									
		1	2	3	4	5	6	7	14	21	28
Sulfathiazoline	25	100	100	100	100	96	88	80	48	4	4
Sulfathiazole	25	100	88	88	84	80	76	72	28	16	8
Controls	25	100	96	80	16	0					

These results represent a summary of 5 individual experiments.

CONCLUSIONS

1. When tested on mice, rabbits, and dogs, sulfathiazoline proved to be lower in toxicity than sulfathiazole.
2. The therapeutic effect of sulfathiazoline in mice with type II and III pneumococcic infection was about the same as that observed with sulfathiazole.
3. The percentage of survivals of mice infected with *Staphylococcus aureus* and treated with sulfathiazoline was found to be higher in the first fourteen days of observation, while in periods of twenty-one and twenty-eight days sulfathiazole showed more survivals.

THE SURFACE AREA OF THE HUMAN ERYTHROCYTE*

MOLLIE BERNSTEIN, M.T., AND HERMAN M. CHESLUK, M.D.
ELOISE, MICH.

IN THE study of the anemias it has been customary to consider the amount of hemoglobin, the number and size (volume and diameter) of the red blood cells, and the relationship between them. All this is based upon the assumption that the hemoglobin is evenly and diffusely distributed throughout the cell mass. However, evidence has been brought forth to show that the molecules of hemoglobin are deposited on the surface of the cell rather than within the cell body.¹⁰ If this were the case, one might indeed imagine that this would increase the efficiency of hemoglobin as an oxygen carrier, its chief function. Emmons,² after determining and comparing the red blood cell count, volume, thickness, area, and the hemoglobin content of several species of animals, showed that, although these values varied considerably in different species, the total surface area of the red cells per unit volume of blood was remarkably constant in all of them. This fact also would favor the concept that hemoglobin is limited to the surface of the cell. The surface area then would seem to be an important factor in evaluating oxygen-carrying efficiency of the red blood cells in a case of anemia.

The earliest attempt to calculate the surface area of the red cell was by Burkner,² who used the formula $A = \pi \frac{D^2}{2}$ (D representing the diameter), neglecting the thickness of the cell and assuming the cell to be flat. Values thus obtained were, on the face of it, untrue, since they were less than that of a sphere of the same volume—the form that displays the smallest area per volume.

If we assume the erythrocyte to be a short cylinder or flat disk, the area can be computed mathematically by a simple formula. Knowing the diameter, we can determine the top surface area by the formula πr^2 (r representing radius). The area around the cell is equal to the circumference ($2\pi r$) multiplied by the thickness. Since the volume equals the top area multiplied by the thickness, the latter can be computed by dividing the volume by the top area, or $T = \frac{V}{\pi r^2}$ (T representing thickness and V representing volume). The total area is twice the area of the top surface plus that around the cell. The formula then would be $A = 2\pi r^2 + 2\pi rT$ or $A = 2\pi r (r + T)$.

The red cell, however, has a characteristic curved configuration and so would exhibit a larger area. By the use of Guldin's theorems of Integral Calculus, Emmons² computed the surface area for several species of animals. The neces-

Received for publication, December 17, 1941.

sary values had to be obtained by actually constructing models of the red cells and taking direct measurements. Such a method is obviously a very laborious and impractical one. If the above-mentioned formula would give close enough results, we would have a very simple and practicable method.

Fig. 1.

Fig. 2.

The object of this work is to develop a simple method of determining and establishing the normal value for the surface area of the human erythrocyte. This can then form a basis from which many of the hematologic relationships and implications can be investigated. We studied a series of 50 normal young adults (doctors, nurses, and hospital attendants), 27 males and 23 females.² All the determinations were done on venous blood. The anticoagulant used was prepared according to the method of Wintrobe as follows: 0.6 Gm. of ammonium oxalate and 0.4 Gm. of potassium oxalate was dissolved in 100 c.c. of water. One cubic centimeter of this solution was placed in each test tube, and the tube was then dried in the oven. This amount of anticoagulant was used for 10 c.c. of blood. The hemoglobin was determined by the Haden-Hausser method (100 per cent = 15.8 Gm. per 100 c.c.). The hematocrit was determined by the Sanford-Magath method. Cell measurements were made with the filar micrometer measuring to within 0.5 microns. Thickness was computed by dividing the mean corpuscular volume by πr^2 , r being the mean radius of the cell. The formula used to compute the surface area was $A = 2\pi r(r + T)$, T being the thickness.

Table I represents our figures and results. The surface area of the entire series of cases ranged from 129.09 to 142.56 square microns, the average being

²Nine of the female subjects were nurses of the University Hospital, Ann Arbor, Mich. In these cases the hemoglobin was determined by the Sahli method and the hematocrit by the Wintrobe method.

135.44, with a standard deviation of 3.517. In 80 per cent of our cases the values ranged from 130 to 140 square microns. Table II represents the distribution of the cases for the various values obtained in our series. The value obtained by Emmons,² using this very exact but very laborious method described above, was 144.8 square microns.

We recognize the fallacies of our method. It is based on the assumption that the erythrocyte is a flat disk, while it is known that it has a curved configuration. But perhaps the fallacy is not quite as great as it may appear to be. Fig. 1 represents a cross section of the normal configuration of the red blood cell. Let us, for the sake of discussion, exaggerate the curves to the point of making straight lines to assume the appearance of Fig. 2. The rectangular figure superimposed is the flat disk used in our computations. The area $A'B'C$, omitted in our calculations, would be compensated for by the area $A B C$.

We feel deeply indebted to Dr. Raphael Isaacs, formerly associate professor of medicine, University of Michigan, School of Medicine, Ann Arbor, Mich., for his guidance and valuable suggestions in carrying out this work.

To summarize, a practicable technique for determining the mean surface area of the human erythrocyte with the normal value and range is presented. By this method the average total surface area of the normal human erythrocyte is 135.44 ± 3.517 square microns. Eighty per cent of the cases ranged between 130 and 140 square microns. These results compare favorably with those obtained by more exact and much more difficult methods. This procedure opens possibilities for further investigations into the interrelationships of the surface area with other hematologic values and into the question of the distribution of hemoglobin in the red blood cell.

SARCOIDOSIS

A CONSIDERATION OF THE CLINICAL AND HISTOLOGIC CRITERIA DIFFERENTIATING SARCOIDOSIS FROM TUBERCULOSIS

HAROLD L. RAKOV, M.D.,* AND J. SPOTTISWOOD TAYLOR, M.D.†
KINGSTON, N. Y.

INTRODUCTION

JONATHAN HUTCHINSON¹ in 1875 was the first to call attention to a peculiar malady of the skin in a woman named Mortimer which was characterized by granulomatous infiltration and which he referred to as Mortimer's malady. Besnier,² fourteen years later, reported similar and more detailed clinical observations of this disease, but it was not until 1899 that Caesar Boeck³ recorded the pathologic histology of these granulomatous lesions and described an associated lymphadenopathy. Many subsequent investigators frequently mentioned that the cutaneous lesions were accompanied by widespread adenopathy, dactylitis, and roentgenographic changes in the fingers and toes, yet Kuznitzky and Bittorf⁴ in 1915 were the first to demonstrate conclusively diffuse sarcoid lesions and to establish definitely Boeck's sarcoidosis as a generalized pathologic process. Although their observations have been corroborated many times, the disseminated character of the disease is still far too often not appreciated.

Practically every organ in the body may be involved, but lesions occur most frequently in the skin, lymph nodes, bones of the hands and feet, and in the lungs. The skin eruption, as described by Boeck, is usually widespread, symmetrical, nodular, pigmented, and infiltrative but never ulcerative. It affects usually the face, ears, nose, and extensor surfaces of the extremities. The adenopathy may be generalized or limited, superficial or deep seated; it often occurs in persons who never develop lesions in the skin. When the enlargement of the lymph nodes is confined to a single group, the condition is usually diagnosed as tuberculosis and may even be considered Hodgkin's disease or lymphosarcoma. Frequently the earliest signs and symptoms are referable to the lungs where roentgenologically there may be observed a marked bilateral and symmetrical enlargement of the hilar and peribronchial lymph nodes, a soft infiltration resembling caseous pneumonic tuberculosis, and often a peculiar basilar infiltration suggesting miliary tuberculosis. In spite of such marked roentgenographic involvement, the clinical manifestations of pulmonary disease are exceedingly few, since only a mild febrile reaction accompanies transitory chest pains and a slight nonproductive cough. Hemoptysis does occur, but it is rare.

*From the Kingston Hospital.

†From the City of Kingston Laboratories.

Received for publication, January 15, 1942.

The alterations in the bones of the hands and feet have been described adequately roentgenologically by Kienboeck⁷ and Jüdling⁸ as punched out or reticulated areas of rarefaction in the medulla of the phalanges, with no involvement of the periosteum and joints.

In extensive studies of the blood Harrell⁷ found definite increases in the content of calcium, protein, and phosphatase, but normal values for nonprotein nitrogen and phosphorus. In his series of cases Bence-Jones protein was usually present. In addition there were an increased sedimentation rate of the erythrocytes, a low or normal white blood cell count with neutropenia, eosinophilia, and relative monocytosis.

The disease occurs usually in early adult life and is generally benign, but it has been the cause of death in a few instances.^{7, 9} In Longcope and Pierson's¹⁰ group and in Harrell's series Negroes predominated. Although for years it has been felt that the disease was related to tuberculosis, no investigator has been able to isolate the tubercle bacillus from the lesion or through animal inoculation. At present it is almost universally agreed that the etiology remains obscure. That the disease does occur without any abnormalities of the skin has been demonstrated by many observers. It was absent in three of Harrell's eleven cases, while 50 per cent of those published by Longcope and Pierson failed to show cutaneous lesions. We are presenting three patients with Boeck's sarcoidosis, in none of whom at any time did skin manifestations appear. In two of our cases the lymph nodes in localized regions only were clinically affected, while in the third case there was widespread involvement of the lymph nodes, and in addition lesions of the liver and lungs. The failure of clinicians to consider Boeck's sarcoidosis in the differential diagnosis of the lymphadenopathies and also the failure of roentgenologists to include this disease in the differential diagnosis of pulmonary changes resembling tuberculosis, but which cannot be proved to be such by any of the many laboratory procedures now available for this purpose, are emphasized. Moreover, these cases show how easily the histologic picture may be misinterpreted by the pathologist who is not familiar with it.

CASE HISTORIES

CASE 1.—K. G., a 38-year-old white woman, had at the age of 12 years a lump in her neck which first appeared at the angle of the jaw on the right side. It reached the diameter of 1 cm.; it was painless and unassociated with any systemic manifestations, such as fever, loss of weight, etc. This lump persisted apparently unchanged for twenty years, until at the age of 32 it began to enlarge without any detectable lymphadenopathy elsewhere. At that time there were no accompanying signs of systemic disease, yet a tonsillectomy was deemed advisable and was performed six months later, on March 28, 1935. Because no appreciable effect was noted upon the enlarging mass in the neck following the operation, the mass was extricated on April 29, 1941. At operation a firm, encapsulated oval mass, 3 by 2 cm., was found lying beneath the superficial fascia of the neck, near the right carotid artery at the angle of the jaw. No alterations in the near-by lymph nodes were found, and nodes were not palpable elsewhere.

Upon gross section the incised mass appeared to be composed of lymphoid tissue surrounded by a well-defined capsule. The cut surface was nodular and did not conform exactly to the picture of a merely hyperplastic lymph node. Microscopic examination revealed a lymph node, largely occupied by tubercle-like lesions composed of epithelioid cells among which there were small giant cells, not arranged in typical tubercles. At no place could

Fig. 1.

Fig. 2.

caseation be found. Minute foci of necrosis were present but extended search resulted in failure to demonstrate any acid-fast bacilli. The changes, on the other hand, were typical of those found in Boeck's sarcoidosis (Fig. 1). These findings stimulated roentgenologic examinations of the chest and of the bones of the hands and feet, yet no evidence of generalized Boeck's sarcoidosis could be found. The skin reaction to tuberculin in a dilution of 1:1,000 was negative, and there was never any drainage from the biopsy incision. Finally, the tonsils removed five years previously were re-examined in a series of sections, and a single sarcoid in one tonsil was found which was not evident in the routine sections (Fig. 2). Unfortunately we cannot say whether or not this is the tonsil from the same side as the excised lymph node from the neck.

Fig. 3.

CASE 2.—J. C., a 27-year-old white man, a member of the Kingston Fire Department, had noted a swelling of the right axillary region for six months; the mass was not painful. He was never "feverish" and had not lost weight. On November 15, 1939, a mass, 6 by 5 by 3 cm., was excised as well as three smaller oval structures resembling lymph nodes. All of these masses were well encapsulated and upon gross section showed slightly yellowish, minutely lobulated cut surfaces without evidence of softening or caseation. Microscopically, numerous lesions resembling so-called "hard tubercles" were found, and these consisted of large epithelioid cells in clusters but were devoid of typical Langhans' cells or caseation which characterize true tubercles. A few of these lesions did contain giant cells. No acid-fast bacilli could be found in the lesions, but in spite of these observations recorded at the time of the original examination, a diagnosis of tuberculous lymphadenitis was made. Not until one year later was the diagnosis questioned by the attending surgeon, who failed to observe other clinical signs or symptoms of an acid-fast infection. Upon re-examination of the sections in the light of recently acquired experience with the lesions of Boeck's sarcoidosis, it became clear at once that the original diagnosis was in error and that the changes were typical of the latter condition (Fig. 3).

Subsequent to the submission of a revised pathologic report, roentgenologic examination of the chest and of the bones of the hands and feet failed to demonstrate any changes, including those of generalized Boeck's sarcoidosis, and intradermal tuberculin in a dilution of 1:1,000 gave no reaction.

Fig. 4.

CASE 3.—G. E., a colored man, 31 years old, had been in excellent health all his life except for the usual childhood diseases until he became aware of an increasing dyspnea upon exertion early in January, 1935. Finally the dyspnea became so marked when at rest that it was necessary to hospitalize him on January 16. Upon admission to the Kingston Hospital the positive findings were those of marked dyspnea while lying in bed, pain and tenderness over the abdomen, more particularly in the gall bladder region, and changes in the lungs revealed only by roentgenograms. These latter changes were thought to be the result of either bronchopneumonia or miliary tuberculosis, in spite of normal temperature, no increase in the pulse rate, and the failure to demonstrate specific incitant organisms in the sputum after exhaustive search. There was a normal blood picture with perhaps a slight relative lymphocytosis. During two weeks' stay in the hospital he was afebrile, the pain in the abdomen subsided, and the dyspnea was relieved. A few days after discharge the pains recurred and were accompanied by "indigestion." The liver was now slightly enlarged and exquisitely tender. Upon readmission to the hospital the temperature was 100.2° F. and the pulse rate had increased to 108. No evidence of disease of the gall bladder and gastrointestinal tract was shown by x-ray studies and many other laboratory procedures. He became more comfortable upon the administration of sedatives and was discharged a few days later with a diagnosis of hepatitis.

During another admission in March of this same year an exploratory laparotomy yielded no additional information. The liver was large and bluish gray, and the gall bladder was

drained. Recovery from the operation was uneventful, but because of persistent changes in the lungs suggestive of tuberculosis, the patient was referred to the out-patient department of the Ulster County Tuberculosis Hospital. Later, owing to the difficulty in confirming a diagnosis of tuberculosis, he was admitted to this hospital for more intensive study. The observations of Dr. George Weber were most interesting: "The physical findings and x-ray plates (Fig. 4) seem to show a tuberculous process of the caseous-pneumonic type, involving chiefly the middle and lower lobes of the right lung with some spread to the left side. An enlarged mediastinal shadow, which looks like tumor growth, cannot be explained on the basis of tuberculous involvement in an adult." The sputum never yielded acid-fast bacilli, and several guinea pigs inoculated with sputum remained well. The general condition of the patient was always good, and there was a steady gain in weight. Upon discharge from the Tuberculosis Hospital, Dr. Weber further recorded that there was grave doubt of the diagnosis of pulmonary tuberculosis, but no other disease process suggested itself.

Fig. 5.

About the time the patient left this hospital, enlargement of lymph nodes over the body began and they increased in size rapidly. This lymphadenopathy was accompanied by the loss of 30 pounds in weight. One node was removed from the inguinal region on October 16, 1935, measuring 10 cm. in its greatest dimension. Enlarged glands were also present in the neck, postauricular and epitrochlear regions, and in the axillae. Histopathologic studies revealed lesions which resembled tubercles of the so-called "hard" variety in which no acid-fast bacilli could be found after extensive search. In spite of this failure to find the organisms a diagnosis of tuberculous lymphadenitis was submitted.

Because of the loss of weight, glandular enlargement, and a histologic diagnosis of tuberculous lymphadenopathy, the patient was kept in the out-patient clinic at the Tuberculosis Hospital.

Early in January, 1936, acute abdominal pain and distress began and increased in severity over a period of four weeks, after which time a second laparotomy was done at the Kingston Hospital. The liver this time was found to be far larger than upon the previous laparotomy, and its edge extended 10 to 12 cm. below the costal margin. It was studded with innumerable grayish-white nodules, most of which were only a few millimeters in diameter. Great enlargement of the perigastric lymph nodes was also seen. One of these lymph nodes and a small piece of liver containing one of the small nodules were removed for microscopic examination. Again the histologic diagnosis was tuberculosis involving the liver (Fig. 5) and perigastric nodes (Fig. 6), even though no acid-fast bacilli could be found in the lesions and macerated tissue injected into guinea pigs produced no disease.

Fig. 6.

Following this last operation and without specific therapy of any sort, the patient began to improve rapidly. During the period from February 16, 1936, to August 16, 1940, the clinical manifestations of the disease practically disappeared. He has been working for almost five years at his regular occupation as day laborer and feels entirely well. Early in August, 1940, inoculations of old tuberculin were done intracutaneously for the first time, in dilutions varying from 1:100,000 to 1:100, and yielded questionable reactions only in the lowest dilution. In June, 1941, small lymph nodes, barely palpable, were the only residual manifestation of the disease, while roentgenograms revealed complete resolution of the pulmonary and mediastinal changes previously observed, and no changes in the bones of the hands and feet could be demonstrated. Chemical examinations of the blood showed normal levels for calcium, cholesterol, total protein, and an albumin-globulin ratio of 2.75. No Bence-Jones protein was ever found in the urine.

COMMENT

Although Hutchinson, Besnier, and Boeck described this malady as a dermatologic affection, it became evident to subsequent investigators that the cutaneous manifestations were merely part of a diffuse systemic disease of a granulomatous nature. Moreover, it is now clear that this skin eruption not only may not be prominent but often does not appear at all. Schaumann¹¹ in 1914 mentioned the possibility of the disease pursuing a concealed existence in the lymphatic and internal organs without giving rise to skin lesions, and that in all probability the skin was attacked in comparatively rare instances. Our cases demonstrate a predilection for the lymphatic system without skin manifestations and afford additional evidence of the validity of Schaumann's original assumption.

In the light of present knowledge it is difficult to accept our first two cases as instances of isolated glandular involvement. With the limited clinical means of exploring the body, obscure involvement of other lymphatic structures might well have been present. Although a thorough clinical examination of the peripheral glands and radiographic studies of the chest revealed no evidence of adenopathy, it has been pointed out that histologic examination of the clinically normal appearing lymphatic structures will often reveal sarcoids. Thus in Case 1, only after re-examination of a series of sections of tonsils removed five years previously was a single miliary sarcoid demonstrated. Unfortunately, since no further studies were permitted, we were unable to observe the histology of nonpalpable glands or tonsils of Case 2.

The third case presented many signs and symptoms of a disseminated tuberculous process. There were slight fever with cough, weight loss, enlargement of the cervical, axillary, inguinal, mediastinal, and mesenteric lymph nodes, as well as pulmonary parenchymal infiltration of a caseous pneumonic type, and marked enlargement of the hilar shadows. Lesions in the liver and perigastric lymph nodes were found which resembled tubercles of the "hard" variety. Skin manifestations were absent, the tuberculin reactions were not significant, and tubercle bacilli could not be found in the sputum or excised tissues. The subsequent clinical course proved the diagnosis of miliary tuberculosis to be incorrect, and re-examination of the extirpated glands established the true diagnosis. Since generalized Boeck's sarcoidosis is usually a benign, nonfatal disease, there is no doubt that many reported cures of miliary tuberculosis are in fact instances of recovered sarcoidosis.

In this connection it is recalled with a great deal of interest by one of us how Dr. William S. Thayer at one time was thoroughly convinced that he had observed a case of miliary tuberculosis which eventually recovered. A biopsy of the skin in his case revealed lesions which he and the pathologist interpreted as tubercles, but in which no acid-fast bacilli could be found. He was never quite satisfied that exhaustive search might not have revealed the presence of tubercle bacilli, and often regretted that animal inoculation had been rendered useless because of the fixation of the specimen before it reached the pathologic laboratory.

The true nature of the lesions has not been appreciated by many trained observers even though numerous descriptions of the histologic pathology have been recorded. Boeck mentioned sharply circumscribed foci of "new growth" composed of epithelioid connective tissue cells with giant cells of "sarcomatous" nature. Schaumann¹² in 1924 characterized the lesions as sharply circumscribed epithelioid tubercles without necrosis and very little lymphoid reaction. Nickerson¹³ believes the following findings are of assistance in differentiating sarcoid from tuberculosis: (1) Caseation is never present. (2) The giant cells are different from those seen in tuberculosis. (3) Lesions in tissues other than the lungs do not contain carbon pigment. (4) In the liver the lesions are most numerous in the portal triads, with only a few in the mid-zones of the lobules.

Fig. 7.

In miliary tuberculosis the reverse is true. (5) With silver impregnation, delicate reticulum is always present in the lesion. In tuberculosis this is destroyed by the onset of caseation.

In our experience we have found it exceedingly difficult to differentiate sarcoidosis from truly noncaseating tuberculosis which even to the present time are not considered separate entities by some careful students of tuberculosis (Pinner¹⁴). However, recently our studies on the cases herein reported have convinced us that sarcoidosis is not an unusual form of tuberculosis but rather a distinct disease entity whose etiology is still obscure. The reasoning of Pinner

is interesting but not convincing. Often the problem confronting the pathologist is impossible of solution by mere histologic examination, yet there is a pattern presented by the sarcoid lesions to one who is familiar with them that enables him to distinguish the sarcoid from the noncaseating tubercle. Every student of sarcoidosis has recognized the absence of caseation and the slight peripheral lymphocytic reaction about the sarcoids, yet in a given true noncaseating tubercle a similar situation often obtains. Each attempt thus far to point out the distinguishing features between the sarcoid and the noncaseating tubercle has failed to convey in words what may readily be seen in sections. Our attempt perhaps also is futile, but it seems to us that the epithelioid cells in the individual sarcoid are usually larger and more cuboidal and that the individual sarcoids do not fuse to produce a conglomerate sarcoid in the manner that primary tubercles produce the conglomerate tubercle. The size of the giant cell, as well as the position and number of their nuclei, throw little light on the diagnosis. It can be seen in Fig. 7 that typical Langhans' giant cells may be present.

We urge those pathologists who do not yet recognize these sarcoid lesions to study all their cases of noncaseating tuberculosis with this disease in mind. Doubtless many clinicians, as well as pathologists, will need to observe a recovered case of "miliary tuberculosis," as was true with us, before they are convinced that the clinical-histologic picture is not that of tuberculosis but instead that of sarcoidosis.

We acknowledge our indebtedness to Doctors Fred S. Carr, Douw S. Meyers, and Frank A. Johnston for the privilege of studying these cases with them. The clinical observations herein recorded are essentially those made by these respective physicians. The photomicrographs were made by Mr. Lionel B. Herrington.

CLINICAL CHEMISTRY

CLINICAL STUDIES WITH THE AID OF RADIO-PHOSPHORUS*

V. EARLY EFFECTS OF SMALL AMOUNTS OF RADIO-PHOSPHORUS ON BLOOD CELL LEVELS, UPTAKE, AND EXCRETION

B. V. A. LOW-BEER AND ANNE DE G. TREADWELL
BERKELEY, CALIF.

IT IS KNOWN that radioactive phosphorus emits β rays. Its half life is 14.3 days. When radio-phosphorus is administered orally or intravenously it has been found to localize in certain tissues of the body, namely, bone, bone marrow, neoplastic and leucemic tissue.¹ For this reason, radio-phosphorus has been used as a therapeutic agent in the treatment of leucemia, polycythemia vera, and lymphosarcoma. Extensive studies concerning the early absorption and distribution in blood and the early excretion in urine of therapeutic doses of radio-phosphorus in leucemia and polycythemia vera and in normal persons have been carried out.² These investigations have established definite patterns of response in the three groups in question when moderate-sized therapeutic doses are used. No standardization by means of very small doses has heretofore been attempted nor have any studies, so far as we are aware, been directed to the early effects of radio-phosphorus on blood cell levels in any of the three groups.

It is known that x-rays even in small doses produce biological effects long before therapeutic responses can be observed.³ Such effects occur within the first twenty-four hours and concern fluctuations in peripheral blood levels, of red and white cells, reticulocytes, and platelets, and the relationships of cells in the differential count. It has been our purpose in the present study to determine whether internal radiation resulting from intravenous administration of radio-phosphorus in small doses elicits similar responses. We have been concerned also with the early absorption and distribution in the blood of such doses, and with the rate of excretion in the urine. Attention has been given to the influence of previous x-radiation on the early response to radio-phosphorus, and we have attempted to differentiate between the effect of inert phosphorus and its radioactive isotope. Finally, we have observed the spontaneous fluctuations of blood cell levels over a period of three hours in some of the cases here presented.

The dose chosen was approximately 500 microcuries. Assuming a total body weight of 60 to 65 kg. and an even distribution of the radioactive metabolite, there would be 0.006 to 0.009 microcuries P^{32} per gram of body weight. We have arbitrarily called this a "threshold dose" for two reasons: First, in order

*From the Radiation Laboratory, University of California, Berkeley.

This work has been supported by the Columbia Fund for Medical Physics of the Columbia Foundation.

Received for publication, March 21, 1942.

to distinguish it from tracer doses used in animal experiments⁴; and second, because the biological effects are transitory and thus differ from so-called therapeutic effects.

The subjects have included apparently healthy persons and patients with various types of leucemia and with polycythemia vera.

METHODS

Radioactive phosphorus was produced in the 60-inch cyclotron⁵ by the bombardment of red phosphorus which was then transformed into isotonic Na_2HPO_4 solution containing 15 mg. of the compound per cubic centimeter. Subjects came to the laboratory in a fasting condition. Prior to the injection a blood count was made. This was repeated hourly for the first three hours after injection and at twenty-four hours. Withdrawal of 15 to 20 c.c. of blood by venipuncture was done at hourly intervals for the first three hours after injection and at twenty-four hours for the normal persons and for some of the patients. In one group of cases urine was collected at hourly intervals during the first three hours and at twenty-four hours.

One group of three leucemia patients prior to receiving any radio-phosphorus were given intravenously 3 c.c. (45 mg.) of inert Na_2HPO_4 . Counts were made on these patients prior to injection and at hourly intervals for the first three hours and at twenty-four hours. A second group of patients was observed over a period of three hours for spontaneous fluctuations in blood cell levels.

The counts included: hemoglobin by the Osgood-Sahli method; red and white cell counts; platelets and reticulocytes by the cover slip method, using 1 per cent brilliant cresyl blue in 3.8 per cent sodium citrate. Smears were stained by the Wright-Giemsa technique, and at least 200 cells were enumerated for each differential count. The blood withdrawn from the veins was heparinized, cooled, and centrifuged for twenty minutes at $1,450 \times$ gravity to insure constant volume. The plasma was removed, the buffy coat was aspirated, suspended in Riger's solution, and centrifuged again for twenty minutes at $1,450 \times$ gravity.^{2a} Finally the red blood cells were aspirated.

Materials for radioactive assay were measured, dried at 90°C ., and assayed in a standard DuBridge electrometer and compared with a uranium standard. The amounts measured did not exceed 20 to 30 mg. per square centimeter, and, therefore, no correction for β ray absorption is necessary.

RESULTS

Spontaneous fluctuations were negligible for all aspects of the blood count for each of the three patients observed. These included one case of chronic myeloid and two cases of chronic lymphoid leucemia. The other results are summarized in Tables I, II, and III.

The effects of inert Na_2HPO_4 on two patients with chronic lymphoid leucemia and one with chronic myeloid leucemia are shown in Table I. The case of F. B. was characterized by only very slight elevation of the total white blood cell count, but this was made up almost entirely of lymphoid cells many of which were immature forms. The platelet count was very low from the outset.

TABLE I
CHANGES IN BLOOD CELL LEVELS FOLLOWING ADMINISTRATION OF INERT Na_2HPO_4

None of the elements of the blood count exhibited any significant change. The case of chronic myeloid leucemia, which had been treated with x-rays up to three weeks before admission, exhibited some lability of the white blood cell count, possibly attributable to x-rays.

Cases 1, 2, and 3 of Table II show the typical hematologic response to 500 microcuries of P^{32} in three healthy persons. In all these subjects the platelets show marked deviations from the original levels during the first three hours. The shapes of the curves are the same in all three cases. There is a deviation beyond physiologic limits in the red blood cell count and hemoglobin, and this is closely correlated with the response of the reticulocytes. The total white blood cell count in all these cases remained unaffected.

Cases 4 through 10 of Table II show hematologic responses in lymphoid and myeloid leucemia patients. There is a definite effect on all elements of the blood count in these cases with the exception of the total white blood cell count of Case 4. Here it will be noted that the initial level of the white blood cells was only slightly elevated above normal. The platelet count in this case, which was unaffected by inert Na_2HPO_4 , shows a definite rise and fall similar to those of the other cases of this group. The early radiation effect on the reticulocytes is especially pronounced in Cases 7 and 9. In all cases the point at which the reticulocyte level is at maximum the platelets are at minimum.

Cases 11 through 13 of Table II show hematologic responses in polycythemia vera. The red blood cells and the hemoglobin are the elements most profoundly affected, although all elements show some lability. The deviation of the reticulocytes is downward. The platelet count is markedly changed, but there seems to be no pattern of platelet response characteristic for this condition.

Case 14 of Table II shows the hematologic response in one case of polycythemia vera with leucemoid reaction. It would appear from this case that the typical responses of leucemia and polycythemia patients are here combined, with lability of the red blood cells, white blood cells, and platelets, and the reticulocytes exhibiting an upward trend.

Cases 1, 2, and 3 of Table III illustrate rates of uptake in three normal persons. The maximum excretion is approximately the same in all cases and is reached in all within the first three hours. Case 2 exhibits a somewhat higher uptake by white blood cells than the other two cases in this group. This may well be correlated with the somewhat higher level of the total white blood cell count in this person.

Cases 4, 5, 7, 9, 10 of Table III illustrate rates of uptake in leucemia patients. In Case 5 the utilization of phosphorus by white blood cells is in keeping with the excessive white blood cell proliferation as opposed to Case 4 where the total white blood cell count was never higher than 20,000. Case 9 shows a strikingly high uptake of phosphorus by white blood cells, despite the relatively low total white blood cell count. This may be explained on the basis that the differential count in this case consistently showed 85 to 90 per cent myeloblasts. It has been shown by Marshak⁶ that cells in the early stages of mitosis are the largest consumers of phosphorus. Case 4 with a relatively low total white blood

cell count shows a high level of excretion at the first hour, while the excretion rate of Case 5 with over 100,000 cells (white) reaches its peak at the third hour. The excretion of Case 7 is considerably lower than that of the normal persons or of the other patients in this group. This would seem to be in accord with the progressive uptake of phosphorus by newly forming white cells.

Case 11 of Table III shows uptake in a case of polycythemia vera. The red blood cells here show the highest uptake of phosphorus during the twenty-four-hour period of any of the groups studied. The difference between this case and the normal person in this respect, however, is very much less than the difference demonstrated between polycythemia and leucemia. The work of Erf and Lawrence^{2b} indicates that the uptake of phosphorus by red blood cells is the same in normal persons and polycythemia patients at the twenty-four-hour point. These authors extended their observations beyond the first day, and their results

showed an increased uptake by red blood cells in one case of polycythemia vera at the forty-eight-hour point. It appears that no real basis of comparison exists for these findings and those of the present study for the following reasons: One point only in the uptake curves, namely, the twenty-four-hour period, is common to both investigations; the doses of radio-phosphorus (and the amounts in milligrams of salt in which they were incorporated) used by Erf and Lawrence are different for the patients and for the normal persons and in both groups the doses are considerably larger than the "threshold amounts" used in this study; finally the total number of cases observed in both studies is too small to rule out the existence of individual differences in response. The possibility that the red blood cells in polycythemia vera utilize radio-phosphorus to a greater extent than do normal red blood cells, suggests that investigations similar to those here discussed might well be extended to a larger group of

polycythemia patients, in the hope of establishing conclusively the uptake pattern in this condition. In the case here presented the excretion rate is correlated with the uptake phenomena and the curve is, therefore, lower in degree and opposite in trend from the excretion curves of healthy persons and leucemia patients.

Fig. 1.—Hematologic response of normal persons to 500 microcuries P^{32} administered intravenously.

Case 14 of Table III shows uptake in the case of polycythemia with leucemoid reaction. The gradual increase in total activity of whole blood is in contrast to all other cases studied, and is no doubt accounted for by the high uptake of both red and white blood cells. The excretion curve follows those of the

leucemia patients in direction but differs in degree by reason of increased retention of radio-phosphorus by the blood.

With respect to the differential count, all the leucemia patients showed a slight increase in primitive cells (absolute numbers) during the twenty-four-hour period. This tendency did not appear in the polycythemia patients, although a few primitive cells were present in all these cases. The polycythemia patient with leucemoid reaction showed a decrease in primitive cells. There were

FIG. 2.—Typical early hematologic response of leukemia patients to 500 microcuries of P^{32} administered intravenously.

no shifts in the relationships of granulocytes and agranulocytes in any of the leucemia patients. The polycythemia patients showed a transitory increase in the relative number of lymphocytes during the first three hours.

The three normal persons showed no primitive cells at any time. Shifts in the relationships of other cells occurred, the most consistent being a transitory reduction in the absolute number of lymphocytes.

Fig. 3.—Typical early hematologic response of polycythemia vera patients to 500 microcuries of P^{32} administered intravenously.

DISCUSSION

The results show that radio-phosphorus in amounts of 0.006 to 0.009 microcuries per gram of body weight produces early radiation effects. These biological effects of very small activities of radio-phosphorus again indicate the importance of determining the "safe tracer dose" for each biological system studied.⁴ The dose of radio-phosphorus used in these studies has been termed arbitrarily a "threshold dose." Experience in this study indicates that the actual threshold dose is individually conditioned by such factors as previous treatment and rate of cell production. Because of the known metabolic changes in leucemia and

polycythemia, knowledge of the basal metabolic rate might aid in predicting accurately a specific "threshold dose."

Group differences in uptake and excretion indicate the early function of the homeostatic mechanism in effecting an immediate distribution of P^{32} to the blood elements of highest metabolic rate. The excretion rate in normal persons is accordingly appreciably higher than in any of the patients.

SUMMARY

1. A threshold dose of radio-phosphorus has been arbitrarily defined.
2. Such a dose administered intravenously causes a definite "early radiation effect" on blood cell levels which is characteristic for each of the following groups: healthy persons, leucemia patients, and polycythemia patients.
3. This "early radiation effect" is further conditioned by the rate of cell production and by previous radiation treatment.
4. The uptake of P^{32} in the fractions of the blood and the rate of its excretion are roughly characteristic for each of the three groups.

We wish to express our appreciation to the staff of the Radiation Laboratory for their generous cooperation in providing the supply of radio-phosphorus used in this study.

The suggestions and criticisms of Dr. John H. Lawrence are gratefully acknowledged. One of us (B. V. A. L-B) wishes to express his appreciation for the privilege of taking part in this work at the Radiation Laboratory.

CHANGES IN THE CREATININE CLEARANCE AND URINE FLOW OF THE DOG DURING FEVER*

HENRY J. NICHOLS, PH.D., BEN L. BOYNTON, M.D., AND
RAYMOND C. HERRIN, PH.D., M.D., MADISON, WIS.

IN 1931 Goldring¹ reported that the urea clearances of human patients were usually higher in the acute febrile stage of rheumatic infection than the highest observed normal. He interpreted this as indicating a state of renal hyperfunction during the acute stage as a response to the demand of increased protein catabolism. In 1934 Grant and Medes² reported that the creatinine clearances of a large number of human patients with fever caused by infection were considerably higher when the body temperature was 38.9° C. or more, than when the temperature was between 36.7° and 37.1° C.

Grant and Medes² also reported that the creatinine clearance of normal unanesthetized dogs was increased after elevation of the body temperature by heating with conventional diathermy. But in the same year Page³ reported that no significant change was observed in the urea clearances or in the urine flow of normal human subjects and patients with kidney disease during or after conventional diathermy. Farr and Moen⁴ reported that the average urea clearance of rheumatic patients, placed in a cabinet heated by carbon filament lamps, with only the head and neck protruding, was 62 per cent of normal while the body temperature was rising and 75 per cent of normal when the body temperature was at a maximum of 104.8° to 106.7° F. Severe oliguria occurred in two experiments even though large quantities of water was given orally.

A new method of producing heat in tissues by high-frequency electromagnetic induction was introduced in 1934 by Merriman, Holmquest, and Osborne.⁵ Mortimer and Osborne⁶ found that during elevation of the body temperature of anesthetized dogs by this method, with the coil about the thorax, there existed a definite thermal gradient from the skin, which was heated to the highest temperature to the deeper tissues. The temperature of organs lying outside the short-wave field was elevated to a lesser degree. After heat induction was discontinued, the rectal temperature continued to rise for a short time while other parts of the body lost heat, showing that the heat was widely distributed by the circulation of the blood. Karr and Nasset⁷ have elevated the body temperature of dogs, anesthetized with sodium amytal, to as much as 42.8° C. over a period of six hours by electromagnetic induction, during which time urine was collected by means of ureteral cannulae in hourly periods. They reported a decrease in total nitrogen excretion roughly parallel to the decrease in rate of urine

*From the Department of Physiology, University of Wisconsin, Madison.

This study received financial support by grants from the Wisconsin Alumni Research Foundation.

Received for publication, April 6, 1942.

flow, and found that oliguria and anuria were almost invariable sequelae to hyperthermia carried to 42° C. or higher. The blood pressure of their animals remained at a relatively high level until just prior to their death.

In 1938 Chasis, Ranges, Goldring, and Smith⁸ reported that hyperemia of the kidneys occurred in human subjects during typhoid vaccine pyrexia. In the typical example they present, intravenous injection of 75 million organisms was followed in a few minutes by chills and a slight fall in body temperature, with a slight decrease in the inulin clearance. Within half an hour the inulin clearance increased about 10 per cent above normal and remained at that level, while the body temperature slowly increased over a period of six hours to a maximum of 6° F. above normal. Smith and his associates⁹ have produced hyperemia of the kidneys of human beings by the intravenous injection of pyrogenic inulin. In the typical example presented, the body temperature began to increase slowly about an hour after administration of 80 mg. of pyrogenic inulin, and thirty minutes later the renal blood flow increased about 40 per cent and the inulin clearance increased about 50 per cent. The renal blood flow remained 40 to 50 per cent above the control level, and the inulin clearance varied between 10 and 50 per cent above the control level, while the body temperature increased slowly to a maximum of 4° above normal in a period of three hours.

This paper is a report of the effect of body temperature elevation upon the plasma creatinine clearance in unanesthetized dogs. The hyperthermia was produced by high-frequency electromagnetic induction, or by conventional diathermy, or by the intravenous injection of typhoid-paratyphoid vaccine, or by exposure to a current of cold air in a cold room.

EXPERIMENTAL PROCEDURE

Female dogs, trained to lie quietly during catheterization, vascular puncture, and heating, were used in the postabsorptive condition, sixteen to twenty-four hours after the last meal. Water was given by stomach tube in three or four doses before the first collection period in order to produce a urine flow of 2 to 5 c.c. per minute, and enough creatinine was given orally in order that the plasma creatinine should seldom fall below 10 mg. per 100 c.c. The bladder was washed twice with 20 c.c. of sterile 1 per cent sodium chloride solution before the first and at the end of each collection period. Approximately in the middle of each period enough blood was drawn to yield 1 c.c. of plasma for analysis. The plasma proteins were precipitated by means of the acid cadmium sulfate method of Miller and Van Slyke.¹⁰ Creatinine was determined in the appropriately diluted urines and plasma filtrates by adaptation of the alkaline picrate colorimetric method¹¹ to the Evelyn photoelectric colorimeter,¹² with the following procedure:

Four cubic centimeters of a solution containing between 1.600 and 0.080 mg. per 100 c.c. of creatinine are pipetted into a dry photoelectric colorimeter tube. Into another such tube are put 4 c.c. of water, to be used as a blank. With each are mixed 2 c.c. of alkaline picrate reagent. After fifteen minutes the galvanometer is adjusted to read 100 with the tube of blank in the photoelectric colorimeter, using the No. 520 color filter and the No. 6 diaphragm. The blank is then replaced by the tube of unknown and the new galvanometer reading is recorded. From a table of known concentrations of creatinine and corresponding galvanometer readings, the creatinine content of the unknown is found.

Rectal temperature was measured at frequent intervals with a standard clinical thermometer. In these experiments fever is reported in degrees and tenths of a degree of temperature Fahrenheit above the rectal temperature of the dog during the control clearance periods.

High-frequency electromagnetic induction was accomplished with a Burdick SWD-10 Triplex. The electric current, with a frequency of 12 million cycles per second, was conducted through a flexible, heavily-insulated cable, supported by hard rubber clips in the form of a helix of three turns about the part of the body to be heated, from which it was separated by additional insulation of four layers of bath toweling. When heat was induced in the head of a dog, the helix was just posterior to the eyes and about the posterior part of the lower mandible. When heat was induced in the region of the kidneys, the helix was obliquely about the caudal three or four thoracic vertebrae and the anterior abdominal region. When heat was induced in the region of the pelvis, the helix was obliquely about the sacral vertebrae and the middle abdominal region. Two or three control clearance periods preceded a twenty-minute period of heat induction, immediately after which the cable and toweling were removed from the dog to allow the body temperature to return to normal, during which time there were one to six clearance periods. The controls of the apparatus were set to give approximately the same power output in each experiment. In two experiments a fever of approximately three hours' duration was maintained by intermittent high-frequency electromagnetic induction, in which ten-minute periods with induction were alternated with ten-minute periods without induction. In three dogs the lumbar sympathetic chains and the first sacral ganglia were excised and the splanchnic nerves were sectioned in two operations upon each dog. In two other dogs the kidneys only were denervated. When the wounds had healed, heat was induced for twenty minutes in the kidney region in two, three, or four experiments with each dog. In two electromagnetic induction experiments upon a normal dog and in one experiment upon a dog with lumbar sympathectomy, the diodrast clearance was used as a measure of renal plasma flow.¹³ The analytical technique of White and Rolf¹⁴ was used in the determination of diodrast iodine in urines and plasma filtrates.

Conventional diathermy was accomplished with equipment which included a Victor spark-gap diathermy machine, made by the General Electric X-ray Corporation, and a pair of pad electrodes, each of which was a thin sheet of lead, $4\frac{1}{2}$ by $8\frac{1}{2}$ inches in size, covered by several layers of surgical gauze. An electrode was held tightly against each of the shaved sides of a dog between the foreleg and the flank with a pad of toweling, about 1 inch thick 6 inches wide and 12 inches long, with several strips of water-proof adhesive tape completely encircling the pads and body of the animal. The electrodes and pads were kept wet with a 1 per cent sodium chloride solution, and a high-frequency alternating current of 1,500 milliamperes was allowed to flow through the body of the dog for one to three hours. There were clearance periods before, during, and after diathermy.

After two or three control clearance periods typhoid vaccine pyrexia was produced by the intravenous injection of doses of typhoid-paratyphoid vaccine

containing from 25 million to 2 billion killed organisms. The vaccine was obtained from the Wisconsin State Laboratory of Hygiene.

Two experiments were made with a dog, in each of which, after three control clearance periods in the moderately warm laboratory, the carriage supporting the animal was wheeled into a cold room and a current of cold air was blown against the shaved sides and abdomen by means of a large electric fan. After about one hundred minutes of such exposure the carriage was wheeled back into the laboratory and clearance periods were continued for about one hundred more minutes.

RESULTS

High-frequency electromagnetic induction in any one of three body regions caused a rapid and continuous elevation of the rectal temperature, which was accompanied by vigorous panting. In a series of 18 comparative experiments with three dogs the average maximum hyperthermia observed at the end of twenty minutes was 1.0° F. when heat was induced in the head, 1.9° F. when heat was induced in the kidney region, and 3.1° F. when heat was induced in the pelvis. The temperature returned to normal in twenty to seventy minutes, and panting ceased at normal body temperature. The changes in minute volume of urine flow were inversely related to the changes in rectal temperature, as shown in Fig. 1. During maximum hyperthermia there was often an oliguria, but several minutes after the body temperature began to decrease, the rate of urine flow began to increase, until it was again between 2 and 5 c.c. per minute at normal temperature. There was no consistent relationship between the region in which heat was induced and the amount of urine flow decrease.

During the hyperthermia produced by electromagnetic induction, the plasma creatinine clearance generally decreased, but never significantly increased. In the series of 18 comparative experiments with three dogs the average maximum decrease in clearance was 13 per cent when heat was induced in the head, 45 per cent when heat was induced in the kidney region, and 27 per cent when heat was induced in the pelvis. A typical example of the results in each variety of these experiments is shown in Fig. 1, parts *A*, *B*, and *C*. When heat was induced in the kidney region in 28 experiments with nine dogs, a maximum decrease of the creatinine clearance of 12 to 79 per cent occurred twenty-two times, with a maximum hyperthermia of 0.5° to 2.6° F. In 12 of these experiments the clearance immediately increased to the control level as soon as induction was discontinued, even though the hyperthermia persisted. In eight of these experiments the clearance began to increase toward the control level as the body temperature began to decrease. In two experiments the clearance remained low. The eight experiments with no decrease in clearance during hyperthermia were with three large dogs in which it seemed impossible to produce a decrease in clearance except occasionally when the control clearances were high, i.e., more than 66 c.c. per minute.

In two experiments during electromagnetic induction of heat the plasma creatinine clearance decreased 44 and 32 per cent while the renal plasma flow decreased 32 and 35 per cent, respectively. The filtration fraction did not change significantly in either experiment. Immediately after induction was discon-

tinued, the creatinine clearance and the renal plasma flow increased again to the control values in both experiments.

The effect of electromagnetic induction after section of the splanchnic nerves and removal of the lumbar sympathetic ganglia is shown in Table I. The magnitude of decrease of the creatinine clearance during induction was much reduced as compared with that in the unoperated animal, or no decrease in the clearance occurred at all during induction after the operation.

*In this experiment there was no change in the renal plasma flow during or after heating, and the filtration fraction did not change.

After denervation of the kidneys only of each of two dogs, electromagnetic induction could cause a decrease in the creatinine clearance, as shown in Table II. Apparently dog K was one of that type of dog in which a decrease in the creatinine clearance sometimes occurs during induction and sometimes does not.

In order to make the hyperthermia produced by electromagnetic induction comparable to that of conventional diathermy both in magnitude and duration, two dogs were heated by intermittent electromagnetic induction in the kidney region for three hours. The body temperature ranged from 0.8° to 1.3° F. during this period, and the plasma creatinine clearance varied between the control level and 66 per cent of the control level. There was no increase in the clearance.

The effects of conventional diathermy upon five dogs in eight experiments were somewhat variable, as shown in Table III. In the first place, it was difficult

to induce a fever in dogs S and P, because these animals presumably were able to liberate heat very rapidly by violent panting. The other three dogs panted only gently and intermittently during diathermy, but at least an hour was necessary to produce more than a degree Fahrenheit of fever in them. There was only

Fig. 1.—Typical changes in the plasma creatinine clearance and the minute volume of urine flow in a dog during fever produced by electromagnetic induction (A) in the head, (B) in the kidney region, and (C) in the region of the pelvis, and changes in clearance and urine flow in the same dog during fever produced by conventional diathermy.

a moderate, slow diminution of the minute volume of urine flow during the fever of conventional diathermy, as shown in Fig. 1. During diathermy there was either a decrease in the plasma creatinine clearance or no significant change,

except for a transitory increase of about 16 per cent in one experiment. After diathermy the clearance decreased still more in two experiments, decreased below normal in two others, and remained equal to or became equal to the controls in four.

The intravenous injection of typhoid-paratyphoid vaccine containing 25 million killed organisms into dog P was followed in a short time by a fever of 0.5° F., and later by an increase in the creatinine clearance of about 15 per cent. When a larger dose of 100 million killed organisms was used in each of twelve experiments with six dogs, there was no fever in two cases, but slight fever of 0.4° to 0.8° F. in ten; and no significant change in the creatinine clearance in six cases, but a moderate increase of 8 to 38 per cent in six, as shown in Table IV. In Experiments 12 and 13 an increase in the clearance was not observed until four and one-half to six hours after injection of the vaccine. When huge doses of 2 billion killed organisms were injected into dogs B and S, there was an immediate rise in rectal temperature to a maximum of more than 2° F. in about three hours. With subsequent huge doses of vaccine in dog S the onset of fever was later and the pyrexia was not so great as before. In Experiments 14, 15, and 16 the maximum clearance definitely did not coincide with the maximum fever but occurred earlier or later. In Experiments 15 and 17 the injection of the vaccine was immediately followed by an extreme, but transitory, decrease in the clearance. During all fevers by typhoid vaccine injection there was no panting and no decrease in the minute volume of urine flow other than that which normally follows a moderate diuresis.

It was found that exposure to a current of air from an electric fan in a room at 38° and 47° F. caused the dog to shiver violently and the rectal temperature to increase rapidly about a degree Fahrenheit above normal. This was followed by a decrease in the temperature to about half a degree above normal. In one experiment the plasma creatinine clearance increased to nearly 30 per cent above normal and in the other to 18.3 per cent. The minute volume of urine flow decreased only at a rate which normally follows a moderate diuresis. Upon return to the laboratory at 71° to 73° F., the rectal temperature fell to normal very quickly and the clearance decreased slowly toward the level of the controls.

DISCUSSION

The results obtained from these experiments suggest that the changes which occur in the creatinine clearance of the dog during fever or hyperthermia depend upon the causal agent. During hyperthermia produced by an external physical means, such as electromagnetic induction or conventional diathermy, there was generally a decrease in the clearance but never an increase, except in one instance when a transitory increase was followed by a decrease in the clearance. This is in agreement with the results of Farr and Moen,⁴ who employed the external physical means of a heating cabinet, and also with the observation of Karr and Nassett⁷ that heating with electromagnetic induction decreased the total nitrogen excretion. But these results are contrary to those obtained by Grant and Medes² with conventional diathermy. Inasmuch as the postabsorptive clearance of many dogs varies spontaneously from day to day, it is suggested that some of the increases in the creatinine clearance reported by Grant and Medes, which were above the control clearances determined on previous days, might have been found to be equal to or less than control clearances determined just previous to diathermy on the same day.

When fever was caused by vaccine injection or by exposure to cold, there was generally an increase in the clearance, but never a decrease, except in two

instances of transitory decreases followed by increases in the creatinine clearance to or above the control level. Both of these procedures may have produced hyperthermia by virtue of increased metabolic activity. A comparison of the results obtained with these four methods of producing hyperthermia leads to the conclusion that an increase in creatinine clearance was never due to hyperthermia itself, but rather to changes in the tissues which were responsible for the hyperthermia. As further evidence for this idea it may be noted that the maximum increase in clearance did not always coincide with the maximum body temperature, after injection of typhoid-paratyphoid vaccine. This is in agreement with the observations of Chasis, Ranges, Goldring, and Smith⁸ with a human subject. Furthermore, Smith⁹ shows that the inulin clearance of the human subject may increase about 50 per cent after injection of pyrogenic inulin long before the maximum body temperature is attained.

The decrease in creatinine clearance during hyperthermia produced by electromagnetic induction seems to have been due entirely to a reduction of the renal blood flow because of dilatation of blood vessels in the peripheral vascular bed. The fact that a decrease in the renal plasma flow during electromagnetic induction and an increase to the control level immediately after induction occurred simultaneously with the respective decrease and increase to the control level of the creatinine clearance, with no significant change in the filtration fraction, indicates that the decrease in renal blood flow was due either to constriction of the afferent arterioles or to extrarenal shunting of much of the blood to other parts of the body. These activities seem to be brought about in part or entirely by reflexes through the thoracolumbar outflow, because section of the splanchnic nerves and removal of the lumbar chains greatly reduced or entirely abolished the decrease in clearance and, according to one observation, the simultaneous reduction in renal blood flow. That the decrease in renal blood flow is not due to constriction of the afferent arterioles is indicated by the fact that denervation of the kidneys only did not prevent a decrease in the creatinine clearance during electromagnetic induction. The decrease in creatinine clearance during the hyperthermia produced by conventional diathermy may also have been due to a reduction of the renal blood flow because of dilatation of blood vessels in the peripheral vascular bed. It is suggested that the extreme, but transitory, decreases in clearance which occurred in the typhoid vaccine Experiments 15 and 17 of Table IV may have been due to a shunting of a large fraction of the blood from the renal arteries to the splanchnic vascular area because of a transitory shock accompanied by vasodilatation immediately following the injection of the huge dose of vaccine.

The inverse relationship between the minute volume of urine flow and the magnitude of the fever produced by electromagnetic induction was probably due to temporary water conservation and not to dehydration, because the urine flow increased soon after heating ceased. This change in the urine flow did not parallel the change in creatinine clearance throughout the duration of an experiment, nor did the amount of reduction in urine flow correspond to the amount of clearance decrease, as is shown in Fig. 1. Therefore, the regulation of the rate of urine flow seems to have been independent of the rate of glomerular

filtration. It is possible that secretion of the antidiuretic principle by the hypothalamus was increased as the body temperature was rapidly elevated, causing a proportional increase in the rate of water reabsorption in the kidney tubules. Attention is called to the fact that there was neither panting nor marked reduction in the rate of urine flow when fever was produced by typhoid vaccine injection. This may indicate a relationship between the mechanisms responsible for panting and for water conservation.

SUMMARY

During the hyperthermia produced by electromagnetic induction, the plasma creatinine clearance generally decreased, but never significantly increased. Heat induced over the kidney area was most effective in lowering the clearance, less effective when induced in the pelvis, and least effective when induced in the head. When heat was induced over the kidney area in 28 experiments with nine dogs, a maximum decrease of the creatinine clearance of 12 to 79 per cent, with a maximum hyperthermia of 0.5° to 2.6° F., occurred twenty-two times. This decrease of the clearance occurred about five minutes after the initial rise in temperature, but its magnitude was not related to the magnitude of the hyperthermia. The decrease of the clearance was found to be due to a simultaneous decrease of the renal plasma flow. Denervation of the kidneys only did not prevent a decrease of the clearance during the hyperthermia, but section of the splanchnic nerves and removal of the lumbar sympathetic ganglia nearly or completely prohibited this decrease of the plasma creatinine clearance.

An increase in body temperature of 0.5° to 2.3° F., caused by conventional diathermy, resulted in no significant change in the clearance in two experiments and a decrease of 11 to 21 per cent in five experiments. In one other experiment the clearance increased 16 per cent during the initial hyperthermia, but became normal again, even though the hyperthermia was maximum.

The intravenous injection of typhoid-paratyphoid vaccine resulted in a maximum fever of 0.4° to 2.8° in 15 experiments performed on seven dogs. In 10 of these experiments, an increase in clearance of 8 to 47 per cent occurred before, during, or after maximum hyperthermia. In five experiments there was no significant increase in the clearance. In only two of the 15 experiments did a decrease in clearance occur.

An increase in body temperature between 1.0° and 0.5° F. occurred during the exposure of a dog to a current of cold air at 38° and 47° F. in two experiments, during which the clearance increased 30 and 18 per cent, respectively.

Heating by the two electrical methods caused a reduction in the rate of urine flow irrespective of the region of heat production. On the other hand, the hyperthermias of typhoid vaccine injection and exposure to cold had no appreciable effect on the urine flow. A decrease in urine flow was due to an increase in the rate of tubular reabsorption of water and was independent of changes in the creatinine clearance.

LABORATORY METHODS

GENERAL

A STUDY OF THE PHENOMENON OF ERYTHROCYTE SEDIMENTATION*

I. A CRITICAL SURVEY OF LITERATURE

ROY E. NICHOLS, B.V.Sc., M.Sc., PH.D.,† LAFAYETTE, IND.

IN ANY sedimenting system there are two components which must be considered—the suspending medium (dispersing phase) and that which is suspended (the dispersed phase). Blood within the vessels may well be said to have the components necessary to classify it as a system capable of presenting the phenomenon herein referred to as sedimentation. It has a fluid suspending medium (the plasma) and suspended material (the formed elements). A certain degree of sedimentation can be demonstrated even within the vessels themselves if samples at various levels between two tourniquets are examined.⁷³ Before samples of blood drawn from apparently healthy horses can clot, considerable separation of cells and plasma occurs, much as is reported in samples from human beings during severe disease and from women during the latter stages of normal pregnancy.⁷³

However, to measure the complete phenomenon of sedimentation of the formed elements of blood in their own plasma *in vitro* necessitates even in the horse, with its naturally very rapid rate of sedimentation, the use of artificial means of preventing clotting. The effects of this necessary alteration in the normal status of the blood upon the ultimate measurement of the phenomenon of sedimentation *in vitro* will be discussed later. Suffice to say that one should recognize that the determination of sedimentation *in vitro* represents not the phenomenon as it might occur in unaltered blood but rather as it occurs in blood necessarily changed to prevent clotting.

Despite recognition of the fact that a complete theoretical explanation of the phenomenon of sedimentation is probably impossible due to its marked complexity, mention of some of the various factors thought to be involved and the consensus of some of the experimenters concerning the relative value of these factors is included herein principally to convey the source of my conception of the sedimentation phenomenon. Due cognizance is given the possibility that the opinions of some of these workers may have been acquired from results of techniques which have not measured the phenomenon completely.

*From a thesis presented in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Graduate School of the Ohio State University, June, 1941.

This is the first of a series of four articles on the subject to be published in consecutive issues of the JOURNAL.

†Comparative Physiologist, Department of Veterinary Science, Purdue University.

Received for publication, April 3, 1942.

Reported data and opinions were segregated into six general groups: Physical Factors, Chemical Factors, Constancy, Physiological Factors, Technical Factors, and Pathological Factors. These were further subdivided where necessary. A conservative summary follows:

I. PHYSICAL FACTORS

a. *Cells vs. Plasma*.—Both cells and plasma are apparently necessary elements in sedimentation. Changes in any of the physical and chemical properties of cells or of plasma may exert a variable influence upon the rate of sedimentation, the magnitude of this effect apparently being dependent upon not only the degree of alteration in any of these properties but also the properties altered.^{28, 48, 58, 62, 72, 73, 87, 96, 110, 111, 115, 138, 188, 213, 214, 217, 221, 227, 248, 253, 265, 321}

b. *Specific Gravity*.—It would seem reasonable that for settling to take place the specific gravity of the formed elements must be greater than the specific gravity of the plasma. However, it also seems reasonable that the *degree of change* in the ratio of specific gravity of formed elements and plasma cannot by itself explain the magnitude of alterations in the sedimentation velocity which are encountered.^{24, 58, 72, 73, 115, 121, 149, 201, 214, 219, 225, 231, 301}

c. *Viscosity*.—It may be said that ever-present viscosity of the plasma resists the settling of formed elements in plasma but that *changes* in the sedimentation rate cannot be explained wholly upon the basis of *changes* in viscosity.^{8, 17, 24, 25, 58, 67, 72, 73, 93, 115, 124, 130, 150, 187, 214, 225, 229, 231, 253, 255, 258, 263, 265, 301}

d. *Movement of Plasma*.—The general movement of plasma is upward and tends to retard settling.^{72, 115, 150, 191, 241}

e. *Particle Size*.—It would seem that the size of the individual cell has an important bearing upon its fall, particularly in suspensions where there is no rouleaux formation or agglutination. In suspensions where cells aggregate, variations in the size of the agglomerates of cells bear a definite relationship to the changes in sedimentation of the agglomerates—the larger the agglomerate the more rapid its fall.^{2, 22, 24, 31, 38, 40, 50, 52, 58, 72, 73, 115, 145, 150, 214, 220, 225, 227, 241, 242, 250, 263, 288, 301, 321, 344}

f. *Number of Particles*.—Variations in the number of particles in a suspension produce variations in their rate of fall—the more present the slower each individual particle will fall. Since the number of cells present may influence, among other things, the number of aggregates, there probably exists a relationship between the number of aggregates and their rate of fall; with blood as a sedimenting system the more aggregates the slower their rate of fall.^{5, 18, 23-26, 29, 30, 33, 39, 48, 50-52, 58, 61, 67, 68, 72, 73, 76, 82, 89, 93, 96, 97, 99-102, 105-107, 109, 110, 113, 115, 125, 128, 136, 138, 142, 145, 150, 160, 170, 186, 190, 195, 203, 204, 211, 225, 227, 232, 233, 241, 242, 255, 257-259, 263-265, 272, 283, 288, 299, 318, 321, 322, 329-331, 333-335, 340, 341, 343, 344}

g. *Rouleaux Formation and Agglutination*.—It seems universally accepted that the rate of sedimentation is considerably dependent upon rouleaux formation and subsequent agglutination—the larger the agglomerates of cells the more rapid their rate of fall.^{4, 17, 24, 28, 48, 58, 62, 63, 65, 72, 73, 82, 87, 93, 96, 115, 120, 125, 132, 141, 149, 150, 184, 188, 190, 194, 201, 214, 217, 221, 226, 227, 231, 236, 238, 241, 242, 253, 256, 258, 259, 263, 274, 280, 288, 289, 310, 321, 335, 338, 344, 348}

h. Environmental Temperature.—It seems commonly agreed that decreases in the temperature of samples are accompanied by decreases in the rate of sedimentation, and that increases in temperature are associated with increases in the rate. It would appear that there is some difference of opinion as to the effects of heating plasma.^{5, 12, 61, 64, 72, 73, 79, 82, 93, 94, 96, 115, 145, 150, 156, 160, 161, 205, 211, 225, 227, 234, 241-243, 255, 258, 259, 283, 288, 300, 314, 321, 322, 329, 330, 340}

i. Other Physical Forces.—Apparently such forces as the electrical charge of the cell, potential difference, cohesive forces, surface forces, repulsive forces, and osmotic pressure, exert influence either directly upon the sedimentation of agglomerates themselves or indirectly upon the phenomena of rouleaux formation and agglutination.^{3, 8, 24, 28, 41, 48, 70-73, 82, 87, 96, 129, 139, 132, 141, 149, 152, 157, 176, 179, 190, 182-184, 201, 203, 211, 217, 221, 234, 238, 242, 253, 258, 264, 265, 280, 285, 288, 312, 325, 326, 344}

II. CHEMICAL FACTORS

a. Hemoglobin.—That hemoglobin within normal ranges bears a fairly constant relationship to normal values of sedimentation is to be expected but correlation between *changes* in hemoglobin and *changes* in sedimentation is debatable.^{5, 22, 31, 39, 40, 45, 48, 50, 99, 100, 106, 111, 115, 138, 203, 232, 259, 263, 264, 288, 321, 329, 330, 340, 344}

b. Venous, Arterial, and Capillary Blood.—The consensus seems to be that results from tests on venous, arterial, and capillary blood, as commonly obtained, agree.^{28, 54, 164, 204, 245, 258, 288}

c. Oxygen and Carbon Dioxide.—While large variations in the oxygen or carbon dioxide content of blood experimentally may produce some alteration in sedimentation, simple aeration of blood prior to determination of sedimentation seems to be of no important significance.^{26, 73, 82, 100, 139, 155, 172, 204, 211, 234, 235, 245, 258, 260, 261, 327}

d. pH.—There seems to be a difference of opinion as to whether variations in pH influence sedimentation even though some agreement exists that acidosis slows the rate and alkalosis hastens it.^{3, 5, 7, 8, 87, 156, 174, 201, 207, 228, 232, 234, 274, 344}

e. Protein Fractions.—It would appear that increases in fibrinogen, and to a lesser extent perhaps globulin, have an accelerating effect upon sedimentation while increases in albumin have a retarding influence.^{1, 5, 8, 9, 12, 23, 24, 26, 28, 37, 43, 46, 48, 50, 51, 53, 57-59, 69-73, 78, 80, 82, 84, 87, 89, 93, 96, 97, 104-107, 115, 122, 128, 130, 132, 135, 138, 142, 145, 147, 152, 160, 163, 170, 173, 179, 180, 188-190, 196, 199, 201, 204, 206, 213, 214, 218, 227, 230-234, 236, 245, 246, 253, 254, 257, 258, 263, 265, 267, 268, 271, 273-275, 277, 282, 288, 290-292, 299, 305, 312, 325, 327, 328, 330, 333, 337, 342-344, 348}

f. Cholesterol and Lecithin.—Increases in cholesterol are said to be accompanied by increases in sedimentation while increases in lecithin are said to be associated with decreases in sedimentation.^{44, 51, 58, 112, 115, 161, 162, 213, 232, 241, 247, 253, 254, 263, 274, 299, 320, 325}

g. Other Chemical Factors.—That other chemical factors such as bile products, chlorides, lactic acid, lipid equilibrium and nitrogen balance, may influence sedimentation is not doubted, but whether any of these can offer a complete explanation of the phenomenon of sedimentation is assumably dubious.^{5, 8, 12, 25, 28, 39, 58, 96, 115, 130, 169, 182, 183, 234, 252, 254, 262, 265, 325, 344}

III. CONSTANCY

In the opinion of the majority a certain constancy of results during health apparently can be expected. However, there is enough opinion to the contrary to sug-

gest a careful critique of these techniques since a multiplicity of techniques have been employed.^{15, 33, 53, 64, 103, 115, 134, 145, 164, 190, 211, 232, 235, 274, 286, 288, 312, 321, 343, 344}

The more literature that is reviewed the more one comes to realize that the phenomenon of sedimentation is very complex, and its measurement probably does not represent the measurement of any particular constituent or property or any limited group of constituents or properties of the blood sample being considered. It represents a measurement of a balance between, *on the one side*, the influence of *all* the constituents and properties, intrinsic or extrinsic, which augment the separation of the fluid and formed elements of a particular blood sample, altered so as to allow this separation to take place, and, *on the other side*, the influences of *all* the constituents and properties which delay this separation. If this conception be reasonable, then all constituents and properties, intrinsic and extrinsic, must be causal, even though variations in some may be of more relative importance than variations in others.

It would appear that alterations in the balance of these opposing constituents and properties may be the result of changes in the body itself (intrinsic) and changes brought about by the necessary manipulation of the blood sample (extrinsic or technical). Since the clinical value of the test probably lies in its use as a delicate measure of the intrinsic changes in the particular sample the result of disease, then the intrinsic changes of a normal physiologic nature and the extrinsic or technical factors which may produce changes in the manifestation of the phenomenon must be enumerated, evaluated, controlled or allowed for before the measurement of sedimentation can be said to reflect pathology.

IV. PHYSIOLOGICAL FACTORS

a. *Sex*.—The majority believe that the rate of sedimentation is faster in adult women than in adult men. There is some difference of opinion as to whether this difference can be accounted for solely by the difference in volume per cent of cells as noted between men and women.^{10, 53, 72, 73, 96, 103, 105, 106, 108, 137, 138, 202, 259, 264, 340, 343}

b. *Pregnancy*.—Pregnancy is recognized as causing an increase in sedimentation, being first noted after the first few months, reaching its peak at parturition and gradually returning toward normal during puerperium.^{8, 11, 14, 27, 28, 48, 51, 57, 71-74, 82, 93, 96, 103, 127, 138, 180, 183, 184, 194, 201, 202, 211, 233, 250, 267, 270, 274, 283, 322, 330, 343}

c. *Menstruation*.—Some authors find an increase in sedimentation during menstruation. Others doubt an increase above normal limits.^{53, 103, 138, 180, 181, 274, 295, 322, 340, 343}

d. *Age*.—A difference of opinion exists regarding age but the majority find a slower sedimentation in adults than in young or old persons.^{53, 72, 73, 105, 138, 198, 202, 211, 225, 288, 301, 312, 343, 346}

e. *Food*.—That ingestion of food has no effect upon sedimentation seems at least generally accepted.^{48, 61, 97, 105, 145, 211, 258}

f. *Exercise*.—Again a difference of opinion exists. Probably the degree of exercise is important since enforced rest is reported as delaying sedimentation and overwork as increasing it.^{211, 225, 232, 258}

g. *Sweating*.—Profuse sweating by electric baking had no effect on sedimentation.⁸

h. *Excitement*.—Tests taken at times of greater excitement in children gave higher readings.³¹²

i. *Time of Day*.—A difference of opinion exists as to whether or not the time of day has any direct effect upon the sedimentation rate.^{134, 164, 211, 258}

j. *Atmospheric Conditions*.—Atmospheric conditions are reported as having some effect on sedimentation.^{94, 134, 146, 225, 301, 312}

V. TECHNICAL FACTORS

1. It would seem that *agreeable results* upon the same sample can be obtained with certain techniques. However, literature upon this subject is very deficient and techniques differ considerably.^{72, 115, 308, 310}

2. It seems commonly accepted that *venous stasis* should at least be minimized, since if it is applied in excess, sedimentation is usually considerably retarded.^{82, 93, 145, 204, 211, 232, 234, 259, 264, 265, 288, 321, 330}

3. Too little *anticoagulant*, as well as too much anticoagulant, is to be avoided. Anticoagulant and blood must be properly mixed. Different anticoagulants yield different results. Although solutions of sodium citrate have probably been used more than any other anticoagulant, the present tendency is to lean toward the anticoagulant mixture of *Heller and Paul*¹²³ and toward heparin, for these two seemingly produce little variation in cell volume as well as sedimentation. Differences of opinion naturally exist concerning the proper kind and amount of anticoagulant to use.^{8, 20, 23, 29, 32, 39, 50, 51, 58, 60, 64, 72, 76, 95, 101, 105, 109, 115, 119, 123, 125, 133, 140, 190, 216, 221, 224, 232, 235, 241, 245, 249, 257, 258, 264, 280, 288, 311, 321, 322, 329, 340, 341, 345}

4. It would seem that the general consensus is that *delay* in conducting a measurement of the sedimentation of a sample may cause retardation of the rate. The maximum amount of permissible delay reported is variable from a few hours to several hours. It is suggested that the retarding effect of delay may bear some relationship to the kind of anticoagulant used and also the temperature at which the sample is kept.^{29, 51, 54, 60, 64, 72, 75, 93, 108, 115, 119, 136, 142, 154, 156, 164, 185, 186, 201, 211, 224, 227, 239, 240, 242, 258, 259, 281, 283, 288, 329, 330, 338, 340, 344, 348}

5. Although it has been recognized that a *uniform mixture of cells and plasma* is necessary at the start of measurement of sedimentation, it would seem that little attempt has been made to demonstrate that such a uniformity is actually established.^{50, 55, 94, 115, 136, 154, 164, 185, 211, 258, 259, 308}

6. There has been a multiplicity of *tubes* used for the measurement of sedimentation. However, there seem to be certain generalities which are quite commonly accepted. Capillary tubes are thought not to be dependable. The majority of workers used tubes of over 2 mm. bore and apparently thought them satisfactory. The general opinion seems to be that longer tubes yield faster rates, yet there is reason to doubt this upon a physical basis. It seems recognized that the sides of tubes should be parallel and the bottoms should be flat.^{8, 10, 12, 17-19, 26, 28, 29, 33, 36, 50, 51, 54, 55, 57, 58, 60, 64, 72, 76, 78, 79, 82, 94, 96, 101, 106, 108, 109, 114, 115, 118, 137, 145, 154, 164, 171, 180, 193, 198, 204, 211, 214, 225, 227, 234, 235, 241, 250, 258, 259, 263-265, 273, 278, 287, 288, 293, 315, 317, 321, 322, 325, 329, 330, 340, 341, 343, 348}

7. The necessity of *perpendicularity of the tube* seems generally recognized.^{12, 17, 19, 29, 34, 36, 42, 64, 73, 79, 114, 115, 154, 164, 191, 193, 210, 211, 225, 227, 235, 241, 259, 264, 293, 317, 321, 330, 340, 348}

8. It appears generally accepted that sedimentation takes place in three stages: (a) Initial aggregation and accelerated fall. (b) Constant fall. (c) Slowing or retarded fall.

There is evidence that sedimentation occurs as a sigmoid curve. This would render dubious the possibility of a phase of constant fall.^{17, 29, 33, 58, 64, 73, 115, 191, 215, 259}

9. There exists a great variety of *methods of expressing sedimentation*, the great majority of which depend upon a relationship between the position of the line of demarcation between cells and plasma and the amount of time since the test was begun. Some have used the amount of time necessary for the border between cells and plasma to reach a certain mark, some have noted the position of this line at a given time, and others have expressed the descent of this border line by reading its position at definite time intervals. Many of the mentioned methods probably fail to express the phenomenon *completely* and some probably do not represent expression of *any part* of what is generally considered the most important phase of the phenomenon, namely, aggregation. Multiple readings of the degree of settling at frequent time intervals or mechanical means of measuring the rate seem to offer advantages.

It is felt that evidence from results with an automatic photographic device, which continuously records the rate of descent of the line of demarcation between cells and plasma,²¹⁵ is convincing that the best measurement of the phenomenon of sedimentation, as evidenced by the rate of descent of the line of demarcation between cells and plasma, is a continuous measurement with estimation of the point of change in the resulting sigmoid curve. Such estimation, if even partially to express the important aspects of the curve, must include the amount of separation before the point of change takes place, the time at which the point of change occurs, and the rate or velocity of separation immediately preceding the point of change (expressed as an angle between the steepest portion of the sigmoid curve and perpendicularity).^{7, 10, 12, 17-19, 23-25, 29, 30, 33, 36, 37, 50, 53, 55, 57-59, 61, 64, 68, 69, 72, 73, 76, 79, 88, 93, 94, 96, 99-101, 103, 105-108, 110, 113-115, 118, 119, 134, 136, 137, 150, 154, 159, 164, 171, 180, 181, 186, 190, 194, 195, 198, 201, 211, 214, 215, 218, 225, 227, 235, 241, 258, 259, 264, 265, 273, 278, 287-289, 293, 295, 298, 301, 302, 308, 315, 317, 321, 325, 328-331, 333, 334, 340}

VI. PATHOLOGICAL FACTORS

Inclusion of several references brings out the generally accepted theory that alteration of the sedimentation phenomenon portrays metabolic changes—the result of nonspecific destructive disease.^{5, 11, 28, 33, 47, 48, 51, 53, 55, 57, 72, 76, 78, 79, 87, 103, 110, 114, 115, 174, 195, 198, 201, 211, 259, 265, 274, 325, 330, 339, 343}

The second of this series of articles will deal with the establishment of a reliable technique with evidence of its reproducibility and limitations.

THE EFFECT OF OPERATOR ON THE VARIABILITY OF BASAL METABOLISM DATA

DENA CEDERQUIST,* MANHATTAN, KAN.

STUDIES of basal metabolism reported in the literature suggest that all tests were made under standard conditions. Standard conditions for the determination of basal metabolism have come to mean that the person was in a postabsorptive state, comfortably warm, had a normal body temperature, was awake but at complete rest and free from the effects of physical exercise, mental and physical irritation, and fear. As it is almost always possible to meet these conditions, the error associated with technical procedure would be expected to be reduced to a minimum. Thus two successive observations made on one person under the foregoing conditions should agree closely, or in the language of the statistician, the two observations should show little intraday variation. However, in actual practice, more or less variation tends to occur.

In this laboratory 450 tests on 225 women between 15 and 45 years of age were made under what were believed to be standard conditions. A Benedict-Roth closed circuit machine was used. In most cases the subjects were brought to the laboratory by car and were required to rest in bed one-half to one hour before the observations were made. A few of the tests were made in a women's residence hall. For these, the metabolism apparatus was moved into the subject's room, and the observations were made in the morning before she arose. Two eight-minute tests with a three- to five-minute rest period between them were made on each person. All observations were used unless some obviously disturbing factor, as an unexpected noise, affected the test. Five technicians were responsible for collecting these data.

Because the observations were made under standard conditions using the same equipment, it would seem logical to expect that the variation observed in individual records made on the same day would be of the same magnitude for the entire group. To determine if this were true, an analysis of variance was made on the 450 tests with the records divided on the basis of the technician who made the test. That portion of the analysis relative to the variation observed in records made on the same day is shown in Table I.

In the interpretation of this portion of the analysis of variance, the size of the mean square is used as a measure of intraday variation. The larger the value of the mean square, the greater is the variation in the observations made on one person on any given day. It can be seen from Table I that this variation,

*Formerly of the Division of Home Economics, Kansas State College.

Approved for publication by the Advisory Committee as Paper No. 7 of the Regional Project of the North Central States Relating to the Nutritional Status of College Women.

Contribution 95, Department of Home Economics, Kansas Agricultural Experiment Station, Kansas State College.

Contribution 105, Division of Home Economics, Kansas State College.

Received for publication, March 2, 1942.

as indicated by the value of the mean square, is not the same for all technicians. It will be noted that for Technician O the mean square of the records on the same day is about two and one-half times that of Technician B. This difference is great enough to be of statistical importance. It indicates that successive tests made by Technician O show significantly more variability than those made by Technician B. This observation has suggested that in this study, where the same piece of apparatus was used each time under what is believed to be standard conditions, some of the differences in the amount of intradaily variation may be attributed to the technician.

TABLE I
ANALYSIS OF INTRADAILY VARIATION

TECHNICIAN	DEGREES OF FREEDOM*	MEAN SQUARES†
B	62	1.42
C	232	1.61
R	42	2.17
K and C	124	2.18
O	48	3.48

*Degrees of freedom = (n-1) where n refers to the number of observations.

†Mean square or variance = $\frac{\text{sum of the squares of deviation from mean}}{\text{degrees of freedom}}$

No definite explanation for the differences noted between technicians is offered, but a plausible suggestion is that they may be due to differences in sensitivity of the observer. For example, one technician might note every unexpected noise, draft, or bright light which could disturb her subject and would discard the test because it was not done under standard conditions. Another operator might not recognize such disturbing factors and would believe that standard conditions had been established when in reality they had not. Also, not all persons approach a given situation with the same degree of relaxation. If the operator is tense, it is possible to induce a tension in the subject without the latter realizing she has been disturbed. In either case a source of error has been introduced which will increase intradaily variation.

Part of the intradaily variability in basal metabolism tests on the same person may often be attributed, therefore, to some characteristic of the technician. When all technicians are carefully trained, the differences in variability cannot be attributed to careless workmanship, but may be accounted for by differences in sensitivity to the interpretation of standard conditions. This study suggests that, even though standard methods have been outlined for the determination of basal metabolism tests, it is possible for the technician to introduce variability and thus decrease the reliability of the tests.

LABORATORY SHAKING MACHINE*

E. E. MYERS, M.D., PHILIPPI, W. VA.

A STURDY, silent shaking machine, which can be easily built in a small machine shop, is shown in the photograph. The diagram gives detail of construction. The length and period of excursion are those specified for use in the Kahn test. With used connecting rods and a used motor the machine can be built for twenty-five to thirty dollars.

Fig. 1 in the diagram is a side view of the shaking machine. The rocking arms are model A Ford connecting rods with the crankshaft-bearing portions cut off. They are welded together to make an overall length of $10\frac{7}{16}$ inches. The wrist pins must be parallel; this can be accomplished by a wooden jig that has parallel blocks on which the pins are held by clamps during the welding.

The wrist pins are clamped to the baseboard and top board by $\frac{3}{4}$ inch pipe clamps, the boards being hollowed slightly to allow the connecting rod parts which extend beyond the wrist pins to have freedom of movement. Side motion is prevented by the lock rings in the connecting rods. The oil holes on the bottom pieces are plugged with wooden plugs. Celluloid cement can be coated over the ends of the plugs to prevent seepage of oil through the paint. The oil hole at the top is left open to receive oil (about number 10 motor oil is used for lubrication). All wrist pins should be a medium tight fit only.

The throw arm is made from two V-8 Ford connecting rods with a short piece of model A rod welded between them to give a total length of $12\frac{1}{4}$ inches from center to center. The wrist pins of the throw arm are cut off just the width of the throw arm plus the thickness of two fiber washers which go one on either end of the pin. Fig. 7 shows another view of the connection of the throw arm to the rocking arm. The $\frac{3}{8}$ inch bolt is drawn up tightly, holding the wrist pin securely against the surface of the rocking arm, which, where the pin strikes it, is filed to a flat surface. The fiber washers shown as *F* in Fig. 7 then act as spacers for the throw arm, eliminating noise. The connection of the throw arm to the eccentric is made in a similar manner. The plate for the eccentric is shown in Fig. 6. The holes in it must be parallel, and after it is welded to the shaft of the bearing shown in Fig. 5, the surface to which the throw arm is connected should be machined in a lathe to give a flat surface parallel to the throw arm. This is essential to prevent binding of the throw arm during rotation of the eccentric. The $\frac{3}{8}$ inch machine bolts used to fasten the throw arm bearings are somewhat smaller than the holes in the wrist pins through which they pass, and this permits adjustment of the arm on the eccentric to produce the exact excursion of the top board of $1\frac{1}{2}$ inches.

*From the Laboratory of the Myers Clinic, Philippi.
Received for publication, March 5, 1942.

Figs. 1-7.

The bearing illustrated in Figs. 3 and 5 is an automobile packless type water pump ball bearing and shaft, New Departure, No. 885156S, 108556. While welding the plate to the shaft of this bearing, care must be taken to prevent the bearing from becoming too hot, as by wrapping wet asbestos paper around it. Electric welding is necessary here. The bearing case is pressed into a piece of 1 inch pipe coupling which can be used without alteration, i.e., the threads are left intact. Before the bearing is fitted, the coupling is welded to a piece of $1\frac{1}{4}$ inch pipe, as shown in Figs. 3 and 4. This pipe is welded to a plate which forms the base to be attached to the bottom board by four bolts.

Fig. 3.

Fig. 8 is a top view of the completed machine. The boards forming the clamp for the Kahn racks are covered with rubber cut from stair tread. These rubber pieces can be cemented or tacked with small brads. Carriage bolts $\frac{1}{4}$ by $3\frac{1}{2}$ inches are used to attach the end board. A block with a V in it can be made for holding a bottle, permitting it to be clamped in place of a rack.

The motor is a 1,750 r.p.m. and $\frac{1}{30}$ h.p. (or larger). Using a $1\frac{1}{2}$ inch pulley on the motor, the speed will be slightly slower than that required. The speed can be increased by wrapping tire tape around the pulley in a direction opposite that of its rotation. The speed is checked after each addition of one or two layers of tape until the revolutions per minute of the large wheel, as determined by a speed indicator (or by oscillations of the top board), are between 275 and 285.

Diameters of pulleys are $1\frac{1}{2}$ inches and 9 inches. The pulleys may be obtained from Central Die Casting and Manufacturing Co., Chicago, as 150A and 900A, respectively. Length of belt is $33\frac{1}{2}$ inches. It is a V belt, Goodrich, FHP No. 1340.

A METHOD FOR MEASURING THE TENSILE STRENGTH AND STRETCH OF PLASMA CLOTS*

I. M. TARLOV, M.D., ALVIN I. GOLDFARB, M.D.,† AND BERNARD BENJAMIN, M.D.
BROOKLYN, N. Y.

IN THE course of experiments on autologous plasma clot suture of nerves,¹ a somewhat crude but simple method of testing the tensile strength and stretch of clots formed in vitro was devised. This technique has since been improved and in its present form has given fairly consistent measurements which have aided in the determination of the most suitable types of plasma clot for use as nerve suture material. Since the method may be of use in other fields of investigation, particularly the hematologic, a description of it is considered advisable. Careful search of the literature has disclosed previous methods for measuring the tensile strength and stretch of plasma clots.^{2, 3} However, the present method, which was independently evolved, appears simpler, more readily constructed, and seems to us more suitable for accurate determination of these values.

Blood is drawn in a chilled syringe coated with mineral oil and is immediately transferred to paraffin-lined test tubes packed in ice. The tubes are placed in 250 c.c. metal cups filled with ice and are centrifuged for from five to seven minutes at 2,750 r.p.m. Centrifugation for longer periods often results in clotting of the plasma. On removal from the centrifuge the tubes are at once repacked in ice, and the supernatant unmodified plasma is ready for use. If blood to which an anticoagulant has been added is used, it is chilled and centrifuged in an identical fashion.

One cubic centimeter of the plasma is pipetted into a test tube of 8 mm. inside diameter in a water bath at 37° C. and allowed to clot. When a clotting agent is used, it is placed in the test tube in the water bath for a brief interval before addition of the plasma so that the temperatures may be as constant as possible throughout. After coagulation the clot is withdrawn from the tube by touching the tip of a heated platinum wire to the upper surface. The clot adheres to the wire and can easily be lifted out. When clot retraction has not occurred and the clot adheres to the test tube, a fine cool platinum wire is run carefully around the clot to loosen it.

The upper end of the clot is grasped in the rubber-sleeved jaws of a small hemostatic clamp held horizontally by means of a support, clamp holder and clamp. A common pin is pushed through one of the rubber sleeves and points to the zero mark of a millimeter rule held vertically by another clamp affixed

Received for publication, March 6, 1942.

Fig. 1.—A, Metal centrifuge cup and enamelware pot containing test tubes packed in ice; B and C, removal of plasma clots from test tubes by heated platinum wire; D, grasping clot in clamp.

Fig. 2.—A, Application of clip to clot, leaving 1 cm. free for testing; B, stretch of 1.5 mm. following application of clip; C, use of apparatus for measuring tensile strength and stretch of clots. Clot shown supports clip and weights totaling 15 Gm. with stretch of 4.5 mm.

to the same support. The rule is just behind and to the side of the clot. The end of the pin pointer is fixed to the zero mark of the rule with a drop of collodion. This zero mark is permanently adjusted to correspond to the junction of the clot and clamp (Fig. 1). A light "radio clip" with the cylindrical wire guide cut open and bent to form a hook and with rubber-sleeved flattened jaws is clipped to the lower end of the clot. One centimeter of free clot is left for testing. Through one of the rubber sleeves of the clip is another common pin which indicates a mark on the rule level with the junction of clot and clip. A heavy silk thread is knotted about the upper pointer, strung parallel to the rule, and fixed to the clamp below. This serves as a guide for the lower pointer which runs between the rule and the thread and also serves to damp the swing of the clip which results from the addition of weights. The stretch resulting from the application of the clip (weight 4.0 Gm.) and each additional weight load is measured as the increase in distance between the two pointers. Rubber bands (weight 0.5 Gm.) are slit so as to slip over the heads of weights, and the weights are thus gently added to the hook of the clip at intervals of fifteen to forty-five seconds until the clot breaks (Fig. 2). It was found convenient to remove all the weights at 40 or 45 Gm. and to substitute for them, adding the next increment, a single 50 Gm. piece. At this point the tendency of the clot to approximate its original length is recorded. This may be repeated at 90 to 95 Gm. by adding a single 100 Gm. piece after removal of the weights. A cotton padded drinking cup may be placed beneath the weights to catch them and the clip when the clot breaks. The tensile strength of plasma clots from 8 healthy adult human males was found to average 44 Gm. The values obtained from ill persons were frequently considerably higher. The stretch seems to be directly proportional to the weight load; each 10 Gm. increment causes an average stretch of 2 to 3 mm. The final increment causes a greater rapid stretching which results in the break of the clot. Further detailed studies of tensile strength and stretch are being carried out.

METHOD OF SUSPENDING BOTTLE*

E. E. MYERS, M.D., PHILIPPI, W. VA.

AN EASY method for suspending an inverted bottle as for use in a Wangensteen suction apparatus,¹ etc., is described.

Fig. 1.

Either Venetian blind cord or suspender cord is satisfactory. A piece about 3 feet in length (for a gallon bottle) is used to make a ring around the bottle with three loosely tied knots evenly spaced. A second piece of cord, about 10 feet long, is started down through one of these loops, brought around the neck of the bottle, crossed over and brought back up through the next loop. It goes through the iron ring (harness ring $1\frac{1}{4}$ inches in diameter) which is to suspend the bottle, passes down through the third loop and continues as above until there are two ropes through each loop. The ends of the rope are tied together and the knots in the rope around the bottle are drawn tightly.

Fig. 1 shows the appearance of the completed suspension.

PROTECTIVE CAPS FOR GLASS TISSUE GRINDERS*

EDWARD J. FOLEY, NOTRE DAME, IND.

TISSUE grinders consisting of paired tubes one within the other in which tissue fragments or bacterial clumps are emulsified are widely used in virus and bacteriologic work. The tubes are roughened and are made to fit snugly by grinding with abrasive powder.

Two types are principally used: (1) The TenBroeck grinder† made of heavy pyrex glass, and which is designed mainly for manual manipulation, and (2) those more or less similar in design to that described by Hanks, the plungers of which are activated by a mechanical rotary device.²⁻⁴

The use of grinders is accompanied by the risk of contamination of the material being ground by air-borne bacteria and of contamination of the operator with the material through splashing, etc.

The apparatus of Corper and Cohen³ and that of Hanks⁴ have devices to reduce the chances of contamination. The present report is concerned with a simple means of preventing contamination of the material and of protecting the operator when either the TenBroeck or Hanks type of grinder is used.

Devol gum rubber caps, such as are used for nursing bottles or centrifuge tubes, are selected which will fit over the mouth of the receptacle tube. A hole is punched in the center of the cap with a cork borer and the shank of the plunger is pushed through it. The hole should be of such size that the shank of the plunger fits snugly but without binding.

The grinder parts are wrapped separately for sterilization. The receptacle portion is plugged with cotton and may be dry sterilized. The plunger part, because of the rubber cap attached, must be autoclaved. After inserting the material to be emulsified, the lip of the receptacle tube is flamed, the plunger is inserted, and the cap is fitted over the outer tube with aseptic precautions.

The use of the protective cap is advantageous in grinding tissues by hand, since considerable manipulation for a time may be necessary and abundant opportunity for contamination is present.

Likewise, a protective device is desirable when cultures or tissues are emulsified using a mechanical rotor. The gum rubber caps described are more convenient than the holed cork stoppers used by Hanks, since diluting fluids can be aseptically introduced through the cap without stopping the motor by means of a syringe and hypodermic needle after rubbing the surface with alcohol.

A SIMPLE TEST TUBE RACK AND COMPARATOR*

ALFRED LEWIN COPLEY, M.D., KANSAS CITY, KAN.

THE rack for test tubes is very simple and space saving, as can be seen from Fig. 1. If a test tube without a lip is desired, the lip can be easily substituted by a rubber band placed around the top of the tube. Should it be necessary to observe the lower part of the test tubes for extended periods of time, a detachable block may be placed to support each end of the rack (Fig. 2).

Fig. 1.

Fig. 2.

Fig. 3.

Further, the rack can be used to complement a light box for comparative readings and thus is a part of a simple comparator for color intensity or for measuring the brightness of light reflected by the particles in suspension in a tube. It was used in our studies with the toluidine blue reaction for heparin.^{1,2} The interior of the light box is painted white and contains two fluorescent bulbs of sufficient length to fill the longitudinal axis of the box. Their light is reflected through a plate of milk glass and thus illuminates the samples under test. The box can be used also as a titration light.

Fig. 3 illustrates the comparator with a permanent rack for tubes containing standard solutions and a support for the sample rack described above. Both rack and comparator are constructed from wood and are, therefore, inexpensive to manufacture.

AN APPARATUS FOR THE SIMULTANEOUS MEASUREMENT OF INTRAMUSCULAR AND VENOUS PRESSURE*

LEWIS GUNTHER, M.D., AND HENRY H. HENSTELL, M.D.
LOS ANGELES, CALIF.

THE use of Henderson's modification of the instrument devised by Kerr and Scott¹ for the measurement of intramuscular pressure has certain drawbacks. (a) It requires the use of two men, both of whom must be trained in its use. (b) Especially difficult and a source of most errors is the reading of the end point when the meniscus begins to move in the capillary tube. (c) The need to refill constantly the capillary tube with sterile saline when frequent readings are desired.

Principally, the shortcoming of this method is the need for manpower greater than our team could furnish when simultaneous venous pressures were desired.

Tests conducted with the Henderson apparatus and our modification of the instrument by Wells, Youmans, and Miller² convinced us that the macroscopic gravity method for the measurement of the intramuscular pressure gave comparable results.

For convenience, the venous manometer and the intramuscular pressure manometer are mounted together. The sections can easily be disengaged for sterilizing (Fig. 1). The reservoir (*Rr*), which holds 50 c.c. saline, is connected through a glass stopcock (*S*) and a T tube to a 5 mm. glass tube with a 3 mm. bore (*M*). The outlet is controlled by a screw clamp (*Sc*) over a rubber tube which holds the female portion of a metal-connecting link (*C*). The male portion is inserted into rubber tubing, which in turn is connected to a needle adapter, and the 26 gauge needle which is inserted into the muscle.

TABLE I
INTRAMUSCULAR AND VENOUS PRESSURE READINGS OVER A PERIOD OF 60 MINUTES

PATIENT	TIME (MIN.)	INTRAMUSCULAR PRESSURE (MM. H ₂ O)	VENOUS PRESSURE (CM. H ₂ O)
P	0	82	6.9
	7	84	6.6
	12	80	6.7
	17	80	
	20	74	
	30	77	7.9
	35	73	8.1
	45	73	7.9
	60	73	8.2

*From the Cedars of Lebanon Hospital, Los Angeles.

Aided by a grant from the Ciba Pharmaceutical Products, Inc., Lafayette Park, Summit, N. J.

Received for publication, March 9, 1942.

The venous manometer is similarly constructed, but the tubing of the funnel and the manometer is split to facilitate sterilizing. The manometer and the reservoir tubes are connected by standard glass or metal-connecting links (Fig. 2).

Fig. 1.

Fig. 2.

Fig. 1.—Apparatus for the simultaneous measurement of intramuscular and venous pressure, assembled after sterilizing.

Fig. 2.—Upper part of apparatus removed to show glass and metal connections and slot "V."

A vertical piece of metal (*V*) is mounted front and back to reinforce and give rigidity to the extension piece which is slotted (Fig. 2) to slip over the screw that is tightened lightly when the apparatus is assembled.

The venous reservoir (*Rv*) is filled with 3 per cent sodium citrate and the venous pressure needle is gauge 18.

The intramuscular reservoir (*Rm*) is filled with saline. The special slotted needle described by Henderson¹ is inserted into the muscle. The zero level of

the apparatus above the floor is determined by means of a water air bubble level, attached to a stiff steel tape (Fig. 3).

The level of the needle in the vein and in the muscle and the level of the auricle are obtained by the same means. The manometer tubes are filled from the reservoir, and are permitted to attain their level by gravity. It takes about five minutes for the fluid to equilibrate with the muscle and two to three minutes in the vein. Thus continuous readings of the intramuscular and venous pressures can be made at five-minute intervals.

Fig. 3.—Steel tape and water level arrangement for obtaining zero point of apparatus, auricular level, and levels of the intramuscular and intravenous needles.

Difficulty with the reading may be had with the first intramuscular pressure reading. It may be necessary to pull the needle back or to insert it deeper to obtain a free fall of the fluid level in the manometer. A second and a third check reading will ascertain the workability of the apparatus. Thereafter, readings may be obtained over a long period of time merely by refilling the manometer tube from the reservoir to a level above the value of the intramuscular pressure and allowing it to fall by gravity. Likewise, the vein is flushed with 3 per cent sodium citrate from time to time to keep the needle clear, and continuous readings may be taken at will.

It will be found that intramuscular pressure readings will vary over a range of 10 mm., and venous pressure readings over a range of 2 cm. in any series of readings (Table I). The latter will vary only 1 cm. if the patient is quiet, not straining or coughing, but will vary over 2 cm. range if the patient is apprehensive.

AN IMPROVED ROUTINE TISSUE STAINING TECHNIQUE FOR FORMALIN-FIXED TISSUES²

HENRY S. BLANK, A.B., M.D., COLUMBIA, S. C.

AS A MATTER of convenience, time, and economy the time-honored routine tissue stain has been that of hematoxylin and eosin, almost to the exclusion of any other. The technique is simple, even for inexperienced hands; the results are adequate for routine diagnosis of surgical and necropsy pathology. The stain has its limitations, however, particularly in the presentation of certain histologic and pathologic structures. The chromatic expression of these structures in stained sections has given rise to a host of special stains which are individually applicable. Lack of time, material, and technical assistance has limited the use of these techniques. This is especially true of smaller pathologic laboratories. It follows that any technique that will give better and more extensive detail with a minimum of complexity will be welcomed.

Of the several other generally advocated routine tissue staining techniques, the Mallory eosin or phloxine methylene blue procedure has few peers. However, the effective presentation of histologic detail by this method is beset by several difficulties. Among these are the more or less axiomatic requirement of Zenker fixation, length of staining time, individual differentiation of slides under the microscope, and finally, lack of uniformity of results except in expert hands.

It was the aim of this laboratory to effect a staining technique that had the advantages of the methylene blue eosin system with none of its disadvantages.

GENERAL PRINCIPLES

Oehlacher's discovery of the mordanting action of formaldehyde on coal tar dyes was utilized in the preparation of a methylene-blue-azure mixture.¹ Giemsa stain was added to the methylene blue as a source of the azures. It appears to contribute a generally wider chromatic scale by giving additional variation in the shades of blue.

Mercurochrome 220, commonly used as a disinfectant, replaced eosin. This dye is dibrom-oxymerecury-fluorescein and is closely related to eosin which is tetra-bromfluorescein. Conn² quotes Baldwin as stating that it may be used in

It was determined that the 2 per cent aqueous solution gave far too brilliant results, and that a dilution of 0.1 per cent was more than adequate. The stain has an apparent specific affinity for cytoplasmic structures and is not easily washed out. The diffuseness of staining, so characteristic of eosin, is quite absent.

6. Hematoxylin, Delafield—five minutes.
7. Wash in two changes of water to remove excess stain.
8. Decolorize until rose colored in water to which several drops of concentrated hydrochloric acid have been added.
9. Wash in water.
10. Wash until blue in water to which several drops of strong ammonium hydroxide have been added.
11. Wash in water.
12. Mercurochrome solution—one minute.
13. Wash in water to remove excess stain.
14. Methylene blue—azure stain—two minutes.
15. Wash in water to remove excess stain.
16. Decolorize in 95 per cent alcohol until no more color is seen to come off in drippings, about fifteen to thirty seconds.
17. Wash briefly in 95 per cent alcohol and complete dehydration in two changes of absolute alcohol.
18. Clear in two changes of xylol.
19. Mount in balsam.

It is desirable to filter the mercurochrome before using, to remove the bright golden seum which forms on standing for any length of time. A 0.1 per cent aqueous solution has been found satisfactory, without the addition of

alcohol, but the latter appears to give slightly better results. No particular improvement was noted by the addition of colophony to the differentiating alcohol.

Staining by this technique appears to give greater nuclear detail than is observed by hematoxylin and eosin. Fibrous tissue is sharply differentiated from muscle tissue. Inflammatory and blood elements are exceptionally prominent and present detail in both nucleus and cytoplasm. Other structures stain as in the Mallory technique.

SUMMARY

A new staining technique is presented which is suitable to routine tissue sections fixed in formalin. It is simple, does not require individual microscopic differentiation of sections, and produces excellent and uniform results even in inexperienced hands.

A NEW DEVICE FOR THE APPLICATION OF SCALP ELECTRODES IN ELECTROENCEPHALOGRAPHY

ROBERT COHN, M.D., WASHINGTON, D. C.

THE device consists of a spring air valve seated in a brass or plastic casing. Fig. 1 shows in longitudinal section the essential design characteristics and mechanism of the device. The total weight of the electrode applicator, with brass casing, is less than 15 Gm.

METHOD OF USE

The scalp surface is prepared according to standard procedures. The solder pellet electrode is then held in position by placing the valve pin on the electrode and making gentle pressure on the thumb rest of the electrode applicator. A drop or two of collodion is then allowed to flow over the electrode. To hasten the setting of the collodion, it is necessary to disperse its volatile solvents. This is readily accomplished by a blast of air from the device. A moderate increase in the pressure exerted on the thumb rest of the electrode applicator opens the valve and allows the compressed air to escape through the applicator outlet. Three to five pounds per square inch of pressure is quite adequate for efficient drying. Since only low pressures of air are required, the electrode applicator can be con-

*From the Laboratories of St. Elizabeths Hospital, Washington, D. C.

Received for publication, March 31, 1942.

needed to the compressed air-reducing valve (from tank or line) by means of thin-walled rubber tubing. This adds much to the general ease of manipulation of the device.

Fig. 1.

CONCLUSIONS

This electrode applicer simplifies the technique of electrode application for the following reasons:

1. Ease of manipulation resulting from its compactness and lightness.
2. Efficiency of operation.
3. More firm and more uniform application of electrodes result from the minimum pressure required to open the air valve.
4. Rapidity of electrode application because of the proximity of the air blast to the applied electrode.

CHEMICAL

SIMPLIFIED OXYGEN ANALYZER FOR OXYGEN TENTS*

A. H. ANDREWS, JR., M.S., M.D., AND L. W. ROTH, PH.D.
CHICAGO, ILL.

THE importance of oxygen concentrations in the therapeutic uses of oxygen has received considerable emphasis. In spite of this, many oxygen tents are not controlled by oxygen concentration determinations.

Many oxygen tent analyses were made and the majority of the determinations showed oxygen concentrations to be from 30 to 45 per cent. After the nurses were instructed to flood the tents more frequently, the concentrations were somewhat higher but were still not satisfactory. It was also apparent that regulation of the concentration by a technician to 50 per cent or over three times a day would not maintain the concentrations satisfactorily between his visits because of the nursing care which necessitated opening the tents. It was concluded, therefore, that oxygen analysis by the nurses was necessary in order to maintain the desired concentrations.

The following criteria were considered essential for an oxygen analyzer suitable for use by nurses: 1. Use of equipment familiar to nurses. 2. No adjustment of fluid level. 3. Absence of valves. 4. Reasonably foolproof. 5. Inexpensive. 6. Accuracy within plus or minus 2 per cent.

The analyzer described below was devised. The fifteen which were built and used for two years with satisfactory results fulfilled the above-mentioned criteria.

DESCRIPTION

The analyzer consists of a 200 c.c. glass jar (see Fig. 1) filled with No. 30 pure copper cloth. A No. 11½ rubber stopper is drilled to hold a glass tube 8 mm. in external diameter and 10 inches long, and to hold firmly the tip of a standard 10 c.c. syringe. The glass tube extends from the bottom of the jar high enough so the fluid does not overflow. The lower end of the tube is constricted by heating and the upper end is closed with a small toy balloon.

The scale consists of a strip of paper cemented to a strip of light brass and held on the tube with rubber bands. The scale is calibrated by injecting with the syringe the following amounts of air, and after the fluid stops dropping, the level is marked at the concentration as indicated: 10 c.c. of air, 21 per cent; 8.75 c.c., 30 per cent; 7.5 c.c., 40 per cent; 6.25 c.c., 50 per cent; 5 c.c., 60 per cent; and 3.75 c.c., 70 per cent.

The solution in the copper-ammonia-chloride reagent, recommended by Badger,¹ consists of equal amounts of water and concentrated ammonium hy-

*From the Oxygen Therapy and Clinical Research Departments of St. Luke's Hospital and the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.

Received for publication, May 2, 1942.

dioxide (28 per cent) saturated with ammonium chloride. This solution does not give off enough ammonia to be objectionable. As it becomes exhausted, the solution forms a yellow precipitate which can be dissolved with a small quantity of the fresh solution.

Fig. 1.—Simplified oxygen analyzer. 1, Toy balloon; 2, glass tube; 3, scale; 4, syringe; 5, rubber stopper; 6, glass jar; 7, roll of copper cloth.

TECHNIQUE

A 10 c.c. syringe, moistened occasionally with water, is attached to the oxygen sampling outlet or catheter extending into the tent and flushed four to six times. The plunger is withdrawn to the 10 c.c. mark, the syringe is detached, and the tip is covered with the finger. The tip is inserted into the hole in the rubber stopper, care being taken not to let the plunger move during the procedure. The plunger then is pushed down gently and twisted until it sticks. After the fluid level in the tube is stationary (within twenty seconds to one minute), the concentration is read on the scale. The syringe is left in place until the next analysis.

Once every day or two the scale is checked by an injection of 10 c.c. of air. If the level does not stop at the 21 per cent mark, the scale is adjusted as necessary. This, like the replacing of the solution, should be done by a technician or by the supervisor of the oxygen therapy.

DISCUSSION

An oxygen tent is no better than the oxygen concentration. Oxygen administration is similar to administration of any medicine, and the significance of

the dosage should be recognized and controlled. Analysis by a technician at intervals is valuable, but inasmuch as the tent may have to be opened for nursing attention between analyses, there are periods when the concentration drops.

This analyzer is designed for the nurse to use. She is instructed to make an analysis each time the tent has been opened and closed, and to adjust immediately the concentration to 50 per cent or over. In addition, the concentration is determined every hour. This frequent testing of the concentration also makes the nurse realize that frequent unnecessary opening of the tent is detrimental to the patient.

The time required for the analysis is almost negligible. Withdrawing the sample and injecting it into the analyzer requires less than thirty seconds, and the nurse can return in a minute or two and read the concentration.

The cost of the material for making the analyzer itself is small; the syringe, furthermore, is a standard hospital item. The apparatus can be made in any laboratory equipped with the necessary hole cutters and metal shears. This inexpensiveness makes it possible to have several on hand. When the solution becomes exhausted, another can be substituted.

SUMMARY

An oxygen analyzer is described, which has been designed specifically for use by nurses. The analyzer is reasonably accurate, simple to use, inexpensive, and can be made in the ordinary laboratory.

Analysis of the oxygen concentration after each time the tent is closed and at frequent intervals increases the efficiency of the therapy.

THE SPECTROPHOTOMETRIC DETERMINATION OF PHOSPHORUS AND CHOLESTEROL*

MILDRED KAUCHER, M.S., VIRGINIA BUTTON, A.B., AND
HAROLD H. WILLIAMS, PH.D., DETROIT, MICH.

RECENT advances in the development of spectrophotometric instruments for precise color measurement make it possible to attain equal or greater accuracy in chemical analysis and to employ procedures which have been hitherto unavailable. Furthermore, they offer the advantage of increasing the number of determinations that may be performed in a given time. This paper presents the adaptation of phosphorus and cholesterol methods to the spectrophotometer.

PHOSPHORUS DETERMINATION

The boundaries of quantitative biochemistry have been greatly extended by Van Slyke and his associates through the development and application of the gasometric technique for the microdetermination of organic carbon.¹⁻³ The principle of their procedure has been adapted successfully to microquantities of inorganic phosphate,⁴ sulfate,⁵ calcium,⁶ and magnesium⁷ by manometric combustion of their organic precipitates. The introduction and use of special combustion centrifuge tubes^{5, 6, 8} permitting, without transfer, precipitation, washing, and combustion of the organic compound has simplified the method and expedited the time needed for carrying out the determination.

From the viewpoint of microtechnique and accuracy, the gasometric determination of phosphorus is ideal. The laboratory possessing a spectrophotometer, however, may use the present adaptation to advantage, since it facilitates with a similar degree of accuracy the analysis of large numbers of samples with less highly skilled and trained personnel, and eliminates any interference from contaminants such as atmospheric dust and carbon dioxide. Applying the following procedure, it has been possible to perform a large series of phosphorus analyses in one day whereas formerly two or three days were required.

The procedure of Kirk⁴ is followed up to the washing of the precipitated phosphoric acid in the form of strychnine phosphomolybdate. An aliquot (usually 6 ml.) of the phosphoric acid sample is placed in an ordinary 15 ml. conical pyrex centrifuge test tube. Two milliliters of the strychnine molybdate are added dropwise with continuous shaking and allowed to stand not less than ten minutes.† The tube is centrifuged, the supernatant liquid is decanted, and

*From the Research Laboratory of the Children's Fund of Michigan, Detroit.

Received for publication, May 4, 1942.

†In the original procedure of Kirk the reagent is added rapidly to the sample and the contents of the tube are thoroughly mixed. The tube is then permitted to stand for twenty to forty-five minutes to complete the precipitation. If carried out by the above modification, there is saving in time since precipitation is complete at the end of ten minutes.

Fig. 1.—Transmittance wave length curve for color of strychnine phosphomolybdate in dilute sodium hydroxide. Filter No. PC 6 used from 350 to 400 mμ. Filter No. PC 4 used from 400 to 700 mμ. Concentration of phosphorus, 0.025 mg. in 100 ml.

Fig. 2.—Concentration of phosphorus vs. transmittance.

the mouth of the tube is wiped free of any remaining liquid. Two milliliters of 1 per cent nitric acid are added, the precipitate is stirred with a glass rod, and the tube is centrifuged for five minutes. The washing with nitric acid is repeated twice (three washings in all); no stirring is necessary in the last wash. The precipitate is then dissolved in 2 ml. of 1 per cent sodium hydroxide, and

Fig. 3.—Transmittance wave length curve for color developed by cholesterol (clear circles) and cholesterol digitonide (filled in circles). Cholesterol concentration 0.6 mg. in 6 ml.

Fig. 4.—Concentration of cholesterol vs. transmittance. Maximum average deviation ± 0.6 .

the contents of the tube are completely transferred into a 100 ml. volumetric flask with distilled water. After making to volume, the sample is ready for color measurement.*

Fig. 1 shows the spectral transmittance curve of the strychnine phosphomolybdate in a dilute sodium hydroxide solution. From 400 to 550 $m\mu$ the

*In the present study the Coleman Universal Spectrophotometer was used. Any similar device that will allow for the selection of light of the proper wave length should be suitable.

absorption decreases to zero and remains there until 650 $m\mu$ is reached. Above 650 $m\mu$ there is slight absorption. Since the maximum absorption between 400 to 700 $m\mu$ was at 400, the spectral properties of the solution were examined between 350 and 400 $m\mu$. The maximum absorption was obtained at 375 $m\mu$.

TABLE I

COMPARISON OF SPECTROPHOTOMETRIC AND GASOMETRIC DETERMINATION OF PHOSPHORUS

PHOSPHORUS MG.	GASOMETRIC PHOSPHORUS MG.	RECOVERY GASOMETRIC PHOSPHORUS PER CENT	TRANSMITTANCE* PER CENT
0.0064	0.00648	101.3	77.0
0.0080	0.00808	101.0	71.0
0.0096	0.0098	102.2	65.3
0.0128	0.01276	99.6	56.4
0.0160	0.01388	99.3	48.3
0.0192	0.01922	100.1	41.4
0.020	0.0197	98.5	39.5
0.024	0.0244	101.6	32.6
0.0288	-	-	25.8
0.032	-	-	22.1

*Maximum average deviation ± 0.9 .

Table I shows the comparative values of a series of standards ranging from 0.0064 mg. to 0.032 mg. of phosphorus, as determined by both the spectrophotometric method and by the gasometric microtechnique. By plotting the transmission values against the quantities of phosphorus on semilog paper, a straight line results, as illustrated in Fig. 2, thus demonstrating that Beer's law is obeyed over the range of concentrations studied.

CHOLESTEROL DETERMINATION

There have been many procedures proposed for the determination of cholesterol. The microprocedure for the determination of free and combined cholesterol of Schoenheimer and Sperry⁹ achieves a degree of accuracy which has previously been obtainable only with the classical macrogravimetric technique of Windaus. Because of the weak color intensity in the small volume required by the method, the use of this excellent and precise procedure, unfortunately, has been limited to only those investigators possessing a photometer. Most of the available photoelectric measuring devices are not equipped with cells of the proper depth to volume ratio to make accurate measurement of the limited amount of faintly colored solution.¹⁰ The colorimeter has been employed for measuring the color, but it has not been altogether practical.^{9, 10} The Coleman Universal Spectrophotometer, however, which employs a square cuvette giving a depth of approximately 1.3 cm. for a volume of 6 ml., has proved satisfactory, provided the cholesterol digitonide is dissolved in double the quantities of reagents, as recommended⁹ for large precipitates.

The method up to the dissolving of the cholesterol digitonide for color measurement is exactly as given by Schoenheimer and Sperry,⁹ including the more recent improvements recommended by Sperry.^{8, 10} The cholesterol digitonide is dissolved in 2 ml. of glacial acetic acid, 4 ml. of acetic anhydride, and 0.2 ml. of concentrated sulfuric acid. After developing the color in accordance with the original method,⁹ it is measured in the spectrophotometer employing the

630 $m\mu$ wave band. From the spectral transmittance curves of cholesterol and cholesterol digitonide, as shown in Fig. 3, it may be noted that the maximum absorption occurs between 620 and 635 $m\mu$ for both compounds. Noninterference of the digitonide with the light absorption of cholesterol is a decided advantage, as was pointed out originally.⁹

Transmittance values were determined for 0.04 mg. to 0.7 mg. of cholesterol, encompassing a range higher than that given in the original method (0.02 to 0.015 mg.). This wider range has been made possible by doubling the amounts of digitonin used for precipitation of the cholesterol. The 1 ml. of digitonin solution recommended⁹ will precipitate the cholesterol completely up to and including 0.3 mg. Above 0.3 to 0.7 mg., however, 2 ml. of the digitonin solution are required to precipitate the cholesterol completely. If there is doubt as to the quantity of cholesterol in an unknown, 2 ml. of the digitonin solution may be used with as low as 0.1 mg. of cholesterol. A series of samples containing from 0.1 mg. to 0.3 mg. gave the same per cent transmittance values when precipitated with 1 ml. of digitonin solution as with 2 ml. Plotting the transmittance values against the concentration of cholesterol (Fig. 4), it may be noted that Beer's law operates over the range of concentrations studied.

SUMMARY

The gasometric phosphorus and the colorimetric cholesterol digitonide methods have been adapted successfully to use with the spectrophotometer without sacrificing original features of microtechnique, specificity, and accuracy. Phosphorus may be determined within the range of 0.006 to 0.3 mg., quantities similar to the gasometric method. For cholesterol it has been possible to enlarge the quantities (0.04 to 0.7 mg.) determined without loss of accuracy. As a result of these adaptations the above micromethods should find a wider application.

A MECHANICAL MANIPULATOR FOR SMALL PIPETTES*

FRANKLIN HOLLANDER, PH.D., AND JULIUS STEIN, B.S.
NEW YORK, N. Y.

IN THE course of some work on the chemical properties of native mucous secretion from the digestive tract, we encountered difficulty in delivering exact volumes of this extremely viscous material for microchemical analysis. Our analytical methods aim at a precision of better than 1 per cent, and they call for the delivery of 0.1 ml. samples with a considerable degree of reproducibility.

Fig. 1.—Manipulator for small pipettes.

Because of its extreme viscosity and tenacity, we found it necessary to draw the material up into the sampling pipette without overshooting the graduation as well as to deliver the sample with rinsing. Consequently, the usual oral method of manipulating a pipette was unsuited for this purpose, and it became necessary to employ a mechanical device. The following arrangement, embodying a simple mechanical principle, has proved so very efficient in our work, as well as for other purposes, that we describe it for the benefit of others, especially workers in clinical laboratories who frequently work with 0.1 ml. quantities.

Contrary to the usual procedure, the pipette and manipulator are supported rigidly in a ring stand. The vessel containing the material for analysis is supported underneath by one hand while the sample is being taken. Suction and delivery are both effected by mechanically controlled changes in the volume of air trapped in a small piece of rubber tubing. The upper end of this tubing (A) is closed with a piece of glass rod or with rubber cement; the pipette stem is at-

*From the Laboratories of the Mount Sinai Hospital, New York City.
This work was supported in part by a grant from the Friedsam Foundation.
Received for publication, May 18, 1942.

tached to its lower end at (*B*). The tubing is held between two rigid metal plates, the front one of which (*C*) can be driven gradually against the back one (*D*) by means of a screw with knurled knob (*E*). These plates are both 5 cm. long; their widths are 13 and 35 mm., respectively. The distance between the front of the supporting frame and the back plate is about 15 mm. A nut (*F*) soldered to the inside of the supporting frame serves to steady the movement of the screw without increasing the weight of the device. The pins (*G*) serve only to keep the front plate (*C*) from swerving from side to side, and the 15 cm. rod (*H*) supports the device on a ring stand.

Before the pipette is immersed in the liquid, the tubing must be compressed to a moderate degree; thereafter, gradual release of this pressure will serve to draw the liquid up to the graduation mark without overshooting the mark, and recompression will serve to deliver the sample as required. In order to insure complete filling and emptying of the pipette, the volume of air contained in the rubber tubing must be slightly greater than the capacity of the pipette. For 0.1 ml. samples we use a piece of red rubber tubing (inside diameter 4.5 mm., wall thickness 1 mm.) about 6 cm. long, exclusion of the upper and lower ends which are filled with glass. A similar device of slightly larger dimensions has been employed for pipettes of greater capacity.

SIMPLIFIED MICROMETHOD FOR BLOOD SULFONAMIDE DETERMINATION*

GILBERT M. JORGENSEN, M.D., ANCON, CANAL ZONE

IN THIS report is described a modification of the diazotization method¹ for quantitative determination of unconjugated sulfonamides in blood. The modification permits the use of smaller quantities of blood and lessens the time required for performance of the test. In accomplishing these advantages only a small degree of accuracy has been sacrificed.

A reduction in the amount of blood required to only 0.02 c.c. has made possible blood sulfonamide determinations on small laboratory animals without sacrificing their lives. The method has been applied without difficulty for blood sulfonamide determinations on mice. It has been used for six months for routine determinations on children receiving sulfonamides, and has proved satisfactory.

A saving in time required for performance of the test has been accomplished by omitting the precipitation of blood proteins which permits the determination to be carried out in one vessel.

An Evelyn photoelectric colorimeter with filter 540 M has been employed, though other photoelectric colorimeters should serve equally well. For measuring the blood ordinary 0.02 c.c. "hemoglobin" pipettes have been used.

*From the Department of Pediatrics, Columbia Medical School, and the Babies Hospital, New York.

Received for publication, June 1, 1942.

The reagents required are glacial acetic acid, 0.1 per cent aqueous solution of sodium nitrite, 0.5 per cent aqueous solution of ammonium sulfamate, and a 1 per cent aqueous solution of N-(naphthyl) ethylenediamine dihydrochloride.

PROCEDURE

To 2 c.c. of distilled water in a colorimeter tube add 0.02 c.c. of capillary blood with a "hemoglobin" pipette. Add 2 c.c. of glacial acetic acid and 1 c.c. of a 0.1 per cent aqueous solution of sodium nitrite. Shake. After one minute or more add 1 c.c. of a 0.5 per cent aqueous solution of ammonium sulfamate. Shake. As soon as the bubbles have risen to the surface, insert the tube into the Evelyn photoelectric colorimeter after adjusting the tube holder for 6 c.c. volumes and inserting filter 540 M. To obtain the first of the two readings necessary, adjust the galvanometer string to 5.0 on the lower scale (the midpoint, sometimes designated 50), remove the tube, and read the galvanometer. This first reading (air setting) serves as a blank and also enables one to calculate the hemoglobin concentration.

After the first reading has been obtained, add 0.02 c.c. of a 1 per cent aqueous solution of N-(naphthyl) ethylenediamine dihydrochloride from a dropper calibrated to deliver that amount per drop. Shake. After three minutes or more adjust the galvanometer string to the first reading, insert the tube, and obtain the second reading.

Calculation of the concentration of the sulfonamide present involves the use of the following formula:

Concentration of sulfonamide = $K (\log 5.0 - \log \text{second reading}) + C$.
K is a constant determined by using a hemoglobin-free solution of a sulfonamide of known concentration. C is a correction made necessary because of the presence of hemoglobin; within the range of hemoglobin values encountered, the correction necessary is approximately proportional to the hemoglobin concentration.

The concentration of hemoglobin may be calculated from the following formula:

Concentration of hemoglobin = $K' (\log \text{first reading} - \log \text{first reading of hemoglobin-free blank})$.

The correction $C = K (\log 5.0 - \log \text{second reading}) - K'' (\log \text{first reading} - \log \text{first reading of hemoglobin-free blank})$ may be incorporated into the first formula as follows:

Concentration of sulfonamide = $K (\log 5.0 - \log \text{second reading}) + K (\log 5.0 - \log \text{second reading}) - K'' (\log \text{first reading} - \log \text{first reading of hemoglobin-free blank})$. K, K', and K'' may be determined from standards of known concentration. The application of the above formula appears rather laborious; however, with the aid of a calculating machine one may prepare in a few hours a table listing the values for all galvanometer readings.

The correction, C, is not large; for sulfanilamide it amounts to about 1 per cent per gram of hemoglobin. For routine determinations, if an error up to 10 per cent is acceptable, one may simplify the standardization and the prepara-

tion of a reference table by omitting C from the formula and determining a constant K''' , using blood of average hemoglobin concentration in addition to a standard sulfonamide solution. A blank is not necessary except for the determination of the constants.

The most likely source of error results from the occasional adherence of bubbles to the side of the colorimeter tube. If the tubes are cleaned with cleaning solution, bubbles seldom adhere to the glass, and when present, they usually may be dislodged by shaking the tube.

ITEM

Meeting of Scientific Photographers

The Biological Photographic Association will hold its Twelfth Annual Convention in New York City September 10, 11, and 12. Present-day methods of obtaining photographs for teaching and scientific records will be discussed in detail. Particular emphasis will be placed on the types of photographs needed in the present emergency. The Convention Chairman will be Mr. Joseph Haulenbeek, Illustration Division, Rockefeller Institute for Medical Research, New York City. Further particulars about the meeting and the program may be had by writing him.

The Biological Photographic Association is a national, nonprofit organization, formed to act as a clearing house for information on the methods of scientific illustration. Its members are scientific photographers, scientists interested in the application of photography to their fields, and the makers of precision photographic equipment. Information on various techniques, collected from experienced workers all over the country, is dispensed by means of the Association's Quarterly Journal, Travelling Loan Albums and Print Salons, and direct correspondence through the office of the Secretary. The 1942 Salon of medical and biological prints will be on view at the Convention.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

HEMOGLOBINOMETRY, Rimington, C. Brit. M. J. 1: 177, 1942.

The following method is described:

A 1:500 dilution of blood in decinormal sodium hydroxide is made, using a standard or calibrated pipette. This dilution may, of course, be made in two steps, if it is preferred, as in the worked example quoted below. After a few minutes at room temperature a convenient volume, such as 10 c.c., is measured into a small flask, and one-fifth of the volume of pyridine is added. Upon mixing by gentle rotation the conversion of the hemepigments into the alkaline parahematin is completed within a few seconds; hence there is no necessity to allow the original blood dilution to stand for ten, twenty, or even forty minutes before proceeding, or alternatively to heat in a boiling water bath, as is required when the alkaline hematin method is used.

A pinch of good quality sodium hydrosulfite ($\text{Na}_2\text{S}_2\text{O}_4$) is now added to the mixture, and the contents of the flask are swirled gently until the solid has dissolved. The immediate color change to pink denotes the conversion of the pigments into pyridine hemochromogen. Without undue delay (to guard against reoxidation) the solution is transferred to a photoelectric colorimeter cell, and the light absorption in the region 550 to 555 μ is measured, using a suitable filter (e.g., Ilford spectrum filter No. 605—yellow green). From the calibration factor, obtained by using known weights of pure hemin instead of blood and proceeding as above, the hemoglobin content of the blood is then calculated.

Molecular weight of hemin, $\text{C}_{34}\text{H}_{32}\text{O}_4\text{N}_4\text{FeCl}$ = 651.4

Iron content of hemoglobin = 0.334 per cent

Therefore, Molecular weight of hemoglobin = 66,890

$$\frac{\text{Hemoglobin}}{\text{Hemin}} = \frac{66,890}{4 \times 651.4} = 25.66$$

Should it be contended that the error involved in calculating the molecular weight of hemoglobin from its iron content is undesirably large, the results might alternatively be expressed in terms of hemin or hematin. The extension of pyridine-hemochromogen prepared from crystalline hemin and using a photoelectric absorptiometer with Ilford No. 605 filter and 1 cm. cell was found to be 0.108 at a concentration of 1 mg. per 100 c.c.

Should no photoelectric colorimeter be available, the concentration of the pyridine-hemochromogen solution may be determined by one of the alternative methods, such as color comparison in a colorimeter with a standard prepared from hemin (standard solutions of hemin in alkali should be kept in the dark) or dilution while viewing with a hand spectroscope until the intensity of the absorption band matches that of a standard, as described by Roets (1940). This last method is certainly the most simple and rapid, although not quite so accurate as the use of a colorimeter. Pure hemin is easily prepared according to Gattermann (1937), but should be recrystallized as follows:

Five grams of hemin are dissolved in 15 c.c. of pyridine, and 40 c.c. of chloroform are added. The solution is passed through a No. 3 or No. 4 sintered-glass filter to remove any protein and is run into a mixture of 250 c.c. of acetic acid plus 5 c.c. of saturated sodium chloride plus 4 c.c. of concentrated hydrochloric acid, which is maintained at water-bath temperature. After cooling to room temperature the crystals are filtered and washed successively with 50 per cent acetic acid, water, alcohol, and ether, and then dried.

The author has used the pyridine-hemochromogen method with equal success for specimens of plasma and urine containing hemoglobin, myohemoglobin, or mixtures of these with their derivatives. It is only necessary to adjust the initial dilution so that the concentration of pigment in the final solution falls within the comfortable range for measurement.

Example: 1 c.c. of blood was diluted to 100 c.c. with decinormal sodium hydroxide. To 1 c.c. of this solution was added 3 c.c. of the alkalin, then 1 c.c. of pyridine and, after mixing, a pinch of sodium hydrosulfite. In a 1 cm. cell the reading on the Hilger-Nutting photometer at 552 m μ was 0.573. The calibration for this instrument had been found to be 0.62. Hence:

$$\text{Hb. per c.c. of blood} = 0.573 \times 0.62 \times 500 = 177.6 \text{ mg. per c.c., i.e., 17.76 per cent}$$

The same result was obtained whether the determination was completed within five minutes or after allowing the mixture with alkali to stand for one hour and that with pyridine for a further half hour.

B. DYSENTERIAE (Flexner), Experience With the Wilson and Blair Medium for, Bradshaw, D. B. Brit. M. J. 1: 181, 1942.

Table of results with Wilson and Blair medium and those with MacConkey's Agar:

Case No.	Acute or Convalescent	No. of Flexner Colonies		Remarks

Positive on Wilson and Blair's medium only: 10				
Positive on MacConkey agar only: 2				
Total positive on Wilson and Blair's medium: 19 (90 per cent)				
Total positive on MacConkey's agar: 10 (50 per cent)				

TAKATA-ARA REACTION, the Diagnostic Value of, Waugh, T. B., and McKenna, R. D. Am. J. M. Sc. 203: 722, 1942.

Analysis of a series of 300 Takata-Ara reactions, carried out for the most part on patients who showed a hyperbilirubinemia or who gave reason to suspect the presence of hepatic disease, indicates that the test has considerable diagnostic value. It would appear that the difference of opinion which has arisen in the literature concerning its value is due to the use of various techniques and a lack of precision in reading the results. A means is described whereby more accurate results may be obtained.

The method used by the authors follows:

The test may be done on blood serum, plasma, or transudates such as ascitic fluid. Most of our results were obtained from oxalated plasma procured at the time of carrying out

a complete hemogram. Blood is usually taken for such tests in the morning, between 10 and 12 o'clock, to avoid any effect of digestive processes on the plasma. At least 1 c.c., free from hemolysis and cells, is required.

A series of 8 tubes, approximately 10 cm. in length and the inner bore of 1 cm., are placed in a rack. The tubes must, of course, be thoroughly clean. One cubic centimeter of 0.9 per cent sodium chloride is pipetted into each tube, and 1 c.c. of plasma is added to the first tube. This is mixed with the saline by shaking, and 1 c.c. of the mixture is withdrawn and placed in the second tube. By continuing in this manner and discarding 1 c.c. from the last tube a series of increasing dilutions (1:2 to 1:256) of plasma in saline is set up. To each tube, first 0.25 c.c. of a 10 per cent solution of sodium carbonate and then 0.15 c.c. of 0.5 per cent bichloride of mercury is added. Complete mixing is obtained by shaking after each solution has been placed in the tube. A slight precipitate, which disappears on shaking, may occur after addition of the mercury. The tubes are then allowed to stand at room temperature for twenty-four hours.

At the end of this interval the result of the test is read by estimating the amount of precipitate in each tube. This is expressed as 0, T (trace), 1, 2, 3, or 4. Precipitates classed as "4" occupy approximately the lower third of the solution in the tube. In doubtful cases, accurate reading of the amount of precipitate may be accomplished by thoroughly shaking up the tube and filling a Wintrobe sedimentation tube to the 10 cm. mark with a portion of the contents. The Wintrobe tube is then centrifugalized at high speed for fifteen minutes. Less than 1 mm. of whitish sediment in the bottom of the tube is classed as a trace (T), 1 to 2 mm. as "1," 2 to 3 mm. as "2," and so on. Any amount over 4 mm. is designated "4."

The Takata-Ara reaction is positive when two adjacent tubes show a grade "4" degree of precipitate and the next tube is at least a grade "3," for example (00T2441) or (00134421). Plus-minus reactions are reported whenever the criteria for the positive reaction are not reached, but at least two tubes show a grade "3" sediment, for example (00T12431), (0001331), or (000TT332). All reactions of lower degree are negative as (000TT231) or (000TT1TT). It would appear that accurate reading of the reaction is extremely important.

C. DIPHTHERIAE, Further Studies on the Serological Classification of, Huang, C. H. Am. J. Hyg. 35: 335, 1942.

Eight serologic types and an unidentified remainder have been found among the diphtheria bacilli isolated from the throats of 268 clinical patients with diphtheria.

Avirulent organisms, besides the virulent ones, were occasionally found in diphtheria patients in the acute and convalescent stages. In no instance was an avirulent organism found which was at the same time agglutinable by our S-type antisera, affording, therefore, no evidence for the transformation of a virulent diphtheria organism into an avirulent one in the throat of diphtheria patients.

The failure to find an avirulent organism, which is at the same time agglutinable by S-type antisera in acute and convalescent cases, together with the consistent finding of virulence in all the diphtheria organisms which belonged serologically to the author's S types, suggested the possibility of using the serologic agglutination as an indirect, but more convenient, means of determining the virulence of organisms in acute and convalescent cases.

Laryngeal diphtheria is less frequently observed in patients who were infected by type D₁ organisms than with other types of organisms. It happened that type D₁ is the only type of diphtheria organisms which possesses both gravis and intermedius strains.

The prevalence of types of organisms varies in different years.

Simultaneous and repeated swabs from the throat of the same patient practically always revealed the same type of organism. Only two patients were found to be infected by two different types of virulent organisms at the same time.

PROGRESS

VARIATIONS IN SERUM MAGNESIUM IN HEALTH AND DISEASE: A REVIEW*

VICTOR G. HACRY, M.D., PHILADELPHIA, PA.

INTRODUCTION

UNTIL 1932, when Kruse and his co-workers¹ demonstrated that magnesium is essential for the maintenance of life, very little physiologic significance was attached to it. In recent years, however, much more attention has been given to this element, particularly in regard to its variation in diseased states. It is unfortunate that such abundant researches on the biological significance of calcium should have been performed with an almost total omission of concomitant magnesium studies. This is all the more unfortunate since we now appreciate the close physiologic relationship which exists between calcium and magnesium.

The literature abounds with evidence that a derangement in calcium metabolism is either the cause or the effect of various clinical entities. Such information could have been obtained only by virtue of a great many studies made by the clinical chemists. Obviously the same must be done before any clinical significance can be attached to magnesium. A quotation from a recent editorial on "Magnesium in Nutrition"² adequately summarizes the present status of the magnesium problem. . . . "So little is known of the function of magnesium in the organism that clinically observable abnormalities in man cannot at present be said with certainty to be due to magnesium deficiency or to a disorder of magnesium metabolism. The systematic study of magnesium metabolism by accurate analytical and experimental methods is little more than begun. Future investigations may be expected to add considerably to our knowledge of this problem."

*From the Department of Pharmacology, the Jefferson Medical College of Philadelphia.
Received for publication, December 22, 1941.

Our attempt in this paper has been to review and to evaluate the scattered literature relative to the changes in blood magnesium in various diseases. The material is arranged, in so far as is possible, under the various clinical entities.

No definite conclusions can be drawn in most instances as to whether or not a hypomagnesemia or hypermagnesemia exists in a particular disease. Indeed, in some instances diametrically opposite results are reported by the various investigators. We can only report the facts as they are found, make criticisms where they are warranted, and point out certain trends if sufficient data existed to do so. It is hoped that this paper may serve to correlate, at least to some degree, the literature on this subject, and to stimulate further investigations on this vital and interesting subject.

NORMAL BLOOD VALUES

There is some disagreement in the literature as to what should be considered the serum magnesium level of normal persons. This discrepancy is due partly to the fact that the investigators used different methods for the determination of this element, and partly because some¹⁹ considered results obtained from hospital patients as being normal. Obviously, such persons should not be considered as being normal, even if they do not have any apparent metabolic disturbances. The concentration of normal serum magnesium as determined by 18 different authors and the methods employed by each are shown in Table I.

TABLE I
CONCENTRATION OF SERUM MAGNESIUM IN NORMAL PERSONS

AUTHORS	PRECIPITATING AGENT	METHOD	RANGE OF VALUE	MEAN
Briggs ³	Phosphate	Colorimetric	2.23-2.50	
Kramer and Tisdall ⁴	Phosphate	Colorimetric	1.80-2.30	2.10
Bogert and Plass ⁵	Phosphate	Colorimetric	1.90-2.70	2.30
Watchorn and McCance ⁶	Phosphate	Colorimetric	2.30-2.66	2.48
Becher ⁷	Phosphate	Colorimetric	1.80-2.30	
Wacker and Fahrig ⁸	Phosphate	Colorimetric	2.00-2.97	2.40
Cope ⁹	Phosphate	Colorimetric	1.82-2.63	2.06
Walker and Walker ¹⁰	Phosphate	Colorimetric	1.60-3.00	2.20
Brookfield ¹¹	Phosphate	Colorimetric	1.89-2.19	2.04
Bomskov ¹²	Hydroxyquinoline	Bromination	1.70-2.60	
Greenberg and associates ¹³	Hydroxyquinoline	Bromination	2.00-3.66	2.74
Velluz and Velluz ¹⁴	Hydroxyquinoline	Bromination	1.60-2.40	2.00
Raices ¹⁵	Hydroxyquinoline	Bromination	1.69-3.00	2.44
Hoffman ¹⁶	Hydroxyquinoline	Colorimetric	1.90-2.50	2.18
Hirschfelder and Haury ¹⁷	Titan yellow*	Colorimetric	1.80-2.40	2.11
Haury ¹⁸	Titan yellow	Colorimetric	1.70-3.10	2.33
Bernstein and Simkins ¹⁹	Titan yellow	Colorimetric	1.23-3.54	
Wolf ^{20*}	Titan yellow	Colorimetric	2.90-4.00	3.61

*For whole blood.

As seen from this table, the mean serum magnesium value of all the authors lies in the neighborhood of 2.4 mg. per 100 c.c. This is in close agreement to the value for serum magnesium of normal persons, as found by Tibbetts and Aub,⁵⁰ and corresponds closely to the mean value (2.33 mg.) found in normal medical students, as recently reported by Haury.¹⁸ With the exception of the figures given by Greenberg, Lucia, Mackey, and Tufts,¹³ and Bernstein and Simkins,¹⁹ the serum magnesium of normal persons seems to lie between the lower and upper limits of 1.7 and 3.0 mg. per 100 c.c., respectively. Inasmuch as Wolf²⁰

determined the magnesium content of whole blood, and since Greenberg and others¹³ noted the fact that the red blood corpuscles contain from 5 to 9 mg. magnesium per 100 c.c., we would expect Wolf's figures to be higher than those obtained by other investigators using blood serum or plasma alone. In his review Shohl¹⁴ states that the serum magnesium of normal persons lies somewhere between 1.0 and 3.0 mg. We believe, from our work and from the work of others, that the normal range is from 1.7 to 3.0 mg. per 100 c.c. of blood plasma or serum.

RENAL DISORDERS

Probably the first indication of a disturbance in magnesium metabolism was noted in cases of renal inadequacy. In 1923 Salvesen and Linder²² reported a series of 15 cases in which the serum magnesium varied from 1.5 to 4.6 mg. per 100 c.c. of serum. In the same year Denis and Hobson²³ reported normal magnesium and potassium values in a series of 19 nephritic patients. They state, however, that the serum calcium was below normal in 5 cases. In view of the inverse relationship which exists between magnesium and calcium, i.e., as the serum magnesium increases the calcium decreases, and vice versa,^{11, 24-25} one would be inclined to suspect an elevated serum magnesium in some of the patients studied by Denis and Hobson. In more recent years evidence has accumulated which seems to indicate that retention of magnesium is a common occurrence in cases of renal insufficiency.

In 1932 Beecher and Hamann²⁹ demonstrated that patients with diseased kidneys but with normal renal function had a normal serum magnesium (2.07 mg.). Patients showing a renal insufficiency, however, had a definitely elevated serum magnesium (3.49 mg. per 100 c.c.). In the same year Watchorn and McCance⁶ reported 8 cases of uremia in which the serum magnesium ranged from 3.07 to 10.34 mg. per 100 c.c. Two years later Hirschfelder and Haury³⁰ demonstrated that in nephrectomized animals and in animals with injured kidneys, ingestion of magnesium sulfate caused a rapid increase in plasma magnesium, even to the point of coma. They suggested at that time that "uremic" coma may actually be produced or at least abetted by purgation with magnesium salts. It was pointed out also at that time³¹ that a retention of magnesium was a common finding in uremic patients. Numerous papers appeared during the past few years confirming the foregoing findings.^{10, 11, 15, 32, 33}

Occasionally a hypomagnesemia may be associated with renal insufficiency. In 1934 Hirschfelder and Haury³¹ reported 4 cases of glomerulonephritis in which the serum magnesium was definitely below normal (0.9 to 1.31 mg. per 100 c.c.). In each of these cases either muscular twitchings or convulsions were present. This is of particular interest, since the publication of a report by Kruse, Orent, and McCollum,¹ in which they showed that animals raised on a magnesium-deficient diet have a tendency to become irritable and eventually have severe convulsive seizures. A few years later, Hoobler, Kruse, and McCollum³⁴ showed that this form of tetany is definitely due to a hypomagnesemia. It now becomes apparent that at least some of the so-called idiopathic tetanias, which cannot be explained on the basis of a low blood calcium, might be accounted for on the basis of a low blood magnesium. Perhaps the case of uremic convulsions described and treated with magnesium sulfate by Watson³⁵ was actually due to a concomitant hypomagnesemia.

On the grounds of Loeb's³⁶ pure physiologic work relative to the influence of ions on irritability, we could reasonably conclude that tetany can be due to a deficiency of serum magnesium. From his work we may set up the following relationship: $\frac{\text{Na}^+ + \text{K}^+ + \text{OH}^-}{\text{Ca}^{++} + \text{Mg}^{++} + \text{H}^+}$, as determining the state of irritability. An increase in any of the ions in the numerator, or a reduction of any of the ions in the denominator, will increase the irritability. From this scheme it becomes apparent that a reduction of magnesium is at least one possible factor in the etiology of hyperirritability.

As yet no human pathology has been demonstrated which can be attributed with certainty to a magnesium deficiency. Moreover, since Sherman³⁷ has shown that the ordinary diet contains more than enough magnesium to meet the daily requirement, it is questionable if a magnesium deficiency ever exists spontaneously in man. On the other hand, in animals we find a disease known as "grass staggers," the symptoms of which are strikingly similar to those seen in experimental magnesium tetany. Sjollem and Seekles,^{38, 39} and Metzger,⁴⁰ made an extensive study of this form of tetany. They found that the animals become nervous and restless, develop an unsteady gait, and finally die in violent convulsions. Blood chemistry studies in this disease show that the calcium and phosphorus levels are usually low, and that the magnesium is always low. Hopkirk⁴¹ and Cunningham⁴² confirmed these findings, and further demonstrated that the symptoms noted in these animals could be overcome by increasing the blood magnesium. It is interesting to note in this connection that Duncan, Huffman, and Robinson⁴³ produced an experimental tetany in 20 calves fed on whole milk or milk supplemented by iron, copper, manganese, silicon, aluminum, and cod-liver oil. Five of the animals which died in tetany had a normal blood plasma, calcium, and phosphorus, but a low blood plasma magnesium value. The tetanics in the calves due to a low blood magnesium were indistinguishable from those due to a low blood calcium. These could be differentiated only by determining the amounts of calcium and magnesium in the blood. The mean plasma magnesium value of the 5 calves (44 determinations) which died in tetany was 1.6 mg., as compared with the mean value of 2.41 mg. per 100 c.c. in 107 normal calves.⁴⁴ McGhee⁴⁵ showed that canine hysteria is due to a deficiency in blood magnesium rather than calcium.

We must also consider the possibility that some endocrine organ may control or at least influence magnesium metabolism. This possibility does not seem too hypothetical if one reviews the relationship which exists between sodium and the adrenal glands, iodine and the thyroid gland, and calcium and the parathyroids. Indeed, Coppo and Frugoni^{46, 47} believe that the primary action of the parathyroids is to decrease the blood magnesium and that the calcium rises secondarily to antagonize the magnesium. Whether or not hypermagnesemia or hypomagnesemia is due to some endocrine dysfunction must be answered by future investigations.

Other pathologic conditions often associated with a hypomagnesemia will be discussed later under Endocrine Disturbances, Epilepsy, Carcinoma, and Asthma.

DISEASES OF THE CIRCULATORY SYSTEM

Only fragmentary reports have been made on the serum magnesium value in circulatory diseases. In 1923 Weil, Guillaumin, and Weismann-Netter¹⁸ observed an increase in the serum magnesium values of a few cases of essential hypertension. A few years later Blumgarten and Rohdenburg¹⁹ reported 3 patients with arteriosclerosis and one with myocarditis having a high blood magnesium. Unfortunately, their results, obtained on whole blood, are difficult to compare with those of other investigators using serum or plasma. Wacker and Fahrig,⁵ Walker and Walker,¹⁰ and Bernstein and Simkins¹⁹ demonstrated only a slight increase in serum magnesium in hypertensive cases not complicated with severe kidney damage. Beeher and Hamann²⁰ showed that the serum magnesium is nearly double the normal value in those patients having hypertension associated with kidney disease. Assuming that all patients with a severe hypertension have also an abnormal kidney function, one would expect at least some elevation in serum magnesium in nearly all cases suffering with this disease.

ENDOCRINE DISTURBANCES

(a) *Diabetes Mellitus*.—Tibbetts and Aub have shown²⁰ that the ingestion of an acid-producing salt (NH_4Cl) causes a negative calcium balance. Their studies suggest further that magnesium may be used in the body as a substitute for calcium base, the excess usually appearing in the urine. From what we already know of the inverse relationship between calcium and magnesium, we would expect the serum magnesium in such conditions to be definitely elevated. We could speculate then that in cases of diabetic acidosis, as well as in acidosis due to any other cause, a negative calcium balance should exist with a simultaneous elevation in serum magnesium. Our factual information in this direction is entirely inadequate. Brookfield,¹¹ and Watchorn and McCance,⁶ reported three patients with diabetic coma as having a high serum magnesium, whereas a number of similar cases not in coma were said to have a normal serum magnesium. Three of the 7 cases reported by Blumgarten and Rohdenburg¹⁹ were found to have a high and two were found to have a low blood magnesium. None of their patients were in coma.

(b) *Diseases of the Thyroid*.—Blumgarten and Rohdenburg¹⁹ reported 45 patients with goiter on whom blood magnesium determinations were made. In these 15 showed a slight hypomagnesemia and 5 showed a slight hypermagnesemia. Watchorn and McCance,⁶ and Beeher and Hamann,²⁰ found normal values in the few cases they reported.

Recently Soffer and co-workers^{21a} made an interesting study on the state of the serum magnesium in 31 patients with hyperthyroidism. They found the total serum magnesium in these patients to vary between 1.85 and 2.96, with an average of 2.44 mg. per cent. The total serum magnesium of 14 normal persons varied between 2.12 and 2.76, with an average of 2.52 mg. per cent. However, a striking difference in the ultrafiltrable magnesium was noted. In normal persons this varied between 77.9 and 96.9, with an average of 85.5 per cent. In the patients with hyperthyroidism the ultrafiltrable magnesium was greatly diminished, varying between 38.4 and 78.5, with an average of only 64 per cent. In a

later paper Soffer and associates^{51b} made a similar study on an additional 50 patients with hyperthyroidism. Essentially the same results were obtained. In addition they reported that in patients with myxedema, as well as in totally thyroidectomized dogs, the ultrafiltrable serum magnesium is extremely high and frequently is elevated as much as 100 per cent. Since the ultrafiltrable fraction is probably the physiologically important fraction, we could deduce from these results that in hyperthyroidism an actual state of hypomagnesemia exists and that myxedema patients are in a state of hypermagnesemia. This may help to explain the hyperirritability and hypoirritability so commonly associated with Graves' disease and myxedema, respectively. It certainly stresses the importance of determining the amount of physiologically active (diffusible) fraction of this ion before an actual state of hypermagnesemia or hypomagnesemia can be said to exist.

(c) *Diseases of the Parathyroids.*—From the dramatic influence that the parathyroids have on calcium metabolism, we might expect them to have a similar effect on magnesium metabolism. The immediate effect of parathyroid hormone on serum magnesium has been studied in dogs by Scholtz⁵² and by Greenburg and Mackey.⁵³ Their investigations showed that the serum magnesium increased slightly in two to four hours following the injection of the parathyroid hormone. This disappears long before the calcium has reached its maximum value. Bulger and Gausmann⁵⁴ noticed that prolonged administration of parathormone to dogs resulted in no striking alterations in serum magnesium. Following the administration of 200 units of parathormone in human beings, Melli and Karadimova⁵⁵ observed that the serum magnesium increased during the first hour, reached the maximum at the third hour, and fell to normal at the fourth hour. Serum calcium, on the other hand, began to rise only after the fourth hour. Coppo and Pisa⁵⁶ found that one unit of parathormone per day administered to a rat produced an increase in the blood serum calcium and a reduction in the blood serum magnesium. The authors conclude that their analyses furnish an important contribution to the theory that assumes a direct relationship between the function of the parathyroids and the biochemistry of magnesium.^{46, 47} Cantarow, Haury, and Whitbeck⁵⁷ found that large doses of parathormone injected intramuscularly in dogs produced a slight decrease in serum magnesium in the majority of their experiments. In a human subject Watchorn and McCance⁶ also found that intramuscular injections of the hormone produced a slight but definite fall in the serum magnesium.

Denis and Talbot,⁵⁸ Bulger and Gausmann,⁵⁴ and also Hartog and Muller³² found a hypomagnesemia in clinical cases of parathyroid tetany. The few serum magnesium studies made in patients with hyperparathyroidism reported by Tibbetts and Aub⁵⁹ indicate that a relatively normal serum magnesium prevails in spite of the hypercalcemia. Future investigations in this field should prove most interesting.

(d) *Miscellaneous Endocrine Disturbances.*—Practically nothing is known of the status of serum magnesium in other types of endocrine disturbances. Blumgarten and Rohdenburg⁴⁹ found the whole blood magnesium to be within the normal limits in all cases of pituitary dysfunction. Tibbetts and Aub,⁶¹ and

CLINICAL AND EXPERIMENTAL

THE PHARMACOLOGY OF β (3,5 DI-iodo-4-HYDROXYPHENYL) A PHENYL PROPIONIC ACID*

WALTER MODELL, M.D., NEW YORK, N. Y.

BILISELECTAN† has been used in recent years in Germany for gall bladder visualization.¹⁻⁵ Superiority over the radio-opaque phenolphthalein dyes for outlining the gall bladder is claimed because dense shadows may be obtained after oral administration with unpleasant symptoms appearing only rarely. A systematic experimental study of biliselectan has not been published. Inasmuch as the drug may be a useful one the present investigation was undertaken to determine its actions and toxicity.

PHYSICAL AND CHEMICAL PROPERTIES

Biliselectan is β (3,5 diiodo-4-hydroxyphenyl) α phenyl propionic acid. It is a faintly cream-colored powder, insoluble in water, and practically tasteless. It dissolves in alkali, presumably in the form of the sodium salt, when sodium hydroxide is used. Solutions which were used, 2.5 and 5.0 per cent, made up with the minimum amount of sodium hydroxide necessary to bring about complete solution without heat, have a pH of 11.5 or 11.6. These solutions are yellow and clear. A 5.0 per cent solution, kept for forty-eight hours at room temperature in the light, did not show free iodine by the starch test.

EXPERIMENTAL PROCEDURE

Cats were used in several types of experiments, acute and chronic, to study toxicity. The behavior, appearance, and weight of the animals were recorded. Examinations were made for evidence of changes in blood nonprotein nitrogen, red blood cell count, red blood cell fragility, and clotting time. Phenolsulphonphthalein excretion tests were made, and the urine was examined for albumin and reducing substances. These observations were made prior to and for a varying period after the administration of the drug. In the course of the observations on 33 animals, 20 red cell counts, 30 red cell fragility determinations, 20 clotting time determinations, 50 nonprotein nitrogen determinations, 40 phenolsulphonphthalein excretion tests, and 85 urinalyses were made. Most of these tests were made in a series of 12 cats used in chronic experiments.

*From the Department of Pharmacology Cornell University Medical College, New York. Received for publication, February 16, 1942.

†The original proprietary name, Biliselectan, will be used throughout the text, instead of the more cumbersome chemical name. The drug may be secured from the Schering Corporation, which now designate it Priodax.

At autopsy the organs of all animals were examined grossly, and in the case of the animals in the chronic experiments, the livers and kidneys were studied histologically.

All intravenous injections were made with a 2.5 or 5.0 per cent alkaline (pH 11.5 to 11.6) solution, while most of the oral doses were given as the powder in capsules.

TABLE I

EFFECTS OF INTRAVENOUS INJECTIONS OF BILISELECTAN IN UNANESTHETIZED ANIMALS

CAT. NO.	TOTAL DOSE	NUMBER OF INJECTIONS	TIME BETWEEN FIRST AND LAST INJECTION	CONVULSIONS	TIME TO DEATH AFTER FIRST INJECTION	REMARKS
5	150	1	0	Yes	1 minute	
6	285	4	4 days	No	Did not die	
	6.0/50/75/100					
7	150	2	45 minutes	Yes	112 minutes	
	75-75					
8	200	2	26 hours	Yes	27 hours	Small pulmonary hemorrhages
	100/100					
9	100	1	0	Yes	97 minutes	
10	100	1	0	Yes	46 minutes	
11	500	3	24 hours	Yes	25 hours	
	100-150/250					
12	250	2	21 minutes	Yes	Between 12 and 24 hours	Found dead in morning after apparent recovery
	100-150					
13	250	2	27 minutes	Yes	31 minutes	
	100-150					
14	250	2	10 minutes	Yes	150 minutes	
	100-150					

*The numbers underneath the total dose indicate the individual doses. Those doses separated by a dash (-) were given on the same day, whereas those doses separated by a line (/) were given on different days.

RESULTS OF EXPERIMENTS

Effect of pH.—Since the intravenous injections of the alkaline solutions of biliselectan were followed by convulsions and other systemic effects, it was necessary to eliminate the alkali itself as a factor in the production of these effects. Therefore, two unanesthetized cats were injected with a solution of sodium hydroxide with a pH (11.5) the same as that of the biliselectan solutions used. Injections of this solution were without noticeable effect even when used in amounts 2.5 times that of biliselectan doses which produced violent convulsions.

Effects of Intravenous Injections on Circulation and Respiration in Anesthetized Animals.—The effect on cardiodynamics and respiration was studied in 4 cats which were anesthetized with sodium amytal and whose blood pressure and respiration were recorded on a kymograph.

Effects were produced which varied from animal to animal. For example, in one animal (Fig. 1) the first injection of 100 mg. per kilogram* produced

*All drugs were administered in relation to body weight, but for the purpose of convenience the expression "per kilogram" will not be repeated.

Fig. 1.—Respiratory stimulation produced by biliselectan. Respiration is shown in the upper curve; blood pressure and heart rate in the lower. The calibration lines for the blood pressure indicate millimeters of Hg. The next line in descending order indicates the period of injection, while the last indicates the time in seconds.

Fig. 2.—Depression of blood pressure, without respiratory depression, produced by doses similar to those shown in Fig. 1.

marked respiratory stimulation lasting almost five minutes. Subsequent similar doses produced progressively less stimulation. On the other hand, in another animal (Fig. 2) receiving the same doses of the same solution there was no respiratory stimulation, but rather a fall in blood pressure after each dose.

Fatal doses were followed by a fall in blood pressure and respiratory depression. In 2 cats the respiratory failure appeared first, the heart continuing to beat after the cessation of breathing. In the other 2 cats the cardiac and respiratory failure appeared simultaneously. In 3 of the 4 cats the terminal events occurred suddenly and without warning.

Effect of Intravenous Injections in Unanesthetized Animals.—In 10 unanesthetized cats the effects of intravenous injections were observed. The significant data are summarized in Table I.

Lethal dose. Single injections of 50, 60, and 75 mg. were not fatal. Injections of 100 mg. killed 2 of 8 cats. A single injection of 150 mg. killed one cat, while another died of the same dose given in two parts within forty-five minutes. Each of 3 cats died of 250 mg. given within thirty minutes in two doses, while one cat survived this dose.

Convulsions. Biliselectan is a convulsant agent similar to picrotoxin or camphor. It produces typical medullary convulsions with all the autonomic phenomena which are associated with it, salivary stimulation, respiratory stimulation and depression when doses of 100 mg. or more are administered. Doses of 50 and 60 mg. failed to induce convulsions, whereas only one of two injections of 75 mg. was followed by convulsions.

The convulsions were always immediate and violent, and without reflex hyperexcitability. Sometimes the convulsions would persist for as long as four to six hours, but neither the duration nor the intensity of the convulsions was an indication of whether the animal would survive a particular dose.

Antidote. The group of four experiments, already described, in which the blood pressure records were made, were performed with amytal anesthesia. In this group the drug proved to be fatal in divided doses of from 200 to 600 mg. without convulsions. The protective action of amytal against biliselectan was studied in another series of 4 cats in which single intravenous doses of from 200 to 350 mg. were administered after 50 mg. of sodium amytal. The two animals which received 200 mg. of biliselectan were protected against the fatal action as well as the convulsions, whereas the cats receiving 300 to 350 mg., respectively, died, although no convulsions were induced. It is to be assumed, therefore, that the fatal effects of biliselectan are only in part the result of convulsions, since with somewhat larger doses, namely, 300 mg., the animals die, even though convulsions are prevented. It is interesting to note that the large doses of biliselectan, through its stimulation of the higher centers, brought about fleeting signs of reversal of the narcotic action of amytal.

Persistence of action. The persistence of biliselectan action is relatively brief. Very little of a given dose appears to remain after twenty-four hours. For example, cat 6 received on successive days injections of 60, 50, 75, and 100 mg. of biliselectan. Each injection was followed by systemic effects: excitement, ataxia, depression, respiratory stimulation, yet the animal recovered

completely after each injection, even the last, although a total of 285 mg. had been administered.

Tissue changes. The post-mortem examination of the organs revealed abnormal findings in only one case. In that there were found minute hemorrhages in the lungs surrounded by small pink areolae. These may have been pin-point pulmonary emboli. Examination for the fragility of the red blood cells was made in 4 cats and no change was found.

TABLE II
EFFECTS OF SINGLE ORAL DOSES OF BILISELECTAN

CAT NO.	DOSE	PERIOD OF OBSERVATION (DAYS)	INTERVAL BEFORE VOMITING	IMPAIRED APPETITE. DURATION (DAYS)	ALBUMINURIA		REMARKS
					DEGREE	DURATION (DAYS)	
15	100	28	No vomiting	None	+	1	Less than 10 per cent drug lost in vomiting. Diarrhea for one day
16	250	28	5¼ hours	1	++	1	
21	250	5	No vomiting	None	+	2	
22	250	2	No vomiting	None	0		
23	250	8	No vomiting	None	0		
17	500	15	20 minutes	1	+	6	About 50 per cent drug lost in vomiting. Pregnant—aborted second day. Depressed for five days
20	500	28	3 hours	1	+	7	Less than 10 per cent drug lost in vomiting. Hematuria and glycosuria for one day
24	500	6	2½ hours	6	++	6	Nonprotein nitrogen rises to 127, cloudy swelling of tubules, marked depression
25	500	2	1 hour*	2	+++	2	Died on sixth day. Marked depression
26	500	6	2½ hours*	6	++	4 plus	
18	1,000	28	7 minutes	2	+	1	About 75 per cent drug lost in vomiting. Diarrhea for one day, depressed for one day
19	1,000	8	No vomiting	8	+	1	Depressed for eight days. Died of pneumonia
31	1,000	1	Vomiting prevented with morphine	1	+++	1	Found dead morning after drug was administered
32	1,000	1		1	?	?	Found dead morning after drug was administered
33	1,000	28		4	++++	5	Glycosuria five days; moderate depression for seven days

*In these animals there was no loss of the drug by vomiting, since there was no expulsion, only retching.

Chronic Experiments—Oral Administration.—The effect of a single oral dose of from 100 to 1,000 mg. was studied in 12 cats for a period of from two to twenty-eight days. The drug was administered usually in capsules after food had been withheld for twelve hours.

The effects are summarized in Table II. There were two deaths which could be ascribed to the biliselectan. Both animals received 500 mg. One died on the sixth day and the other was killed on the sixth day when it was moribund. Another cat which received 1,000 mg. died of a respiratory infection.

Albuminuria was produced in 10 of the 12 cats. It was present in all 7 cats which received 500 mg. or more and in 3 of the 5 cats which received 100 and 250 mg. The albuminuria was transient. It persisted from one to seven days. Glycosuria occurred in one cat, in which it lasted only one day.

Digestive disturbances were common. Vomiting was seen in 7 of the 12 cats; in 1 of 4 which received 250 mg., in all 5 which received 500 mg., and in 1 of 2 which received 1,000 mg. In two instances vomiting was noted seven and twenty minutes after the drug was administered. In the other cases it was delayed for from one to five hours. The appetite was impaired in all the cats which received 500 mg. or more and in one of 5 receiving less. The impairment of the appetite lasted only a day or two in most cats but persisted as long as six to eight days in 3 cats which died. Post-mortem examination did not reveal any evidence of intestinal irritation, but since the intravenous injections did not produce vomiting it was assumed that the digestive disturbances were produced by a local rather than a central action. The loss of biliselectan by vomiting was as indicated in the table, in most cases not sufficient to influence the results.

There was a varying degree of general depression in 5 cats (indisposition to move, lethargy) after doses of 500 mg. or more which usually lasted for from five to eight days.

The average weight of the 4 cats which were permitted to survive for twenty-eight days was 2.42 kg. as compared with 2.61 kg. when the experiment was started. Such a small loss of weight (10 per cent) for cats confined for a four-week experimental period cannot be attributed to the drug.

Biliselectan produced no change in the red cell count, red cell fragility, and clotting time of the blood. In only one cat was there a rise in the non-protein nitrogen level. None of the phenolsulphonphthalein excretion tests indicated a significant deviation from the control.

The post-mortem examinations and the histologic studies of the livers and kidneys were negative with the exception of one animal discussed below.

The two animals which were killed by the 500 mg. dose of biliselectan suffered from a persistent albuminuria, vomiting, depression, and a loss of appetite which became progressively more profound. One was found dead in a state of decomposition which precluded examination of blood or tissues. In the other the nonprotein nitrogen level in the blood had risen to 127 mg. per cent on the day of death. On the sixth day it appeared moribund and began to vomit again. It was killed in order to obtain satisfactory tissue for histologic study. In the gross examination of the organs there was no significant finding other than the pale kidneys and a small pneumonic patch in the right lung. On microscopic examination of the kidneys, cloudy swelling of the renal tubules was found.

In another series of chronic experiments the complicating factor of vomiting and expulsion of the drug was removed. Three cats were given morphine intravenously to prevent vomiting and a dose of 1,000 mg. of biliselectan orally. Two of the 3 cats were depressed and suffered complete loss of appetite within four hours, and were found dead the following morning. In one of these 2 animals albumin was found in the bladder urine and venous congestion and

parenchymatous degeneration of the tubules of the kidneys on microscopic examination, but no evidence of gastrointestinal irritation. The kidney was normal in the other and its bladder was empty when found so that no urine examination could be performed.

The third cat was slightly depressed for seven days with impairment of appetite for four days. Albumin and glucose were found in the urine for the first five days. There was no significant change in the blood nonprotein nitrogen at any time. After a week the animal appeared entirely normal and continued so for the duration of the experiment (twenty-eight days). On gross and microscopic examination of the organs at the end of this period no pathologic changes were found.

SUMMARY AND CONCLUSIONS

The pharmacology of biliselectan, β (3,5 di-iodo-4-hydroxyphenyl) α phenyl propionic acid, a substance which has been used for gall bladder visualization, was studied in acute and chronic experiments in 33 cats.

By intravenous injection biliselectan acts as a medullary convulsant. Intravenous doses as small as 50 to 75 mg. per kilogram cause excitement with respiratory stimulation. Larger doses cause myoclonic convulsions with stimulation and secondary depression of the circulation and respiration. The intravenous LD 50 ranges about 150 mg. per kilogram. The convulsant action can be abolished by the barbiturate, sodium amytal. In that case, a somewhat larger dose proves fatal by vasomotor and respiratory paralysis without convulsions.

The persistence of action of the intravenous dose appears to be brief, of the order of twenty-four hours or less, as seen by the fact that little cumulation is in evidence when intravenous doses are repeated. However, very large doses by mouth may cause a form of injury which tends to be progressive, so that an animal may die six days after a large oral dose.

The drug is much less toxic by oral administration. By this route animals survive doses as high as 1,000 mg. per kilogram, suggesting that the absorption is very imperfect. Marked individual differences, however, occur. Thus, one animal, after 1,000 mg. per kilogram (vomiting prevented by morphine), showed impaired appetite and slight depression within a few hours after the dose, albuminuria the following day, all of these effects wearing off within seven days; another animal receiving 500 mg. per kilogram showed more severe gastrointestinal symptoms which increased progressively until the animal became moribund and died on the sixth day. Biliselectan given orally does not produce convulsions.

In a total of 15 chronic experiments the effects of single oral doses were observed for periods up to twenty-eight days. Doses of 250 mg. per kilogram or larger cause impaired appetite, nausea, and vomiting and general depression. The intensity of these effects increases with the dose. The emetic effect is due to local action in the gastrointestinal tract, since it does not occur after the intravenous injection. Albuminuria is an outstanding effect. It occurs with doses as low as 100 mg. per kilogram. It is transient, and the duration of this effect varies with the dose.

Doses of from 100 to 1,000 mg. per kilogram are without effect on the non-protein nitrogen level of the blood, the phenolsulphonphthalein excretion, the red blood cell count, the red blood cell fragility, and the blood clotting time, even though some of the larger doses prove fatal. There are no histologic changes in the kidneys. There were two exceptions, one animal which became depressed after 500 mg. per kilogram, and a nonprotein nitrogen determination during the moribund state (on the day of death) showed a very high level, namely, 127 mg. per cent, and another was found dead the morning after 1,000 mg. In these animals the kidney tubules showed cloudy swelling. Since 1,000 mg. doses failed to cause this effect in 4 other animals, the possibility remains that the blood and renal changes in these cases may have been related to the profound depression of the circulation.

THE OCCURRENCE OF *TRICHINELLA SPIRALIS* LARVAE IN TISSUES OTHER THAN SKELETAL MUSCLES*

EVELYN A. MAUSS, SC.D., AND G. F. OTTO, SC.D.
BALTIMORE, MD.

WHILE the larvae of *Trichinella spiralis* develop primarily in the skeletal muscles, there have been reported in the medical literature about 20 fatal cases of trichinosis in which other organs and tissues have been involved. In such cases the myocardium⁶ and, to a lesser extent, the central nervous system⁴ have been most frequently injured, but larvae have also been reported from the pancreas, kidney, liver, gall bladder, smooth muscles of the intestine, and tissues of the respiratory tract. In addition to the fatal cases there has been reported a far greater number of nonfatal cases with apparent involvement of various organs and systems other than the skeletal muscles. In this connection, we have been particularly impressed by the number of patients who have shown temporary loss of reflexes, and by the number whose spinal fluids have been found positive for larvae.^{1, 5}

From our knowledge of the life history of *T. spiralis*, it seems altogether likely that the so-called migrating larvae are carried passively in the blood stream to all parts of the body. Since the larvae have a diameter in cross sec-

Received for publication, January 31, 1942.

tion of about 6μ , i.e., less than that of an erythrocyte, it is possible that they are able to negotiate the various capillary beds and to continue uninterruptedly in the blood stream until they reach the skeletal muscles, where they escape from the vascular system, penetrate the muscle fibers, and encyst. A second possibility, however, is that they are carried in the blood to all organs and tissues which they indiscriminately invade, but in none of which, except striated muscle, are they able to develop. Weight is given to this alternative by the cases referred to above, and by reports such as that of Dunlop and Weller³ in which it was demonstrated that larvae invade the myocardium of rats and are destroyed in situ. The purpose of this study was to ascertain as precisely as possible the extent to which migrating trichina larvae are found in tissues other than skeletal muscles.

MATERIALS AND METHODS

Young mice (5 to 6 weeks old) were infected by esophageal tube with 450 one- to two-month-old trichina larvae freshly isolated from rat muscle by artificial digestion (1.0 per cent pepsin and 0.7 per cent hydrochloric acid). The mice were sacrificed four to fifteen days later and exsanguinated. The blood was collected in sodium citrate, mixed with sufficient distilled water to lyse the cells, and centrifuged, and the sediment was examined for larvae. In attempting to recover the larvae from the tissues of the experimental mice, the foregoing digestion method and the use of other digesting agents failed because the migrating larvae were too young to withstand digestion. Likewise, a modified Baermann apparatus² maintained at various temperatures was unsuccessful because the larvae did not migrate out of the macerated tissues and into the funnel. Most of the results reported herein were obtained by direct microscopic examination with 16 mm. objective and 10 \times oculars, of tissues teased apart and pressed between slides. Attempts at supravital staining in such preparations were abandoned after four commonly used stains (Janus green B, sudan III, Bismarck brown, and methylene blue) failed to facilitate the finding of larvae. The results obtained by direct examination were supplemented by the even more laborious study of serial sections of various tissues.

RESULTS

About 200 slides of serially sectioned tissues of 22 mice were examined. Larvae were seen in the skeletal muscles of animals killed as early as the sixth day after infection. In addition, a few inflammatory foci suggestive of the presence of worms were seen in the myocardium of mice twelve to fourteen days after infection but, since this has been adequately described by Dunlop and Weller,³ no effort was made to pursue the subject. The direct examination of teased and pressed tissues was on the whole more satisfactory. Unbroken living larvae could be readily seen and identified even in the very young stages, and an entire organ could be examined effectively in much less time than was required for examination of serial sections of equivalent amounts of tissue. Even by this process, however, only 31 larvae were found in addition to those seen in the skeletal muscles and lysed blood (Table I). Of these 31 larvae 24 were recovered from the myocardium. It will be recalled that the methods used did not

permit our determining whether such larvae were free in the tissues or whether they were confined within the vascular system of the organs involved.

In experiments designed to determine whether or not the very young larvae had the capacity of directional movement and could, therefore, respond actively to stimuli, larvae freshly isolated from the uteri of six-day-old female worms were placed on warm, moist slides. Such larvae were observed in more or less continuous motion for several hours, but they never moved from the spot in which they were placed. The addition of freshly teased muscle fibers and of small amounts of other tissues failed to induce directional movement.

DISCUSSION

It becomes evident from the foregoing experiments that no great number of *T. spiralis* larvae normally penetrates tissues other than striated muscle in white mice. Despite the afore-mentioned impossibility of determining whether the few larvae that were observed in other tissues had left the vascular system or not, it is interesting to consider the ratio of such larvae to the total number. Since the mice were killed early in the course of their infections, we have no direct measure of the number of larvae which would have developed. In other experiments, however, it was found (Mauss, MSS.) that an average of 26,000 larvae was produced in 13 white mice receiving infective doses of 210 to 1,320 larvae. Using this figure as at least a crude measure of the infections in question, we find that 31 larvae were recovered from organs and tissues other than the striated muscle (or lysed blood) out of a possible final total of 312,000 larvae in the 12 animals killed between the seventh and fifteenth day. This is roughly one in 10,000.

Since it seems unlikely that the situation could be materially different in man than in the white mouse, it would appear that there is usually relatively little trauma in tissues and organs other than skeletal muscles in human trichinosis. Temporary neurologic disturbances or other clinical manifestations may

result from the occasional larvae entering the nervous system or other tissues. In the fatal cases of trichinosis the much heavier infection could increase the likelihood of damage to various organs and tissues without any change in the proportion of larvae invading such tissues. The possibility should not be overlooked, however, that some abnormal distribution of larvae may have operated in those heavier infections of the reported fatal cases.

SUMMARY

Thirty-one migrating larvae were recovered from the carefully examined tissues and organs other than muscles and blood of 12 white mice killed seven to fifteen days after infection with *T. spiralis*. It is estimated that approximately 10,000 times as many larvae are found in the skeletal muscles of mice receiving comparable infections. Apparently, then, invasion of organs and tissues other than skeletal muscles is of minor significance except in peculiarly heavy infections.

THE TREATMENT OF ACUTE MERCURY POISONING WITH SODIUM FORMALDEHYDE SULFOXYLATE WITH A REVIEW OF TWENTY CASES*

RALPH WOLPAW, M.D., AND NATHAN ALPERS, M.D.
CLEVELAND, OHIO

THERE are two fundamental concepts in the formulation of any method of therapy for acute mercury poisoning. The first is the removal of the unabsorbed mercury as soon as possible in order to prevent further absorption. The second is the removal of the absorbed mercury rapidly with the least toxic effect to the organism.

In cases of oral ingestion the first of these concepts is best carried out by simple gastric lavage, using large quantities of fluid. Thus, any unabsorbed mercury is washed out. If such a procedure has been preceded by vomiting, so much the better, and, when immediate lavage cannot be instituted, fluid should be given after which vomiting should be induced.

*From the Medical Services of the Mount Sinai Hospital, Cleveland. Dr. S. S. Berger, chief of service.

Dr. Wolpaw is now a Captain, Medical Corps, U. S. Army, stationed at Stark General Hospital, Charleston, S. C.; Dr. Alpers is a First Lieutenant, Medical Corps, at Camp Edwards, Mass.

Received for publication, January 21, 1942.

However, even when vomiting is prompt and lavage is done soon after ingestion, absorption of the mercury is rapid, particularly since it is going through damaged tissue and is causing increased peristalsis by its irritating action. Following absorption, the mercury is distributed relatively equally throughout the body tissues, ordinarily in such small concentrations that it causes no appreciable damage. Excretion begins almost immediately by three major pathways. The first of these is the renal route. The mercury is collected in the kidneys and passes out in the urine. Concentrations of mercury reach a level sufficient to be toxic so that cellular damage (tubular necrosis) results. In like manner, cellular damage (gangrenous colitis) may occur in the colon, which is an important if somewhat later excretory avenue. The third and least important excretory area is the mouth where damage (stomatitis) frequently occurs but is usually not serious. Hence there are three regions in which mercury reaches toxic concentrations and from which it should be removed as rapidly as possible in order to minimize cellular destruction and also to preserve organic integrity.

Of these regions the kidneys are the least accessible and the earliest involved. Direct lavage is technically difficult even in so far as the pelves and calices, where damage is minimal, are concerned, and, at present, technically impossible with regard to the tubules where damage is maximal. Physiologic lavage by massive diuresis is then the method of choice. Fluids in large amounts by mouth and parenterally serve as the best diuretics. Early use of fluids is imperative because the action of the mercury is such as to decrease the excretory powers of the kidneys to the vanishing point (anuria).

The colon is affected by the mercury at first directly by contact and later indirectly by excretion. Early diarrhea is a prominent symptom of acute mercury poisoning and is evidence of the presence of mercury which has passed through from the stomach to the colon. Later, excretion of mercury begins with continuation or renewal of the symptoms of colitis. Here again, the method of choice for treatment is lavage or irrigation in an attempt to wash out the mercury. High colonic irrigations begun immediately and repeated at regular intervals fill this requirement.

Finally, lavage or irrigation of the mouth for both direct and indirect toxic effects of the mercury is indicated in order to remove the metal from this area as rapidly as possible.

The foregoing outline is a very general one of a rational method of treatment of acute mercury poisoning. It is obvious that a neutralizing or antidotal agent for mercury to be used in conjunction with the general method would be of great value. Therefore, after careful consideration of these things, Rosenthal¹ in 1933 reported the results of the use of various antidotes in experimentally produced mercury poisoning in dogs and rats. He advocated the use of sodium formaldehyde sulfoxylate because of its relative stability, low toxicity, and rapid reaction with mercury in vivo and in vitro. He reported the effects of this drug in one human case and outlined a routine of therapy to be followed with the drug. A little later² he reported excellent results in 10 human cases following essentially the same routine which he had suggested previously.

This consisted of:

1. Gastric lavage with 5 per cent sodium formaldehyde sulfoxylate, leaving 200 c.c. of solution in the stomach.

2. Ten grams of sodium formaldehyde sulfoxylate in 100 to 200 c.c. of water intravenously in twenty to thirty minutes. If poisoning is severe, this is repeated in four to six hours with 5 to 10 Gm.

3. If colitis develops, high colonic irrigations are to be given once or twice a day with 1:1,000 sodium formaldehyde sulfoxylate.

Brown and Kolmer³ repeated some of the experimental work on rabbits, and they concluded that sodium formaldehyde sulfoxylate had a definite toxicity which was increased in the presence of mercuric chloride. They felt that there was a certain danger in using the drug intravenously, and the best effects were obtained by oral use as soon as possible. Monte and Hull⁴ treated seven cases with the method of Rosenthal, utilizing also physiologic supportive measures. Four of the seven patients showed evidences of severe poisoning, three of them dying. Soon afterward, Rosenthal⁵ confirmed the results of Brown and Kolmer, showing that the toxicity of sodium formaldehyde sulfoxylate was increased in the presence of mercuric chloride, but he stated that the increase was not as great as they reported. He suggested that the second intravenous dose should contain 5 Gm. or less of the drug and he showed that the speed of injection affected the toxicity directly. In addition, he cited 25 human cases of his own and about 25 from other clinics in which the results of treatment were good without untoward effects. Following this, in 1937, Modell and associates⁶ performed further experiments on animals which had been given fatal doses of mercury. They concluded that the protection afforded by sodium formaldehyde sulfoxylate was limited by the speed of action of the mercury. Moreover, they showed that the end product of the reaction between mercury and sodium formaldehyde sulfoxylate was one-half to one-third as toxic as the mercury itself. Of most importance, however, was their demonstration that the alkalization of the media increased the speed of reaction of the sodium formaldehyde sulfoxylate with mercury. The last point is of definite significance, especially in cases of oral ingestion of mercury where the poison enters the strongly acid stomach secretion.

Hug⁷ reported a series of 72 cases of acute mercury poisoning treated with sodium formaldehyde sulfoxylate by gastric lavage and intravenous injection. There were five deaths, although about one-half the patients showed definite evidence of kidney damage by urinary changes. On the other hand, Monte and Hull⁸ reported 40 patients treated with sodium formaldehyde sulfoxylate by lavage and intravenous injection as well as by physiologic supportive measures, such as intravenous glucose and saline solutions, morphine, and transfusions. Eighteen patients developed symptoms of acute poisoning, and of these, 14 died. They concluded that there may be a definite danger in the use of the drug because of the apparent increase in mortality over other averages⁹ and also that the drug is valuable only if used very early. Other authors¹⁰⁻¹⁴ have reported cases treated with sodium formaldehyde sulfoxylate by lavage, by intravenous injection, and by colonic irrigation with generally favorable results.

Sodium formaldehyde sulfoxylate is a stable, white, crystalline powder, readily soluble in water. It is relatively nontoxic whether used orally, rectally, or intravenously. It reacts directly with mercuric chloride (more readily in alkaline medium) to precipitate mercury or to form a mercury compound which is one-third to one-half as toxic as the original mercury salt. The last fact accounts for the increase of toxicity of the sodium formaldehyde sulfoxylate in the presence of mercuric chloride. The drug is largely excreted in the urine. Due to these properties sodium formaldehyde sulfoxylate is at present one of the best antidotal agents for acute mercury poisoning. It may be used in all lavage and irrigation fluids as well as intravenously to reach the kidneys. It is easy to handle and it is readily available.

In view of these facts, sodium formaldehyde sulfoxylate was tried in a series of 20 patients over a period of about eighteen months. The routine used was based on that of Rosenthal,^{1, 2, 5} with a number of modifications based on other experimental work⁶ and on certain personal ideas. It consisted of:

1. Immediate gastric lavage, using 4 per cent sodium formaldehyde sulfoxylate in 2 to 3 per cent sodium bicarbonate solution. Five hundred cubic centimeters or more of solution are used, leaving 250 c.c. in the stomach.

2. Injection of 200 c.c. of 5 per cent sodium formaldehyde sulfoxylate intravenously, taking one-half hour for the injection and then following it with a continuous drip of 5 per cent glucose in normal saline. Injection of an additional 100 c.c. of 5 per cent sodium formaldehyde sulfoxylate intravenously six hours later.

3. Use of two high colonic irrigations a day, using 4 to 5 liters of 1:1,000 (0.1 per cent) sodium formaldehyde sulfoxylate for each irrigation.

4. Gastric lavage with 500 c.c. of 4 per cent sodium formaldehyde sulfoxylate in 2 to 3 per cent sodium bicarbonate solution twice a day for two days.

5. Injection of at least 2,000 c.c. of 5 per cent glucose in normal saline intravenously daily for seven to ten days.

6. In the event of stomatitis, use of a mouth wash of 2 per cent sodium formaldehyde sulfoxylate in 2 to 3 per cent sodium bicarbonate solution two to three times daily.

7. Use of morphine, stimulants, and other supportive measures as needed. If shock is present, it is combatted by appropriate methods.

8. Use of soft diet and forced fluids.

A number of laboratory procedures are performed. Daily routine urine examination is done, and daily nonprotein nitrogen, carbon dioxide combining power, and creatinine determinations are made on the blood. Specimens of urine, stool, vomitus, colonic washings, stomach washings, and mouth washings are examined for mercury daily using the electrolytic method. Naturally, the procedure is modified to fit the needs of the individual patient and in accordance with the clinical course.

All the patients had taken mercuric chloride in doses ranging from 7.5 (one tablet) to 45 (six tablets) grains. The average dose was 17.68 grains and

the mean dose was 15 grains. Emesis occurred in all patients at intervals varying from five minutes to two hours after ingestion. In 13 patients emesis occurred within fifteen minutes. The interval between ingestion and therapy with sodium formaldehyde sulfoxylate ranged between fifteen minutes and thirty-six hours. Sixteen patients were treated within one hour, and 11 within one-half hour (see Table I).

TABLE I

CASE	DOSE IN GRAINS	EMESIS INTERVAL	INTERVAL BEFORE THERAPY	URINE	N.P.N. IN MG. PER 100 C.C.	CREAT- ININE IN MG. PER 100 C.C.	COLITIS	MERCURY PRESENT IN

18	7.5	5-10 min.	15 min.	Negative	30-35	1.5-1.6	--	Stool, vomitus, urine
19	30	10 min.	30 min.	3+ albumin, W.B.C., casts	57-121	2.0-7.2	Present	Stool, vomitus, urine
20	15	15 min.	30 min.	Trace albumin, hyaline casts	28-34	1.5	Present	Stool, vomitus, urine

Of the 20 patients 14 (70 per cent) showed evidence of renal damage by changes in the urine, ranging from traces of albumin to 4+ albumin, casts, red and white blood cells. (No urine test was done in one patient who died.) Four cases (20 per cent) showed evidences of renal damage by definite changes in the blood chemistry. No urine examination was done in one patient and no blood chemistry test in two. Thirteen patients (65 per cent) developed colitis, as evidenced by generalized abdominal cramps, and in some cases, bloody diarrhea. Mercury was found in the vomitus, washings, or excreta in 16 of 19 patients examined (84 per cent). In 12 patients (75 per cent of the positive cases) mercury was present in two or more of these groups (see Table I).

Sixteen patients recovered completely with no residual effects. Four patients died. Of these, three developed anuria and uremia, and the other died shortly after ingestion of the mercury in respiratory failure, evidently the result of aspiration of vomited material or edema of the glottis. The case reports of the patients who died are presented here.

CASE 9.—M. W., a 27-year-old white man, swallowed 3 tablets (22.5 grains) of mercuric chloride with a glass of water in an attempted suicide. Fifteen minutes later he vomited blue material, and about one hour later he was brought into the hospital. On admission he appeared acutely ill and he was vomiting bloody mucoid material. His face was blotchy, and his lips, tongue, and pharynx were markedly injected and moderately swollen. Abdomen was tender. He was lavaged with 1,250 c.c. of 4 per cent sodium formaldehyde sulfoxylate in 2 to 3 per cent sodium bicarbonate solution, and he swallowed about 450 c.c. of the same solution. Some of the lavage returns were gray with precipitated mercury. He was then given 200 c.c. of 5 per cent sodium formaldehyde sulfoxylate intravenously and 100 c.c. of the same solution seven hours later. He was lavaged twice a day for one day, with 4 per cent sodium formaldehyde sulfoxylate in sodium bicarbonate solution, and used a mouthwash and gargle of 2 per cent sodium formaldehyde sulfoxylate in sodium bicarbonate solution two to three times a day. In addition, he was given high colonic irrigations with 1:1,000 sodium formaldehyde sulfoxylate twice a day for three days. In spite of all treatment, including 5 per cent glucose in normal saline intravenously daily, the patient became steadily worse, developed marked oliguria on the third hospital day and slight edema with a moderate temperature elevation on the fourth hospital day. On the morning of the fifth hospital day he developed acute pulmonary edema, even though the intravenous fluid had been changed to 5 per cent glucose in distilled water. He responded well to treatment for this complication, but a short time later he gasped suddenly and died. Permission for autopsy was not obtained. Urines when obtained showed 1-3+ albumin and a few red blood cells and white blood cells. Nonprotein nitrogen started at 36 mg. per 100 c.c. and rose to 67 mg. per 100 c.c. Creatinine started at 1.7 mg. per 100 c.c. and at time of death was 8.3 mg. per 100 c.c. Mercury was found in the vomitus, stool, lavage material, and urine.

CASE 11.—H. S., a 28-year-old white woman, took four tablets (30 grains) of mercuric chloride with suicidal intent. She vomited twenty minutes later and was brought into the hospital about one-half hour later. On admission examination revealed an obese woman, appearing acutely ill, vomiting continuously. Her lips were swollen and she showed marked injection of her mouth and throat. Abdomen was slightly tender and showed slight spasm. Remainder of examination was negative. Patient was immediately lavaged with 500 c.c. of 4 per cent sodium formaldehyde sulfoxylate in 4 per cent sodium bicarbonate solution. The washings were dark gray with precipitated mercury. She was washed further with large amounts of normal saline and sodium bicarbonate solution. A continuous intravenous drip of 5 per cent glucose in normal saline was started. Three hours later she was given 200 c.c. of 5 per cent sodium formaldehyde sulfoxylate intravenously, followed by 100 c.c. six hours later. Because of the character of the washings (containing precipitated mercury), a tube was kept in the stomach for thirty-six hours, and the stomach was washed alternately with plain normal saline and sodium bicarbonate solution and 4 per cent sodium formaldehyde sulfoxylate in sodium bicarbonate solution every three hours. She was given two high colonic irrigations a day with 1:1,000 sodium formaldehyde sulfoxylate and continuous intravenous 5 per cent glucose in normal saline, followed later with 5 per cent glucose in distilled water. She was given mouthwashes of 2 per cent sodium formaldehyde sulfoxylate because of the stomatitis and pharyngitis. On the second hospital day she had an oliguria, and on the third day she became completely anuric. She became progressively worse with onset of drowsiness, edema, and abdominal cramps. She developed hemorrhages in the fundi. Despite diathermy to the kidneys and supportive measures, including sodium lactate intravenously to combat the acidosis, the patient died on the eighth hospital day. Her urine when obtained initially showed 3+ albumin, 4 to 6 white blood cells and occasional casts. Her

nonprotein nitrogen ranged from 28 mg. per 100 c.c. on admission to 93 mg. per 100 c.c. at the time of death; her creatinine from 2.8 mg. per 100 c.c. to 13.6 mg. per 100 c.c. Carbon dioxide combining power decreased to 25.1 volumes per cent, but returned to 41.9 volumes per cent at the time of death. Mercury was found in the vomitus, gastric washings, colonic washings, stools, and urine. Permission for autopsy was obtained. The essential findings at autopsy were:

Gross: Pulmonary edema and patchy bronchopneumonia; large, pale, swollen kidneys, with moderately injected pelves, weighing together 400 Gm.; moderate gastritis, enteritis, and colitis with a greenish gray, pseudodiphtheritic membrane in the rectum and a portion of the sigmoid colon.

Microscopic: Lungs showed pulmonary edema and bronchopneumonia; kidneys showed a marked mercury nephrosis with early regeneration and healing; stomach, small intestine, and colon showed simple inflammation, with slight superficial necrosis of the mucosa in the region of the rectum and sigmoid colon.

CASE 12.—H. B., a 37-year-old white male, took 6 tablets (45 grains) of mercuric chloride with suicidal intent. He vomited thirty to sixty minutes later and was brought into the hospital about three hours after ingestion. Examination on admission revealed a comatose man, breathing heavily and with some difficulty. He was cyanotic and vomited bloody material, and was having bloody diarrhea. Skin was moist and cold. There were coarse râles at both lung bases. Blood pressure was 140/100. He was immediately lavaged with large amounts of 4 per cent sodium formaldehyde sulfoxylate and sodium hyposulfite. He was given 200 c.c. of 5 per cent sodium formaldehyde sulfoxylate intravenously, followed by 5 per cent glucose in normal saline in a continuous drip. Preparations were made for transfusion. However, the patient became rapidly and progressively worse and died one hour and forty minutes after admission. Death was evidently due to respiratory failure following either aspiration of vomitus or acute edema of the glottis. It was later discovered that the patient had a history of peptic ulcer. No laboratory studies were done. Autopsy was not performed.

CASE 19.—A. M., a 29-year-old white female, took four tablets (30 grains) of mercuric chloride with suicidal intent. She vomited blue material ten minutes later and was brought into the hospital about thirty minutes after ingestion. On admission examination revealed an acutely ill woman, vomiting large amounts of green fluid and having severe diarrhea. Mouth and pharynx showed considerable injection and swelling. Remainder of the examination was essentially negative. The patient was immediately lavaged with 500 c.c. of 4 per cent sodium formaldehyde sulfoxylate in 2 to 3 per cent sodium bicarbonate solution. About 100 c.c. of solution were left in the stomach. She was then given 200 c.c. of 5 per cent sodium formaldehyde sulfoxylate solution intravenously, followed by a continuous drip of 5 per cent glucose in normal saline. Six hours later an additional 200 c.c. of 5 per cent sodium formaldehyde sulfoxylate were given intravenously. A Levine tube was put down into the stomach and the stomach was washed with 4 per cent sodium formaldehyde sulfoxylate in sodium bicarbonate solution every two hours four times. About twenty-four hours after admission the patient was again given 200 c.c. of 5 per cent sodium formaldehyde sulfoxylate solution intravenously and about 500 c.c. of Fischer's solution as well. She was lavaged with 4 per cent sodium formaldehyde sulfoxylate in sodium bicarbonate twice on the day after admission. She was given two high colonic irrigations a day with 1:1,000 sodium formaldehyde sulfoxylate. She was put on a liquid diet with forced fluids and was given large amounts of 5 per cent glucose in normal saline, alternating with 5 per cent glucose in distilled water up to 4,000 c.c. a day. About eighteen hours after admission the patient began to show definite oliguria, and on the fourth hospital day she became anuric. She became progressively worse, appeared toxic and drowsy, and developed a generalized edema on the sixth hospital day and, despite all supportive measures, died on the seventh hospital day. Urines showed 3+ albumin and many granular casts as well as many white blood cells. Nonprotein nitrogen ranged from 57 mg. per 100 c.c. to 121 mg. per 100 c.c., creatinine

from 2.0 mg. per 100 c.c. to 7.2 mg. per 100 c.c.. Vomitus, gastric washings, urine, stools, and colonic washings were positive for mercury. Permission for autopsy was obtained. The essential findings at autopsy were:

Gross: Generalized edema; moderate pulmonary edema and patchy bronchopneumonia; large, pale, swollen kidneys; a deep ulceration in the stomach, about 1 cm. in diameter, with injection of the stomach mucosa elsewhere and moderate injection of the colon.

Microscopic: Lungs showed edema and bronchopneumonia; kidneys showed a marked mercury nephrosis with early regenerative changes; the stomach showed a deep necrotic area, extending into the muscularis, with a mild inflammatory change elsewhere in the stomach mucosa, and the colon showed a mild catarrhal colitis.

COMMENT

The important element in any method of treatment of acute oral mercury poisoning is not the rapidity with which patients recover nor the presence or absence of residual effects, but it is the actual recovery itself or the resulting mortality rate. The mortality rate of 20 per cent obtained in this small series is slightly better than the 25 per cent rate obtained by Hull and Monte⁹ in a much larger series treated by various other methods. In the same large series they also noted that about 50 per cent of all cases showed evidence, either urinary or otherwise, of real poisoning, half of these dying. In this series 17 cases, or 85 per cent, showed evidences of poisoning with either renal or colonic damage and 10 cases, or 50 per cent, showed both. Nevertheless, in a small series these figures are not too significant.

In the four fatal cases the doses were larger than the average of 17.68 grains, ranging from 22.5 to 45 grains, the time interval from ingestion to emesis was ten minutes or over, and the treatment interval ranged from thirty minutes to three hours. Moreover, in Case 11 intravenous therapy was delayed for over three hours; hence the absorbed mercury was able to reach the kidneys and cause damage before it could be precipitated. In Case 12 death was primarily respiratory. The importance and value of high colonic irrigations are amply demonstrated by the autopsy findings in Cases 11 and 19 where the colons were only superficially involved, indicating that the irrigations were effective in removing the concentrated mercury. The high incidence of colitis even early in the course of the poisoning makes the prompt institution of high colonic irrigations especially significant. Mercury was found in the stools of 14 of the 16 mercury positive cases, and of the mercury positive cases which showed clinical evidence of colitis it was found in the stools of all except one (11 out of 12). This again emphasizes the role of the colon in the excretion of the mercury.

The importance of early and intensive treatment both oral and intravenous cannot be overestimated, inasmuch as the mercury is absorbed rapidly and produces severe damage in a short time. The fact that the substance formed by combination of mercury and sodium formaldehyde sulfoxylate is still toxic should not be overlooked, so that physiologic supportive measures must be maintained encouraging excretion by all avenues. Moreover, the toxic effect of the mercury on the body as a whole must be combatted by the supportive measures.

The method of treatment advocated here is far from ideal. It is attended by certain dangers and requires careful supervision. Each case should be treated individually and each situation should be met as it arises without too

much dependence being placed on the antidotal drug. However, under careful supervision, the general method has a definite value and the drug deserves further trial until a more specific agent is discovered.

SUMMARY

A method of treatment for acute mercury poisoning utilizing sodium formaldehyde sulfoxylate and based on the work of Rosenthal is outlined. It consists of: 1. Immediate gastric lavage with sodium formaldehyde sulfoxylate. 2. Intravenous injection of sodium formaldehyde sulfoxylate. 3. High colonic irrigations with the same drug twice daily. 4. Gastric lavage twice daily for two days. 5. Daily intravenous glucose in saline. 6. Mouthwash with sodium formaldehyde sulfoxylate for stomatitis. 7. Supportive measures as needed. 8. Fluids and soft diet.

The findings and results in 20 cases treated by this method are presented. Four fatal cases are presented and the causes of death are analyzed.

The significance of early treatment, physiologic supportive measures, high colonic irrigations, and individual management are stressed.

The method is not considered to be ideal, but it is felt that it should be used in all cases of acute mercury poisoning until a more efficient routine is discovered.

INFLUENCE OF COMPONENTS OF THE VITAMIN B COMPLEX ON RECOVERY FROM FATIGUE*

E. E. FOLTZ, M.S., M.D., A. C. IVY, PH.D., M.D., AND
C. J. BARBORKA, M.S., M.D., D.Sc., CHICAGO, ILL.

IT IS generally conceded that one of the cardinal symptoms of thiamine deficiency is easy fatigability.¹⁻⁴ It is reported that in patients suffering from thiamine deficiency the blood pyruvate is elevated and that the administration of thiamine causes it to become lower.^{5, 6} Muscular exercise produces a rise in the blood pyruvate level above that found at rest.⁷ Further, thiamine-deficient patients develop a higher level of pyruvic acid in the blood after exercise than do normal persons⁸ and are capable of less work.⁹ Some investigators¹⁰⁻¹² have felt that the administration of thiamine and other components of the vitamin B complex allayed fatigue. For these reasons, an attempt was made to ascertain whether *recovery* could be hastened by the administration of thiamine and other members of the vitamin B complex to fatigued persons.

Five persons under controlled conditions of housing and diet were studied. The diet was adequate in all respects and contained approximately 1.8 mg. of thiamine and 3.5 mg. of riboflavin. "Double work periods"¹³ were used. The work was done on Monday, Wednesday, and Friday afternoons at the same time between 2 and 4 o'clock. The subjects would work to fatigue at a rate of 1,235 kg. per minute, with a pedaling rate of 54 r.p.m. on the bicycle ergometer, described by Kelso and Hellebrandt.¹⁴ The end point was their inability to maintain this rate. Immediately after this first work period the vitamin to be tested was injected intravenously. Then ten minutes after the cessation of the first work period each subject would again work to fatigue. Placebo injections were substituted at random for the vitamin injections. No subject was allowed to watch an injection. The vitamins used were thiamine hydrochloride,† 25 mg., 20 trials; B complex parenteral,† 1 to 5 c.c., 7 trials; cocarboxylase,‡ 10 mg., 4 trials; riboflavin,† 1.25 to 10 mg., 12 trials. The results are shown in Tables I and II.

The results for thiamine, cocarboxylase, and B complex are included in Table I. Since they had no significant effect, the results with each vitamin are

*From the Departments of Medicine and Physiology, Northwestern University Medical School, Chicago.

Thiamine hydrochloride—50 mg. per cubic centimeter. Riboflavin—1 mg. per cubic centimeter. B complex parenteral, each 10 c.c. contains:

Thiamine hydrochloride, 30 mg.

Nicotinamide, 100 mg.

Riboflavin, 3.3 mg.

Pyridoxine hydrochloride, 10 mg.

‡Supplied by Merck and Company.

not tabulated. The riboflavin was administered at a later period of training, and the data on it are in Table II. Referring to Table I, it will be noted that in 2 of the 3 subjects (B and D) the work output of the second work period following the administration of vitamins is insignificantly less than with the placebo; in the other subject (A) it is not significantly elevated. In no case is the total work output greater following vitamin administration than it is in the control or placebo series. These two factors more than cancel the apparently favorable effect of vitamins on per cent recovery, which effect, however, is not statistically significant.

TABLE I
DATA ON THIAMINE, COCARBOXYLASE, AND THE B COMPLEX

SUBJECT	TYPE OF WORK PERIOD	PERIOD OF TRAINING (MONTHS)	NUMBER OF DOUBLE WORK PERIODS	AVERAGES			
				1ST PERIOD WORK OUTPUT (KG.)	2ND PERIOD WORK OUTPUT (KG.)	TOTAL WORK OUTPUT (KG.)	PER CENT RECOVERY
A	Control Vitamin	2 -3	19	13,951	6,356	20,275	46
		3 -3.5	9	13,033	7,156	20,168	56
B	Control Vitamin	1.5 -3.75	21	6,573	4,491	11,142	68
		1.5 -4	15	6,501	4,373	10,889	68
D	Control Vitamin	2 -3.25	15	10,029	5,595	15,540	56
		3.25-3.75	7	8,816	5,530	14,346	63

TABLE II
DATA ON RIBOFLAVIN

SUBJECT	TYPE OF WORK PERIOD	PERIOD OF TRAINING (MONTHS)	NUMBER OF DOUBLE WORK PERIODS	AVERAGES			
				1ST PERIOD WORK OUTPUT (KG.)	2ND PERIOD WORK OUTPUT (KG.)	TOTAL WORK OUTPUT (KG.)	PER CENT RECOVERY
A	Control Riboflavin	8 -8.5	7	8,788	5,900	14,655	70
		8.5 -8.75	3	8,355	5,941	14,297	71
B	Control Riboflavin	8.25-8.75	7	6,079	4,260	10,339	71
		8.75-9	3	6,283	4,384	10,667	70
E	Control Riboflavin	4.5 -5	6	3,770	2,669	6,437	71
		5 -5.25	3	3,931	2,805	6,736	71
F	Control Riboflavin	4.5 -5	6	4,840	2,696	7,536	56
		5 -5.25	3	5,254	2,973	8,032	53

Referring to Table II, it is seen that in the case of A the output of work was insignificantly less following riboflavin than in the control series. Considering the subjects B, E, and F, it is apparent that insignificant increases in work output occurred during the first and second periods and in the total work output after riboflavin. However, the insignificant increment observed after the riboflavin can well be explained by training or experimental variation. Also, if an effect had been produced by the riboflavin, a significant increase in the per cent recovery should have occurred. Such was not the case. Thus no significant effects were observed, and the subjects reported no subjective sensations whatever after receiving any of the vitamins.

These results show that the vitamins administered above do not act promptly to facilitate recovery. This statement is made because it is not to be concluded

that an increase in recovery will not occur when these vitamins are added to a diet containing an insufficient quantity of them.

Further Observations on the Double Work Period Method of Studying Fatigue.—One reason for using the double work period method of studying fatigue is that it assists the investigator in determining whether or not his subjects have worked to complete fatigue. This is based in part on our observations¹³ that the per cent recovery is more constant than the output of a single work period. For example, if a subject does not work to complete fatigue in the first period, he will work longer than usual in the second period, and his per cent recovery will be correspondingly high. If, however, he does work to complete fatigue the first period and does not work to complete fatigue in the second period, his per cent recovery will be unusually low. To check whether or not per cent recovery could be "faked," four subjects were stopped when they had done approximately 75 per cent as much work as average in the first period. In the second period they were asked to stop as far short of fatigue as they had in the first period. In no case was their usual per cent recovery approximated.

TABLE III
INITIAL DOUBLE WORK PERIODS
(25 Subjects)

	RANGE	COEFFICIENT OF VARIATION (%)
1st period work output	1,112-6,133 kg.	40.9
2nd period work output	761-2,511 kg.	23.0
Total work output	1,873-8,023 kg.	31.1
Per cent recovery	31-99 per cent	19.0

To test the double work period method further, the data of the initial double work periods on 25 new subjects at the above standard rate of work were analyzed. The variability of the four items of fatigue data obtained by this method are shown in Table III. These data indicate that even in untrained persons the per cent recovery is the most constant physiologic characteristic of these four manifestations of fatigue and that the first work period, the variability of which corresponds with that of the single work period, is the most variable. That the ten-minute rest period is not too short to reveal the effect of any substance on recovery has been demonstrated by the favorable effects of caffeine.¹³

CONCLUSIONS

Thiamine, cocarboxylase, riboflavin, and parenteral vitamin B complex given intravenously have no immediate influence on recovery from voluntary muscular fatigue in subjects receiving "adequate" nutrition.

The double work period method of studying fatigue enables the investigator to determine whether his subjects are actually working to a designated end point of fatigue.

The per cent recovery is less variable than the first period work output, the second period work output, or the total work output in initially untrained subjects.

CLINICAL CHEMISTRY

CIRRHOSIS OF THE LIVER*

RESULTS OF TREATMENT WITH PARENTERALLY ADMINISTERED AMINO ACIDS

I. DONALD FAGIN, M.D., AND FRANCIS T. ZINN, M.D.
DETROIT, MICH.

PLASMA PROTEINS AND CIRRHOSIS OF THE LIVER

RECENT studies in the relationship between plasma proteins and liver diseases have indicated that in order to maintain an efficient liver function, adequate protein supplies are necessary; and conversely, in order to maintain normal plasma protein levels, the liver must be in a good functional condition.⁶

The finding of decreased concentrations of blood proteins in cirrhosis of the liver was first observed by Grenet and Gilbert in 1907, and has been frequently substantiated since.^{1, 2, 8, 10} In general, total protein content of the serum is usually decreased, primarily because of a depletion of the albumin content, and the A./G. ratio is low or inverted. Occasionally, the serum globulin is increased, apparently compensating for the albumin deficiency, so that total serum proteins may be within normal limits.^{8, 10} The hypoalbuminemia or hypoproteinemia generally found in hepatic cirrhosis may be attributable to one, or to a combination of the following factors:¹¹ (a) Deficiency of protein food intake. (b) Protein loss via drainage of albumin in the ascitic fluid. (c) Increased permeability of the capillary bed with consequent diffusion of proteins into the tissues. (d) Failure of the liver to produce proteins or defective formation of proteins. (e) Deficiency of protein-building materials stored in the normal liver. (f) Other factors as yet undefined.

Deficiency of protein intake has been excluded as a significant factor by Foley and co-workers,¹⁰ who described several patients with severe dietary restrictions, but without clinically recognizable hepatic damage, who, although they exhibited some decrease in total proteins, showed no increase in the globulin concentration and no reversal of the A./G. ratio. Myers and Keefer¹ were unable to demonstrate any effect on plasma proteins by feeding patients with cirrhosis of the liver diets containing from 180 to 300 Gm. of proteins daily, possibly because of the impairment of the proteogenic function of the liver.^{2, 10} The significance of protein loss via ascitic fluid drainage has been minimized by Barrett, Jones, and Cohn³ who reported a patient with hepatic cirrhosis who

*From the Medical Service and Laboratories of the United States Marine Hospital, Detroit.

Received for publication, May 6, 1942.

required frequent paracentesis with removal of an average of 10.2 Gm. of protein per day in the ascitic fluid over a 204-day period, without any definite fall in the plasma protein level. Patients without cirrhosis, but with ascites due to carcinomatous peritoneal or hepatic metastases, or tuberculous peritonitis, or congestive heart failure do not exhibit diminution of plasma protein content, although the protein loss is comparable.¹⁰

Butt and associates¹¹ suggested that the usual protein determination does not adequately reflect the osmotic interplay at the capillary membrane. They actually measured the colloidal osmotic pressure of the blood serum in patients with cirrhosis of the liver and found that in almost all cases the serum colloid osmotic pressure was below normal levels. All the patients with edema and ascites had colloid osmotic pressures below the lowest level of normal, probably because of the hypoalbuminemia, since the smaller albumin molecules have the greater osmotic effect. Using the bromsulfalein excretion and hippuric acid synthesis tests to measure the degree of hepatic damage, Butt and his group found an apparent correlation between the colloid osmotic pressure values and the degree of hepatic insufficiency.

The most likely factor, then, to explain hypoproteinemia in hepatic disease is the impairment of hepatic proteogenic mechanism (possibly due to depletion of protein-building stores in the liver), perhaps acting together with increased permeability of the capillary bed.

Pitting edema of the lower extremities is often seen in cirrhosis of the liver, and the most widely accepted explanation has been that the edema is due either to an increased venous pressure in the lower extremities as a result of increased intra-abdominal tension caused by ascites, or to a concomitant congestive heart failure. Myers and Keefer¹ point out that these factors do not explain the dependent edema sometimes seen in patients with a minimal amount of ascitic fluid and without other evidence of circulatory failure. They studied the blood and ascitic fluid protein values in their patients and concluded that the dependent edema is due, partially at least, to hypoproteinemia and increased venous pressure, the latter occurring only in the presence of massive ascites.

RATIONALE

Lillie and associates⁷ reported the production of cirrhosis in rats maintained on a diet deficient in protein, and also noted an increase in the severity of the hepatic lesions when 20 per cent alcohol solution was used instead of water in conjunction with the protein-deficient diet. Rats maintained on an adequate protein regimen exhibited no liver changes, even when the 20 per cent alcohol was added. The low sulfur content of the protein-poor diet used suggested a possible relationship between the amino acid content of the diet and the ability of the liver to resist orally administered poisons.

In a later report Lowry and co-workers¹² presented the result of treatment of experimental dietary cirrhosis of rat livers produced by a low choline, low casein diet with added cystine. They found that the use of choline, or a high casein diet, or both, resulted in hyperplastic regeneration of the liver cells, with the disappearance of degenerative fatty changes. Grossly, the livers of rats thus treated exhibited a considerable decrease in size.

It has been shown by several observers (Elman and Weiner, Shohl, Blackfan and Butler; Altschuler, Hensel and Sahyun, quoted in reference 13) that nitrogen equilibrium may be maintained by amino acid mixtures. Messinger¹⁴ has reported serum protein regeneration following the use of amino acids in nephrosis. In view of these observations it was deemed advisable to investigate the effects of administering an amino acid mixture to patients with hepatic cirrhosis to determine what effects, if any, would be demonstrable on serum proteins, edema, ascitic fluid production, liver size, and liver function.

METHOD

Five patients with clinical diagnoses of cirrhosis of the liver were selected at random from the wards; four were in the so-called "decompensated" stage of portal cirrhosis (i.e., they exhibited ascites at some time or another), and one was clinically in the so-called "compensated" stage. The clinical features of these patients are summarized in this report. In all cases jaundice subsided before the institution of the study. In order to obtain a base line, the patients were observed during a period varying from two months to five months, during which time daily weight fluctuations were charted, ascitic fluid output was measured by paracenteses performed as indication arose, blood protein values were determined, and liver function tests were performed. The bromsulfalein excretion and hippuric acid synthesis tests were used.

Other laboratory determinations made included blood nonprotein nitrogen, blood counts, urines (to exclude proteinuria), icteric indices, and sedimentation rates. As an index of impairment of carbohydrate metabolism in hepatic disease, we used the glucose tolerance test (Exton-Rose method)³ in preference to the levulose and galactose tolerance tests. During the base-line period of observation, the patients were maintained on a diet of carbohydrate 250 Gm., protein 125 Gm., and fat 60 Gm. (The previous diet was the regular hospital diet, which is adequate in all dietary essentials.) After preliminary determinations were completed, the protein was reduced to 80 Gm., being supplemented by 300 c.c. of a 15 per cent solution of amino acids.

Because of the possibility that patients with cirrhosis of the liver might conceivably exhibit disorders of digestion clinically unrecognizable, the amino acids were administered intravenously in order to be certain that they actually reached the liver. The mixture used was prepared from a casein hydrolysate to which tryptophane was added, and conformed to the following analysis:

Total nitrogen	2.0 per cent
Alpha amino acid nitrogen	83 per cent of total nitrogen
Calcium	0.01-0.02 per cent
Tryptophane added	1.0 per cent
Sulfates	0.01 per cent
Phosphates, iron, magnesium	trace
Acidity	pH 4.0-4.3

The solution was administered daily, intravenously, after the patient's breakfasts, for four weeks (except in the case of patient G. R., in whom the development of an incidental type XIII pneumococcus pneumonia with bacteremia necessitated cessation of the administration of amino acids after three and one-half weeks).

The solution was administered in undiluted form over a period varying from thirty-five minutes to four and one-half hours. Reactions were few and mild. The first dose resulted in an increased number of bowel movements in three of the five patients. The stools were of normal consistency, and the increased number of evacuations was attributed to a hypermotility of the colon. This reaction was observed the first day only and did not recur. Slight nausea, occasional vomiting, or one-half to one degree elevation of temperature, associated with chilly sensations, were occasionally observed during the first week of amino acid administrations. These reactions tended to occur in the patients who were clinically in the poorest condition at the onset of the experiment. The rate of administration of the solution bore no constant relationship to the incidence of such reactions, for a patient occasionally exhibited nausea or a slight fever when the period of administration was four and one-half hours, and no reaction whatsoever when the period was one-half hour. No systemic reactions occurred after the first week of administration of the solution. Local reactions at the sites of intravenous administration of the solution consisted of a slight transient burning sensation if some of the solution leaked into the surrounding tissues, and occasional painless local thrombosis of the veins without associated swelling or inflammatory reaction.

During the month of administration of amino acids frequent determinations of blood proteins were made. The degree of hepatic and splenic enlargement was gauged by measuring the distance of the liver edge or splenic tip from the costal margin in the nipple line. These measurements were made immediately after paracentesis in those patients with ascites to assure greater accuracy.

At the conclusion of the arbitrarily determined month of administration of intravenous amino acids, the bromsulfalein excretion, hippuric acid synthesis, glucose tolerance tests, serum proteins, blood nonprotein nitrogen, icteric index, erythrocyte sedimentation rate, and blood counts were repeated.

CASE REPORTS

CASE 1.—G. R., a 53-year-old white male patrolman, admitted on October 21, 1941, complained of an upper respiratory infection of one month's duration; abdominal swelling, anorexia, exertional dyspnea, and ankle edema of one and one-half weeks' duration. History of left apical tuberculosis, treated from 1929 to 1933 with rest, pneumothorax, and phrenicectomy. The tuberculosis was inactive since 1933. The patient admitted only slight previous indulgence in alcohol. Physical examination: icteric sclerae (icteric index 40); ascites grade 3 (on a basis of severity of grades 1 to 4); grade 1 edema of the legs; diminished breath sounds in both bases; dullness in left apex anteriorly with diminished breath sounds; and liver enlarged to 10 cm. below the costal margin. Grade 4 penile and scrotal edema developed during observation period in hospital. Laboratory data: urine negative; blood Kahn test negative; sputum and ascitic fluid negative for tubercle bacilli; blood sugar and nonprotein nitrogen normal; blood count normal; sedimentation rate 22 mm. in an hour. X-ray examination of the chest revealed thickened pleura of the left lateral chest wall and fibrosis at the left apex with angulation of the trachea. Clinical diagnosis: portal cirrhosis, decompensated; pulmonary tuberculosis, left apex, arrested.

CASE 2.—P. W., a 69-year-old white male seaman, admitted September 17, 1941, had jaundice of ten days' duration, anorexia of one month's duration, and intermittent ankle edema for two years. The patient reported moderately excessive alcoholic indulgence previously. Physical examination: senility; generalized peripheral arteriosclerosis; jaundice (icteric index 75); liver enlarged to 3 cm. below the costal margin; splenic tip barely pal-

pable; grade 3 edema of the lower extremities; slight epigastric tenderness; and an enlarged, tender, boggy prostate. Laboratory data: blood Kahn test negative; urine negative, except for bile during period of jaundice; blood sugar and nonprotein nitrogen normal; blood count normal; sedimentation rate 29 mm. in an hour. Electrocardiogram showed some evidences of myocardial damage. The edema of the lower extremities subsided with rest. Clinical diagnosis: generalized arteriosclerosis and arteriosclerotic heart disease; portal cirrhosis, compensated; chronic prostatitis.

CASE 3.—G. B., a 46-year-old white male laborer, admitted on July 23, 1941, had dyspnea, ascites, and ankle edema of one month's duration. He reported excessive use of alcohol in the past. Physical examination: acutely ill, obese, white male, with scleral icterus (icteric index 25); ascites grade 3; grade 2 edema of the lower extremities; umbilical hernia; bilateral foot drop; liver enlarged to 21 cm. below the costal margin. Laboratory data: urine negative; blood Kahn test negative; blood sugar and nonprotein nitrogen normal; sedimentation rate 21 mm. in an hour. The foot drop cleared rapidly with the use of thiamine chloride, and was attributed to a peripheral neuritis, secondary to previous inadequate dietary intake and chronic alcoholism. During his stay in the hospital the patient developed hematuria (probably due to rupture of a urethral varix) which subsided spontaneously within a few days. Clinical diagnosis: portal cirrhosis, decompensated; chronic alcoholism.

CASE 4.—J. R., a 49-year-old white male laborer, admitted September 22, 1941, complained of ascites of three months' duration, jaundice of three weeks' duration, and ankle edema of five days' duration. He reported exceedingly heavy indulgence in alcohol previously. Physical examination: chronically ill white male; jaundiced (icteric index 145); liver enlarged to 12 cm. below the costal margin; spleen enlarged to 7 cm. below the costal margin; grade 4 ascites; caput medusae; grade 3 edema of the lower extremities and abdominal wall; small umbilical hernia; external hemorrhoids; obesity; and dental caries. Laboratory data: urine negative, except for bile during period of jaundice; blood Kahn test negative; blood count indicated slight anemia; blood nonprotein nitrogen and sugar normal; sedimentation rate 18 mm. in an hour. Clinical diagnosis: portal cirrhosis, decompensated; chronic alcoholism.

CASE 5.—A. G., 52-year-old white male bartender, was admitted October 28, 1941, complaining of anorexia, intermittent nausea, and vomiting, weight loss of 30 pounds, ascites, and weakness, all of six months' duration. He reported moderately excessive previous indulgence in alcohol. Physical examination: generalized icterus (icteric index 18); slight diffuse enlargement of the thyroid; liver enlarged to 11 cm. below the costal margin; spleen enlarged to 7 cm. below the costal margin; minimal pretibial edema; small amount of fluid in the left chest; grade 3 ascites; old gunshot wound of the right lower extremity with an ankylosed right knee; flat feet; varicose veins; and left scrotal hernia. Laboratory data: urine negative; blood count normal; blood Kahn test negative; blood sugar and nonprotein nitrogen within normal limits; sedimentation rate 24 mm. in an hour. The ascites did not recur after initial paracentesis. Clinical diagnosis: portal cirrhosis, early decompensation; left scrotal hernia; old gunshot wound, right lower extremity.

RESULTS

1. *Subjective Effects.*—Clinically, one of the patients (A. G.) reported an excellent improvement in his general condition, associated with moderate gain in strength, great improvement in mental outlook, and an increased feeling of well-being. Three patients (G. R., J. R., and G. B.) reported moderate subjective improvement, and one patient was subjectively unchanged (P. W.). One of the patients (J. R.), however, developed a transitory psychosis three weeks after the cessation of our study, but we believe that this episode represented merely a complicating psychosis in the course of an organic disease rather than any deleterious effect of the therapy per se.

Fig. 1.—The effect of the administration of amino acids on the size of the liver and spleen, and on the hippuric acid synthesis test. Preliminary observations are solid blocks; findings after therapy are represented by lined blocks or the words "not felt."

Fig. 2.—The effect of the administration of amino acids on the glucose tolerance curves. Straight lines represent preliminary determinations; broken lines, after therapy.

TABLE I
EFFECT OF AMINO ACIDS ON ASCITIC FLUID

	J. R.	G. B.
Average interval between paracentesis		
Observation period	8.5 days	7.7 days
Administration period	8.7 days	8.7 days
Average daily output of ascitic fluid		
Observation period	1,333 c.c.	1,451 c.c.
Administration period	1,398 c.c.	1,377 c.c.
Average specific gravity of ascitic fluid		
Observation period	1.015	1.011
Administration period	1.011	1.012
Average protein content of ascitic fluid		
Observation period	730 mg. per 100 c.c.	775 mg. per 100 c.c.
Administration period	600 mg. per 100 c.c.	610 mg. per 100 c.c.

2. *Effect on Size of Liver and Spleen.*—The most striking result of the use of the intravenous amino acids was the dramatic decrease in the size of the liver of all the patients, particularly in the four with “decompensated cirrhosis.” No decrease in size of the liver or spleen had been noted during the period of observation preliminary to the use of amino acids, and the decrease in size was much more rapid and uniform than that usually encountered in the natural course of the disease. The hepatic and splenic measurements in centimeters below the costal margin before and after treatment are represented in Table II, and in graphic form in Fig. 1.

TABLE II
EFFECT OF THE ADMINISTRATION OF AMINO ACIDS ON THE SIZE OF THE LIVER AND SPLEEN, AND ON THE HIPPURIC ACID SYNTHESIS TEST

	A. G.	P. W.	G. R.	G. B.	J. R.
Liver—cm. below right costal margin					
Preliminary	11	3	10	21	12
After therapy	5	1	0	7	7
Spleen—cm. below left costal margin					
Preliminary	7	1	0	0	7
After therapy	0	0	0	0	3
Hippuric acid synthesis—as grams of benzoic acid excreted (normal 3 to 3.5 Gm.)					
Preliminary	2.20	2.00	1.36	1.60	0.75
After therapy	2.36	3.13	1.66	1.82	1.97

In view of the report of Lowry and associates¹² already mentioned, in which the livers of experimentally cirrhotic rats were observed to shrink in size and exhibit disappearance of degenerative fatty changes when treatment with choline or a high-casein diet was instituted, it seems logical to assume that the diminution in size of the livers in these cases is primarily due to resorption of the fat in the liver cells. The decrease in the size of the spleen in those patients who exhibited splenomegaly may be attributable to circulatory readjustments secondary to the decreased size of the liver. The mechanism underlying the resorption of the fat in the liver cells is uncertain, but it probably represents a lipotropic action of the

administered amino acids. Unfortunately, we were unable to follow up our patients with liver biopsies.

The possibility that the shrinkage in the size of the liver reflects a change in the water content of the liver tissue is worthy of consideration, and animal experimentation is necessary to confirm or refute this aspect.

3. *Effect on Peripheral Edema.*—Four patients presented peripheral edema of varying degree at the initiation of the study, and all evidenced complete re-sorption of the edema fluid within two weeks after the start of amino acid administration. We are inclined to believe that this change reflects improvement in the serum proteins and osmotic balance at the capillary membranes.

4. *Effect on the Ascitic Fluid Output.*—The administration of amino acids had no appreciable effect on the output of ascitic fluid, or on the specific gravity of the ascitic fluid. Only two patients required paracentesis a sufficient number of times to warrant consideration, and the characteristics of the ascitic fluid in these patients is presented in Table I. It will be noted that there is a slight but appreciable decrease in the average protein content of the ascitic fluid after the administration of amino acids. We do not believe that the changes in the amount of fluid, or in the interval between paracentesis, or in the specific gravity of the ascitic fluid before and after therapy are of significance. However, the decrease in average protein content of the ascitic fluid during and after therapy may reflect improvement in serum proteins and capillary permeability.

5. *Laboratory Findings.*—(a) Effect on serum proteins: Serum proteins were determined by the use of photoelectric colorimeter, as described by Looney and Walsh.⁹ In our hands the results were too bizarre and variable to warrant consideration. Despite the fact that a large part of the study depended upon our following the serum proteins, we were unable to draw any conclusion thereunto appertaining because of the inaccuracy of the method in our hands. Nevertheless, other findings of sufficient importance developed during the course of the study to warrant presentation of our results.

(b) Effect on hippuric acid synthesis: Reference to Table II indicates that in all cases there was some improvement in the ability of the liver to handle ingested sodium benzoate. In three cases (G. R., J. R., and P. W.) this improvement is of significant degree. These findings are suggestive of a beneficial effect on the detoxification function of the liver, and possibly an improvement in the ability of the liver to manufacture the amino acid glycine, since the hippuric acid test indicates the ability of the liver to conjugate ingested sodium benzoate with glycine, forming hippuric acid, which is excreted in the urine if renal function is adequate.⁴

(c) Effect on glucose tolerance curve: Reference to Fig. 2 indicates that in every instance the glucose tolerance curve changed somewhat in the direction of improved utilization of glucose after the period of amino acid administration. We realize that these tests are subject to criticism in that they represent single examinations and not a summary of daily variations in the glucose tolerance of the individual patient. However, the fact that they all changed in the same direction leads us to believe that intravenous administration of amino acids pro-

moted increased tolerance and utilization of carbohydrates, particularly since the patients were on an adequate diet when the initial determinations were made.

(d) Effect on bromsulfalein excretion: In only one patient (G. R.) was there any appreciable effect on the bromsulfalein excretion. In this patient, prior to the administration of amino acids, there was 40 per cent bromsulfalein retention in the blood stream after one hour, and at the conclusion of the period of intravenous amino acid administration there was only a 12 per cent one-hour retention. The other patients exhibited no significant changes in bromsulfalein excretion.

(e) Effect on other blood constituents: The blood count, nonprotein nitrogen, sedimentation rate, and icteric indices exhibited no significant changes during the course, or at the conclusion of our period of study. As has been noted, clinical jaundice had subsided in all these patients before the study was begun.

SUMMARY

1. A study of the effects of the intravenous administration of amino acids to five patients with cirrhosis of the liver is presented.

2. Clinically, one patient exhibited great general improvement; three exhibited moderate general improvement, and one remained unchanged.

3. The most striking result was shrinkage in the size of the liver and spleen, possibly attributable to resorption of intracellular fat in the liver, with circulatory readjustments secondary to the improved portal circulation resulting in decrease in splenic congestion.

4. Peripheral edema subsided in all patients exhibiting it within two weeks after the initiation of amino acid therapy.

5. Laboratory data accumulated during a preliminary period of observation and at the conclusion of a period of amino acid administration indicated an improvement in glucose tolerance and in hippuric acid synthesis in all patients, and an improvement in bromsulfalein excretion in one patient.

6. Further study and corroboration is needed to determine the degree of benefit obtainable by the use of amino acids in cirrhosis of the liver.

We wish to thank Mr. Raymond L. Charles, chief technician, for his valuable assistance.

The amino acids solution used for this investigation was Amino Acids Parenteral Stearns, supplied through the courtesy of Frederick Stearns & Company, Detroit, Mich.

LABORATORY METHODS

GENERAL

A STUDY OF THE PHENOMENON OF ERYTHROCYTE SEDIMENTATION^{*}

II. THE ESTABLISHMENT OF A RELIABLE MEASUREMENT OF THE PHENOMENON— ITS REPRODUCIBILITY AND LIMITATIONS

ROY E. NICHOLS, B.V.Sc., M.Sc., PH.D.,† LAFAYETTE, IND.

IN A PREVIOUS publication¹ literary evidence of the source of my conception of the status of sedimentation was advanced. It early became evident that choice or development of a suitable technique for the measurement of sedimentation would be a difficult task indeed since there were and still are in use a multiplicity of techniques, many quite different.

The horse was chosen as the experimental subject since large samples of blood could be procured with ease and at fairly frequent intervals. Agglutination of equine red cells and thus sedimentation are very rapid even in healthy subjects. Probably because of its natural rapidity, separation of equine corpuscles seems somewhat more sensitive to such physiologic factors as fear and hard work and such technical factors as delay, degree of agitation, and anticoagulation. It is felt that this greater sensitivity is a desirable quality because factors which are responsible for variations in sedimentation are more easily discerned and their control is more clearly demonstrated.

Many hundreds of tests were conducted comparing many different techniques and modifications of techniques until finally one was observed that would yield quite comparable results upon repetition, and, since measurement was continuous, was thought to be reasonably complete. With the exception of a description of the technique finally obtained and the suggestion of a more practical "field" technique, together with evidence of the reproducibility and limitations of each, inclusion of the various results of this labor hardly seems necessary here.

EQUIPMENT

For collecting bottles ordinary ½ ounce homeopathic vials are measured and scratched at 5 c.c. and 10 c.c. levels. Corks are paraffined. The desired quantity of anticoagulant is added to each vial by first preparing a weak solution of the chosen anticoagulant, adding the volume necessary to each vial and allowing the water to evaporate in the incubator. For routine work a solution of 1.2 per cent ammonium oxalate and 0.8 per cent potassium oxalate is prepared in dis-

^{*}From a thesis presented in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Graduate School of the Ohio State University, June, 1941.

†Comparative Physiologist, Department of Veterinary Science, Purdue University.

Received for publication, April 3, 1942.

tilled water. One cubic centimeter of this solution when evaporated leaves 12 mg. of ammonium oxalate and 8 mg. of potassium oxalate and is suitable for 10 c.c. of blood—0.5 c.c. of this solution for 5 c.c. of blood. An ample reserve of previously prepared vials is kept on hand.

A sharp clean dry 15 gauge 2 inch hypodermic needle and a clean dry glass syringe of the capacity most suitable are usually employed.

Pledgets and some suitable disinfectant for preparing the area for venipuncture are necessary.

An incubator regulated at body temperature is utilized.

Wintrobe modified hematocrit tubes² are employed routinely.

For filling the tubes routinely 18 gauge $4\frac{1}{2}$ inch spinal puncture needles, with round hubs and with the tip ground flat, are used. All filling needles are fitted with rubber medicine dropper bulbs of fairly uniform consistency and capacity. Sixteen gauge 6 inch needles have been more recently used.

Fig. 1.—Shaking apparatus.

For shaking the blood sample previous to filling the Wintrobe tube a mechanical agitator driven by a variable speed motor has been made. The rack for holding the collecting vials is suspended from four $7\frac{3}{4}$ inch spring steel arms. This rack is driven over a distance of $\frac{3}{4}$ inch by a spring steel arm fastened to the bottom of the rack and to a balanced eccentric at the end of a jackshaft. At present the speed of the motor is adjusted to move the rack approximately 564 strokes per minute (Fig. 1).

An automatic recording device employing continuous photography (reported in a previous publication³) was made, utilizing the fact that cells cut out most of the light coming through the Wintrobe tube while plasma does not. An image of a very narrow vertical portion of a blood-filled tube is transferred by a photographic lens onto sensitized paper attached to a revolving drum. As the cells settle out more of the sensitized paper is exposed. Results with this apparatus are illustrated in Fig. 3.

Eastman P.M.C. No. 1 normal bromide paper of single weight is used routinely. For developing and fixing solutions those used for ordinary x-ray work are very satisfactory.

A millimeter rule and a simple cardboard "trigonograph" (Chemical Rubber Company) are of great assistance.

The centrifuge employed is an International No. 1 type SB with a head that accommodates eight 15 c.c. conical centrifuge tube holders. The distance from the center of the shaft of the centrifuge to the center of each trunnion ring is $3\frac{1}{2}$ inches. The speed when the rheostat arm is set at mark "17" is approximately 3,000 r.p.m. with 6 filled Wintrobe tubes. Rubber cushions cut from corks are made for the bottom of the centrifuge tube holders. Side cushions are made from 3 inch lengths of $\frac{1}{8}$ inch wall, $\frac{3}{8}$ inch bore rubber tubing.

A rack for placing tubes in a vertical position for the "field" technique was made by machining parallel V-shaped grooves on the side of a brass casting. These grooves can be rendered perpendicular by adjustable legs, using as a guide a special plumb bob fastened to one end of the machined casting. The sides of the tubes are held against the sides of the V-groove by spring brass clips (Fig. 2).

Fig. 2.—Perpendicular tube rack.

DESCRIPTION OF TECHNIQUE

When all minor details pertaining to equipment, restraint, disinfection of the area, etc., have been taken into consideration, the jugular vein of the animal chosen is raised by thumb pressure. As soon as the needle is in the vein, this pressure is completely released and, after a second's hesitation to allow the establishment of free flow in the vein, the desired quantity of blood is withdrawn into a syringe. After obtaining this desired quantity of blood in the syringe, the collecting vial (or vials as the case may be) is immediately filled to the necessary mark, corked, and is thoroughly agitated immediately to mix the blood and anticoagulant. Of course, the syringe must be washed before clotting can take place.

The collecting vial (or vials) is then placed in a quiet place until the cells have settled, which with horse blood usually requires anywhere from five to twenty or twenty-five minutes. Next the vial (or vials) is placed in the mechanical shaker for fifteen minutes. While the shaker is still in motion, the cork is taken out, a quantity of blood is removed from the bottom of the vial by the filling needle and bulb, and a Wintrobe tube is carefully filled to the "100 mm." mark *avoiding forceful filling* and bubbles. The tube is then placed in the tube holder of the automatic recorder and the shutter is opened. Recording is allowed to take place for whatever time the sample indicates—usually thirty minutes from the time of filling the tube. If settling is not fairly complete, a longer time

can be chosen but routinely this is rarely necessary. After recording, the same sample can be centrifuged (about 3,000 r.p.m. per thirty minutes), and the results are either photographed on the same record or read off directly from the tube.

After the picture is exposed, developed, and dry, measurements of whatever sort desired can be made.

EX. 1.

EX. 2.

Fig. 3.—Examples of results as obtained with the photographic sedimentation recorder.

Examples 1 and 2 are results obtained by the photographic recorder, example 1 being labeled for explanatory purposes (Fig. 3):

DD' is the top of the dark heavy line and represents the bottom of the column of blood. The length of DD' (or AA') represents the time of exposure.

AD represents the height of the column of blood (100 mm.) at the start of the measurement when the cells are dispersed throughout the plasma.

The dark area ABCA' represents the exposed area of the graph brought about by the increasing amount of light passing through the plasma as the cells settle out.

The light area ABCD'D represents the unexposed area brought about by the presence of cells through which the light cannot pass.

AB represents the beginning and gradually accelerated descent of the line of demarcation between cells and plasma.

BC represents the gradually retarded descent of the line of demarcation between the cells and plasma brought about by the gradually increasing effect of heaping of cells in the lower portion of the tube.

B represents the theoretical point of change between the gradually accelerated descent (AB) and the gradually retarded descent (BC) of the line of demarcation between cells and plasma.

Sigmoid curve ABC then represents a graphic record of the descent of the line of demarcation between cells and plasma for a given time.

The small light horizontal lines in area ABCA' represent the millimeter divisions on the tube.

The small vertical lines in area ABCA' occur at intervals of approximately 1.02 minutes as the apparatus is now run.

The narrow dark vertical lines preceding and following exposure of the sedimenting and centrifuged sample are made by slight exposure of the sensitized paper when the tube holder is empty. These are essentially not necessary but are handy.

UW represents the height of the column of blood (100 mm.).

UV represents the height of the column of plasma after centrifugation (volume percentage of plasma).

VW represents the height of the column of cells after centrifugation (volume percentage of cells).

Fig. 4.—Ex. 1 of Fig. 3 plotted graphically.

To clarify some of the measurements made from the afore-mentioned photographs the following graph of example 1 is presented in Fig. 4:

1. Line t_0-t_0 is located by subtracting the time of filling the tube from the time that the exposure is completed, multiplying by 3 (since 3 mm. are the equivalent of one minute on the photograph), and then laying this distance off from $A'D'$, the end of the exposure. Line t_0-t_0 then represents the time of filling of the tube. In some of these examples t_0-t_0 is purposely quite a distance

from AD, this to separate t_0-t_0 from AD to make a clearer graph. In practice t_0-t_0 is usually not more than fifteen to thirty seconds from AD.

2. Times (t) are measured in minutes from t_0-t_0 as t_1, t_2, t_7 , etc., subnumbers representing the number of minutes from t_0-t_0 (3 mm. of horizontal distance equal one minute).

3. Perpendicular distances (m) from line AA' to curve ABC are measured in millimeters as m_2, m_3 , and m_7 , etc., the subnumbers representing times in minutes from t_0-t_0 that these distances are measured. m is affected by variations in filling the tube to the "100 mm." mark and by variations in image size. However, these are usually very small and can be allowed for during measurement.

4. B' is the estimated point of change between the vertical flexion (AB') of curve AB'C and the horizontal flexion (B'C). With care and experience this point can be very accurately adjudged, especially if the curve is tilted in such a way that the eye can follow an imaginary tangent to the steepest portion of curve AB'C. Assistance in judging this point is also furnished by applying a straightedge as a tangent.

5. em is the perpendicular distance from AA' to B'. This measurement is subject to the same variations as m . In Ex. 1: 21 mm.

6. t_{em} is the horizontal distance from t_0-t_0 to B' divided by 3 (since a horizontal distance of 3 mm. on the photograph represents one minute) and expressed as minutes. Ex.: 13.8 minutes.

7. \angle_g is the least angle between the apparently steepest slope of curve AB'C and m . This angle can be measured by lining up AD with one side of a trigonograph and moving the free arm of the trigonograph until it lies tangent to the apparently steepest slope of curve AB'C, this being very closely related to the A side of B'. Considerable error can be observed if the free arm of the trigonograph is lined up with too great a distance on curve AB'. Careful and close scanning will allow use of as little as 1 to 2 mm. on curve AB' as a tangent to the free arm. Ex.: $32^\circ 20'$.

8. I_{em} is an index calculated by the formula:
$$\frac{em}{t_{em} \times 3}.$$

Ex.: $\frac{21}{41.5}$ or 0.51.

If one-minute readings of the height of the column of cells are made, as for instance in Ex. 1:

$t_0 = 100$ mm.	$t_9 = 97$ mm.	$t_{16} = 71$ mm.
$t_1 = 100$ mm.	$t_9 = 94\frac{1}{2}$ mm.	$t_{17} = 67\frac{1}{2}$ mm.
$t_2 = 100$ mm.	$t_{10} = 92$ mm.	$t_{18} = 64$ mm.
$t_3 = 100$ mm.	$t_{11} = 89$ mm.	$t_{19} = 60$ mm.
$t_4 = 100$ mm.	$t_{12} = 86$ mm.	$t_{20} = 57$ mm.
$t_5 = 100$ mm.	$t_{13} = 82\frac{1}{2}$ mm.	$t_{21} = 55$ mm.
$t_6 = 99$ mm.	$t_{14} = 78$ mm.	$t_{22} = 53$ mm.
$t_7 = 98$ mm.	$t_{15} = 74\frac{1}{2}$ mm.	$t_{23} = \text{etc.}$

and if these are subtracted from the height of the column of blood (usually 100 mm.), values of m will be:

$t_0 = 0$ mm.	$t_9 = 3$ mm.	$t_{16} = 29$ mm.
$t_1 = 0$ mm.	$t_9 = 5.5$ mm.	$t_{17} = 32.5$ mm.
$t_2 = 0$ mm.	$t_{10} = 8$ mm.	$t_{18} = 36$ mm.
$t_3 = 0$ mm.	$t_{11} = 11$ mm.	$t_{19} = 40$ mm.
$t_4 = 0$ mm.	$t_{12} = 14$ mm.	$t_{20} = 43$ mm.
$t_5 = 0$ mm.	$t_{13} = 17.5$ mm.	$t_{21} = 45$ mm.
$t_6 = 1$ mm.	$t_{14} = 22$ mm.	$t_{22} = 47$ mm.
$t_7 = 2$ mm.	$t_{15} = 25.5$ mm.	$t_{23} = \text{etc.}$

To continue the definitions:

9. M_1 is the maximum difference in millimeters between any two consecutive minute readings of m . In the above example, $4\frac{1}{2}$ mm.

10. t_{M_1} symbolizes the times in minutes from t_0 - t_0 between which M_1 occurs. In the above example, thirteen to fourteen minutes.

11. I_{M_1} represents an index range calculated by dividing the values of m between which M_1 occurs by their corresponding times multiplied by 3, since 3 mm. is the equivalent of one minute. Ex.: $\frac{17.5}{39} - \frac{22}{42}$ or $0.45 - 0.52$.

12. $\angle M_1$ is measured by calculating on the trigonograph the angle opposite the horizontal side of a right triangle having M_1 as the perpendicular side and 3 mm. (one minute) as the horizontal side. Ex.: $33^\circ 55'$.

13. M_5 is the maximum difference in millimeters between any two consecutive five-minute readings of m starting at t_0 - t_0 ; i.e., the maximum five-minute fall of the line of demarcation between cells and plasma. Ex.: 17.5 mm.

14. t_{M_5} symbolizes the times in minutes from t_0 - t_0 between which M_5 occurs. Ex.: ten to fifteen minutes, fifteen to twenty minutes.

15. I_{M_5} represents an index range calculated by dividing the values of m between which M_5 occurs by their corresponding times multiplied by 3, since 3 mm. are the equivalent of one minute. Ex.: 0.27 to 0.47, 0.57 to 0.72.

16. $\angle M_5$ is equivalent to the angle opposite the horizontal side of a right triangle having M_5 as the perpendicular side and 15 mm. (five minutes) as the horizontal side. Ex.: $40^\circ 40'$.

If readings are made of m every five minutes, starting at times other than t_0 - t_0 , we find differences in M_5 , I_{M_5} , and $\angle M_5$:

Time	M_5	t_{M_5}	I_{M_5}	$\angle M_5$
t_{0-5}	$17\frac{1}{2}$ mm.	$\left\{ \begin{array}{l} 15-20 \text{ min.} \\ 20-25 \text{ min.} \end{array} \right.$	$\left\{ \begin{array}{l} 0.18-0.43 \\ 0.43-0.57 \end{array} \right.$	$40^\circ 40'$
t_{0-4}	18 mm.	15-20 min.	0.24-0.48	40°
t_{0-3}	$18\frac{1}{2}$ mm.	15-20 min.	0.31-0.54	$39^\circ 10'$
t_{0-2}	$18\frac{1}{2}$ mm.	15-20 min.	0.39-0.5	$39^\circ 10'$
t_{0-1}	18 mm.	15-20 min.	0.49-0.67	40°
t_0	$17\frac{1}{2}$ mm.	$\left\{ \begin{array}{l} 10-15 \text{ min.} \\ 15-20 \text{ min.} \end{array} \right.$	$\left\{ \begin{array}{l} 0.27-0.57 \\ 0.57-0.72 \end{array} \right.$	$40^\circ 40'$
t_{0+2}	18 mm.	10-15 min.	0.37-0.64	40°
t_{0+1}	$18\frac{1}{2}$ mm.	10-15 min.	0.47-0.72	$39^\circ 10'$
t_{0+3}	$18\frac{1}{2}$ mm.	10-15 min.	0.58-0.80	$39^\circ 10'$
t_{0+4}	18 mm.	10-15 min.	0.73-0.89	40°
t_{0+5}	$17\frac{1}{2}$ mm.	$\left\{ \begin{array}{l} 5-10 \text{ min.} \\ 10-15 \text{ min.} \end{array} \right.$	$\left\{ \begin{array}{l} 0.53-0.85 \\ 0.85-0.96 \end{array} \right.$	$40^\circ 40'$

To continue the definitions:

17. GM_5 is the largest maximum difference in millimeters between any two consecutive five-minute readings of m beginning anywhere between t_{0-5} and t_{0+5} . Ex.: $18\frac{1}{2}$ mm.

18. SM_5 is the smallest maximum difference in millimeters between any two consecutive five-minute readings of m beginning anywhere between t_{0-5} and t_{0+5} . Ex.: $17\frac{1}{2}$ mm.

19. t_{GM_s} represents the times in minutes between which GM_s occurs. Ex.: 10-15 and 15-20 min.

20. t_{SM_s} represents the times in minutes between which SM_s occurs. Ex.: 10-15 and 15-20 min.

21. I_{GM_s} represents an index range calculated by dividing the values of m between which GM_s occurs by their corresponding times multiplied by 3, since 3 mm. are equivalent to one minute. Ex.: 0.31 to 0.8.

22. I_{SM_s} represents an index range calculated by dividing the values of m between which SM_s occurs by their corresponding times multiplied by 3, since 3 mm. are equivalent to one minute. Ex.: 0.27 to 0.72.

23. \angle_{GM_s} is the angle opposite the horizontal side of a right triangle having GM_s as the perpendicular side and 15 mm. (five minutes) as the horizontal side. Ex.: $39^\circ 10'$.

24. \angle_{SM_s} is the angle opposite the horizontal side of a right triangle having SM_s as the perpendicular side and 15 mm. as the horizontal side. Ex.: $40^\circ 40'$.

25. \overline{M}_s is the mean of the M_s calculations from t_0 - $t_{0.4}$. Ex.: 18.1 mm.

26. $\angle_{\overline{M}_s}$ is the angle opposite the horizontal side of a right triangle having \overline{M}_s as the perpendicular side and 15 mm. (five minutes) as the horizontal side. Ex.: $39^\circ 50'$.

27. $V\%$ is the centrifuged volume per cent of cellular material.

A chart of measurements of examples can now be presented:

	$V\%$	em	t_{em}	I_{em}	$\angle_{\overline{M}_s}$
Ex. 1.	36-	21 mm.	13.8 min.	0.51	$39^\circ 20'$
Ex. 2.	$31\frac{1}{2}$	34 mm.	10.0 min.	1.10	$18^\circ 10'$
	M_1	t_{M_1}	I_{M_1}	$\angle_{M_1}^s$	
Ex. 1.	4.5 mm.	13-14 min.	0.45-0.52	$33^\circ 50'$	
Ex. 2.	9 mm.	9-10 min.	0.93-1.13	$18^\circ 20'$	
	M_s	t_{M_s}	I_{M_s}	$\angle_{M_s}^s$	
Ex. 1.	17.5 mm.	{ 10-15 min.	{ 0.27-0.57	$40^\circ 40'$	
		{ 15-20 min.	{ 0.57-0.72	$26^\circ 00'$	
Ex. 2.	31 mm.	5-10 min.	0.20-1.13		
	GM_s	t_{GM_s}	I_{GM_s}	$\angle_{GM_s}^s$	
Ex. 1.	18.5 mm.	{ 10-15 min.	0.31-0.80	$39^\circ 10'$	
		{ 15-20 min.			
Ex. 2.	34 mm.	{ 5-10 min.	0.23-1.57	$24^\circ 10'$	
		{ 10-15 min.			
	SM_s	t_{SM_s}	I_{SM_s}	$\angle_{SM_s}^s$	
Ex. 1.	17.5 mm.	{ 10-15 min.	{ 0.27-0.57	$40^\circ 40'$	
		{ 15-20 min.	{ 0.57-0.72		
Ex. 2.	29 mm.	{ 5-10 min.	0.83-1.80	$27^\circ 30'$	
		{ 10-15 min.			
	\overline{M}_s	$\angle_{\overline{M}_s}^s$			
Ex. 1.	18.1	$39^\circ 50'$			
Ex. 2.	32.0	$25^\circ 20'$			

COMPARISONS

Several features of the foregoing measurements of examples are quite noticeable:

1. Estimations of em are in all probability quite accurate because t_{em} in each case lies between the limits of t_{M_1} and also t_{M_5} , t_{GM_5} and t_{SM_5} .
2. Since the above is true, calculations of I_{em} are expected to lie and lie within the ranges of I_{M_1} , I_{M_5} , I_{GM_5} , and I_{SM_5} .
3. The nearer t_{em} approaches either of the limits of t_{M_1} , etc., the closer I_{em} approaches the corresponding limit of I_{M_1} , etc. Such would be expected.
4. \angle_g^s are less than $\angle_{M_1}^s$, $\angle_{M_5}^s$, $\angle_{GM_5}^s$, $\angle_{SM_5}^s$, and $\angle_{\overline{M_5}}^s$ and upon examination of Fig. 5 rightfully should be.

When one considers that B' represents in reality not a point on a straight line between A and C , but the point of change of a shallow sigmoid curve between A and C , then one will realize that the least angle between curve AB' and a perpendicular line from B' to AA' will be less than angle ACA' . This also applies to estimates of angles derived from M_5 , GM_5 , SM_5 , and $\overline{M_5}$. On first thought one would say then that the nearer the angles estimated from the differences between interval readings of m approach \angle_g^s , the more accurate they are. One might also say that the longer the interval between readings of m , the more deceiving will be the plotted curve and the more inaccurate the estimation of angles, maximum falls, indexes, etc.

Since smaller measurements are generally accompanied by larger possible errors, M_1 is thought to be accompanied by greater possible error than measurements of M_5 . To illustrate this, consider the effect on M_1 and M_5 that a fifteen-second variation in t_0 will cause. Fifteen seconds is $\frac{1}{4}$ of one minute but only $\frac{1}{20}$ of five minutes. Also consider the effect on M_1 and M_5 that 0.5 mm. variation will cause. In example 1, 0.5 mm. is $\frac{1}{9}$ of 4.5 mm. but only $\frac{1}{35}$ of 17.5 mm. Is it unreasonable to assume then that M_1 is subject to greater variations than M_5 and t_{M_5} in actual measurement? Also is it unreasonable to assume that errors in measurement of M_1 will produce greater error in estimation of \angle_{M_1} than error in measurement of M_5 will produce error in estimation of \angle_{M_5} ? Is it correct to assume then that, although \angle_{M_1} and \angle_{GM_5} more closely approach \angle_g , they are more susceptible to error as estimates of \angle_g than \angle_{M_5} ? In final analysis \angle_{GM_5} is not derived from the maximum five-minute falls where measurement is started at t_0 but at times other than t_0 , sometimes even at $t_{0 \pm 4}$. The same applies to $\angle_{SM_5}^s$ and $\angle_{\overline{M_5}}^s$. Their proximity to \angle_g does not necessarily denote the degree of their accuracy.

Would it be in error to assume that if measurements of M_5 and $\angle_{M_5}^s$ on replicate aliquots are possible with a fair degree of accuracy these would at least roughly represent the separation of formed and fluid elements of the blood?

Evidence is convincing to me at least that the best estimate of separation is the continuous measurement of the line of demarcation between cells and plasma with estimation of the point of change in the resulting sigmoid curve. It is felt that if measurements of the point of change are to express even partially the important aspects of the curve they must include the time at which this point of change occurs (t_{em}), the amount of separation before the point of change takes place (em), and the rate of speed of separation immediately before the point of change (expressed as \angle_{π}).

Fig. 5.—Ex. 1 of Fig. 3—graph of area near B' (enlarged).

However, with practitioners, simplicity of technique is the keynote and often a certain degree of accuracy must be sacrificed for practicability. In view of this a *more practical technique* is devised, results of which will be reported in many instances along with results of the photographic technique and in many instances alone.

With this more practical "field" technique the blood sample can be drawn and divided in the same manner as described under the photographic technique. The vials are allowed to remain at room temperature until settled, are agitated as before, and the Wintrobe tubes are filled as previously described. However,

Fig. 8.—Evidence of the reproducibility of sedimentation curves as obtained from five aliquots of the same sample of blood.

instead of being put into the photographic recorder each tube is placed into the perpendicular slots of the previously described rack, and the line of demarcation between cells and plasma read five minutes after filling and at five-minute intervals thereafter until maximum settling is passed. The greatest difference in millimeters between any two consecutive five-minute readings is recorded. t_{M_5} and \angle_{M_5} are determined. These three measurements can be considered as locat-

ing quite roughly, to be sure, the point of change between increasing and decreasing rate of descent of the line of demarcation between cells and plasma and the speed of separation.

REPRODUCIBILITY

Now it seems logical to test whether several aliquots of the same sample of blood will yield comparable results.

The reproducibility of the photographic technique is demonstrated by Fig. 6, representing curves of sedimentation in Wintrobe tubes filled from five 10 c.c. aliquots of the same sample of blood. Data from these are as follows:

Ex. No.	em	t_{em}	I_{em}	\angle^s_z	V%
1	29 mm.	9.2 min.	1.05	22° 50'	35.3
2	29 mm.	10.0 min.	0.97	22° 10'	35.3
3	29 mm.	9.0 min.	1.07	22° 30'	35.5
4	30 mm.	9.2 min.	1.09	22° 00'	36
5	30 mm.	10.0 min.	1.0	21° 30'	35.7
Mean	29.4 mm.	9.48 min.		22° 24'	35.6

Ex. No.	M_s	t_{M_s}	I_{M_s}	$\angle^s_{M_s}$
1	27 mm.	5-10 min.	0.53-1.17	29° 30'
2	25 mm.	5-10 min.	0.47-1.07	31° 20'
3	27 mm.	5-10 min.	0.67-1.23	29° 30'
4	28 mm.	5-10 min.	0.47-1.17	28° 30'
5	27 mm.	5-10 min.	0.27-1.03	29° 30'
Mean	26.8 mm.	5-10 min.		30° 04'

Since the determinants of I_{em} are em and t_{em} , I_{em} is thought superfluous. In addition I_{em} may be deceiving, since it expresses a ratio and could represent other values of em and t_{em} than those actually measured; for instance, an I_{em} of 1.0 might represent, as in Ex. 5, an em of 30 mm. and a t_{em} of ten minutes (30 mm.), but it might also represent an em of 15 mm. and a t_{em} of five minutes (15 mm.) or any other combination where em in millimeters is equal to t_{em} in millimeters. For this reason its use is dropped. Since I_{M_s} merely places rough limits to I_{em} , it too is dropped. An index of maximum "rise" ("fall" in this means of expression) over "run," which has been employed extensively in human techniques, has been neglected in this work chiefly because \angle_{M_s} in reality is identical with this index. Since \angle_z is felt to represent more accurately the actual "speed" of settling and since \angle_z is best measured and expressed in terms of degrees and fractions thereof, for comparative purposes "speed" in the "field" technique is designated in this same terminology, keeping in mind, of course, that \angle_z must be less than \angle_{M_s} .

Agreement in repetition of the "field" technique can be demonstrated by the following examples derived from measurements with Wintrobe tubes filled from five 10 c.c. aliquots of the same sample of blood:

Aliquot No.	M_s	t_{M_s}	$\angle^s_{M_s}$	V%
1	24 mm.	15-20 min.	32° 20'	34.5
2	23 mm.	15-20 min.	33° 30'	34.5+
3	24 mm.	15-20 min.	32° 20'	35.0-
4	25 mm.	15-20 min.	31° 20'	34.0+
5	25 mm.	15-20 min.	31° 20'	34.5+

Occasionally one will observe very close figures of M_s , $\angle^s M_s$, and $V\%$, but t_{M_s} will vary as in this example:

Aliquot No.	M_s .	t_{M_s}	$\angle^s M_s$	$V\%$
1	19 mm.	15-20 min.	38° 50'	±1.0
2	20 mm.	15-20 min.	37° 20'	±1.0-
3	19 mm.	20-25 min.	38° 50'	±1.0+
4	18 mm.	20-25 min.	40° 10'	±1.0-
5	18 mm.	20-25 min.	40° 10'	±1.0+

This is not thought to be a serious error and the apparent reasons for such will be discussed in a future article under the heading of agitation. Further evidence of the reproducibility of the "field" technique will be observed as one continues through the remainder of this series.

In the next two publications of this series technical sources of variation will be demonstrated and discussed.

OBJECTIVE METHOD FOR DEMONSTRATION OF LOCAL RIGIDITY OF THE ABDOMINAL WALL*

ALEXANDER BARON, M.D., AND JULIUS G. BARON, M.D.
CHICAGO, ILL.

LOCAL rigidity of the abdominal wall is a well-known symptom of some abdominal diseases. This phenomenon is commonly thought to be due to the increase in tension of some abdominal muscles and is detected by comparative palpation of symmetrical parts of the abdominal wall. However, the tactile sense is not reliable; even experienced observers in palpating the abdominal wall may get contradictory results. The assumption that local rigidity is caused by differences between tensions of both sides of the abdominal wall has been challenged by Vaughan.¹ According to him, such differences can be observed only if the two parts are palpated one after the other. Vaughan asserts that palpation of the diseased side elicits a contraction of the abdominal muscles and this contraction occurs equally on both sides. Thus, if both sides are being palpated simultaneously by both hands, there is no difference observed except in

*From the Department of Biology and the Department of Physics, De Paul University, Chicago, and the Alexian Brothers Hospital, Chicago.
Received for publication, February 28, 1942.

the presence of a palpable mass on the affected side. Wrork,² too, questions the occurrence of differences between the tensions of the two sides of the abdominal wall. However, at least the possibility of such differences is shown by the example of the diaphragm. In inflammatory conditions of the abdomen, when the lesion is close to one side of the diaphragm, immobilization of this side of the diaphragm in high position can often be observed by fluoroscopy. Further, in cases of acute appendicitis, Sale³ found that the right diaphragm was, as a rule, flatter than the left.

To compare the resistance of symmetrical parts of the abdominal wall in an *objective* manner, equal forces acting in symmetrical directions and upon equal areas should be applied, and the depth of the depressions measured. However, the movements of the abdominal wall during breathing interfere with the making of such measurements. Evidently the measurements should be made in a respiratory pause and on both sides in the same phase of respiration. Kelley⁴ described an apparatus which he used to make such measurements. However, in Kelley's method the direction of the force cannot be established accurately, and no provisions are set forth for making the measurements in the same respiratory phase. Wrork² made similar measurements in normal and pathologic cases with an apparatus in which a pair of weights are used to exert forces upon symmetrical parts of the abdominal wall. The whole apparatus rests on the abdominal wall. As the result of his measurements, Wrork makes the statement that no differences between the tensions of the two sides of the abdominal wall occur. However, if the forces exerted by the cylindrical weights are to be definite, the longitudinal axes of the weights must be kept exactly vertical. Wrork sets the crossbar of the apparatus in a horizontal position. But the position of the whole apparatus is subject to changes caused by the respiratory movements of the abdominal wall because it seems hardly possible that the subject could hold his breath during the whole time of setting the apparatus by a spirit level and making the measurements. Thus Wrork's measurements do not seem to prove his assertion that no differences occur between the tensions of the two sides of the abdominal wall.

To demonstrate local rigidities of the abdominal wall in an objective way a new method has been developed which is based upon the detection of differences between the respiratory movements of symmetrical parts of the abdominal wall. In this way, instead of being a disturbing factor, the respiratory displacement of the abdominal wall becomes the object of the measurement. In other words, in making the measurements the force originating from the contraction of the diaphragm is used rather than external forces. The contracting diaphragm acts like a piston producing compression, thus increasing the intra-abdominal pressure during inspiration. If the subject is in an exactly horizontal supine position, the pressure forces acting upon equal areas of symmetrical parts of the abdominal wall are equal and of symmetrical direction. The following discussion shows, namely, that the abdominal cavity can be considered as a closed container filled with a liquid, and that the conditions of equilibrium of this cavity and the pressure forces acting upon its surface are subject to the laws of hydrostatics.

VALIDITY OF THE LAW OF PASCAL FOR THE ABDOMINAL CAVITY

The law of Pascal states that if only surface forces are acting upon a liquid, the pressure is the same at every point and in every direction. True, the contents of the abdominal cavity are solids. However, a solid body which does not resist bending and is not acted upon by tensile forces behaves statically like a liquid and obeys Pascal's law. This is true for a considerable part of the abdominal organs (stomach, intestines, peritoneal folds) which, when put into an open container, assume its form and present a horizontal surface. The other group of the abdominal organs are solids in every respect and, therefore, do not obey the laws of hydrostatics in their interior. Their presence, however, does not affect the validity of the law of Pascal for the abdominal cavity just as the presence of solid bodies would be of no consequence upon the validity of the same law for a real fluid. Upon the contents of the abdominal cavity, in addition to surface forces originating from the tension of the abdominal walls, a mass force—gravity—is acting. The effect of the latter is shown by pressure differences between various levels of the cavity, all points of the same level having the same pressure. Since differences in specific gravity of the solid organs and of their surroundings are negligible, these organs float freely, hindered in their movements only by peritoneal bands. Under ordinary conditions the bands are loose and the solid organs are acted upon solely by the intra-abdominal pressure. Naturally, these bodies establish equilibrium by exerting exactly the same pressure on their surroundings. Thus, whether or not the abdominal walls are in direct contact with solid organs, no forces other than originating from the abdominal pressure are acting on their internal surface. There are only two exceptions: First, the anterior and posterior abdominal walls may be forced apart by a solid organ during the whole period of respiration or, more often, during deep expiration only. In this case a local increase in pressure will result while the organ itself undergoes elastic deformation. The other exception concerns gas-filled intestinal loops. Such a loop has a mean specific gravity considerably less than that of its surroundings, and thus it is acted upon by a buoyant force. Hence the loop tends to occupy the highest possible position, either stretching the corresponding bands, or protruding the abdominal wall. With these two exceptions, which will be discussed later, the equilibrium positions of the different parts of the abdominal wall in a given position of the subject are determined by the elastic properties of this wall and by the intra-abdominal pressure. They are not influenced by the position of the abdominal organs, such as adjacency to the abdominal wall. The slow respiratory movements of the abdominal wall can be considered as consisting of a continuous series of equilibrium positions. Thus, with the subject in an exactly horizontal supine position, simultaneous respiratory amplitudes of symmetrical parts of the abdominal wall must be equal if the structures of the two sides of the abdominal wall are in every respect alike. On the other hand, any unilateral change may create a difference between simultaneous respiratory amplitudes of the two sides.

APPARATUS FOR THE OBSERVATION OF DIFFERENCES BETWEEN
RESPIRATORY AMPLITUDES

The method to be described involves the use of an apparatus somewhat resembling a large caliper. It has two aluminum legs (about 15 cm. long) connected at the top by a nearly frictionless hinge which allows them to move freely in only one plane. The length of the legs can be increased to about 30 cm. by screwing on extensions. The end of the legs and of the extensions are pointed. A sharp-pointed steel index rod, about 2 cm. long, is attached to the hinge perpendicularly to the plane of the legs. The weight of the apparatus with extensions is 40 Gm. For the examination the subject is placed in a reclining position so that his frontal plane is horizontal, the knees being slightly bent and supported by pillows. The parts to be compared are covered by small pieces of

Fig. 1.

adhesive tape and the points of the legs are placed thereon. To the table on which the subject is lying a glass plate, 8 by 20 cm., with reference line in the middle, is attached in such a way that the line is vertical. The instrument is then leaned against the plate, the point of the index rod near the reference line (Fig. 1). The angle between the plate and the plane of the legs should be about 10° , and symmetrical points of the legs should be at equal distance from the glass plate. If the distance between the points examined is about 6 to 7 cm. then the shorter legs should be used; if the distance is about 12 to 15 cm. the extensions are required; the angle between the two legs should be approximately 25° . There is little friction between the glass plate and the index point because the weight of the instrument has only a small component perpendicular to the glass plate. During breathing the point of the index rod moves along the glass plate. If the points of the legs are moved through the same distance along vertical lines, then the point of the index rod will also describe a vertical line. On the other hand, if the respiratory amplitudes of the points compared are not the same, the point of the index rod will shift to the one side or the other. Therefore, such a lateral shift signifies an existing difference between the tensions of the two sides of the abdominal wall. In reality the various parts of the abdominal wall move during respiration laterally as well as vertically. However,

these lateral displacements are small compared to the vertical ones, and thus, as a simple geometrical construction shows, only the vertical differences need be considered.

The examination can be made most conveniently when the breathing is purely abdominal and the movements of the abdominal wall are not too small. Most of the subjects may easily be induced to breathe in this manner, particularly so if they are told to breathe with an open mouth. But whatever the type of breathing may be, if the movements of the abdominal wall are large enough, the examination gives clear-cut results. If the intra-abdominal pressure increases, that is, if the abdominal wall moves outward, the index point moves toward the more tense side; if the intra-abdominal pressure decreases, that is, if the abdominal wall moves inward, the shift of the point is to the less tense side; and no sidewise shift signifies the absence of a difference in tension. Since the difference between the respiratory amplitudes changes with various depths of breathing, one should observe the angle between the vertical and the line described by the index point rather than the lateral shift of the index point. Other things being equal, the greater this angle, the greater the difference of tensions of the two sides. A graph of the path of the index point is recorded on the glass plate if it is coated by lampblack. In cases showing differences in tension of the two sides, this curve usually consists of three parts: a lower vertical part, corresponding to deep expiration; a slightly S-shaped part which makes an angle with the vertical, and corresponds to the middle phase of respiration; and an upper vertical part, corresponding to deep inspiration. Experiments made with an unevenly stretched rubber membrane showed that an inanimate structure can behave similarly. If the anterior and posterior abdominal walls are forced apart by a solid organ, the corresponding part of the anterior abdominal wall will not move during respiration. In protrusion of one side of the abdominal wall caused by a gas-filled intestinal loop, the difference in level of the two sides is diminished both in deep inspiration and in deep expiration. Thus the index point will describe a shallow C-shaped curve open to the protruded side. In practical work it is not necessary to record the curve traced by the point of the caliper. It is easy to recognize the shape of the curve and to estimate the angle formed by the middle portion of the curve and the vertical line with sufficient accuracy.

TABLE I

CASE	DEVIATION		
	UPPER RECTUS	LOWER RECTUS	LATERAL
1	-	+ L	+ L
2	-	+ L	+ + L
3	-	+ + L	+ L
4	+ R	+ L	+ L
5	+ L	-	-
6	+ R	+ L	+ L

+ = Slight deviation (up to 15°).

+ + = Marked deviation (between 15° and 30°).

R = to right. L = to left.

Fifty male college students, apparently in good health, were examined by the method described. The subject was placed on a table so that his frontal plane was exactly horizontal. Three pairs of symmetrical points of the ab-

dominal wall were used. One pair between the xyphoid process and the navel, 7 cm. apart (upper rectus points), one pair in the level of the navel, 7 cm. apart (lower rectus points), and a third pair 3 cm. below the navel, 14 cm. apart (lateral points). In 28 cases the point of the caliper moved vertically in all three positions of the caliper, showing that there was no difference between the tensions of the two sides of the abdominal wall. Insignificant deviations in some positions of the caliper (less than 10°) were observed in 16 cases. The results obtained in the remaining 6 cases are shown by Table I.

Observations were also made in a series of patients having abdominal complaints. Deviations greater than 15° (up to 60°) were observed in cases of acute appendicitis, cholecystitis, duodenal ulcer, splenic tumor, and also in spastic conditions of the gastrointestinal tract.

Fig. 2.

These findings were not always in accordance with palpatory findings. This is probably due to the fact that an increase of tension on the side of the pathologic condition may be elicited by palpation itself. Though the observations made in pathologic cases seem to show that the caliper method may have definite clinical value, more extensive observations must be made before the practical importance of this method can be properly established.

COMMENT

Obviously, the observed differences between the respiratory amplitudes of symmetrical parts of the abdominal wall are caused by differences between the structures of the two sides of this wall. These differences may be persistent, either acquired or congenital. More interesting from the standpoint of abdominal pathology are the more or less transitory differences caused by unilateral changes in tone* of the muscles of the abdominal wall. If the tone of one of the rectus muscles increases, the tension on the same side becomes greater and

*The tone of a muscle is considered to depend upon the percentage of the fibers which are in a state of contraction. If the muscle tone is kept constant, then in a given muscle the tension (which is a purely physical conception) is exactly determined by the length of the muscle.

the respiratory amplitude of every point of this side is smaller than that of the corresponding points of the other side. If the tone of the lateral muscles (transversus and obliqui) of one side increases, an increase of the tension of both sides results. However, the following example shows that the tension of the side having the greater tone will be larger. If two strings AB and CD are tied together at O and stretched in directions, as shown in Fig. 2, the tension along AO will be greater than along BO because O is pulled toward B by COD. Thus a difference of tension is present between two parts of a straight string. In the same way different tensions may be present at various points of the stretched abdominal wall or in various directions about a single point. The difference between the respiratory amplitude of the upper parts of the right and left rectus muscles and the difference between the respiratory amplitude of the lower parts can have opposite signs (Cases 4 and 6, Table I) only if the tensions in various segments of the rectus muscle are different. The fact that a major portion of the muscle fibers originates or ends at the tendinous intersections of this muscle makes it possible that considerable differences in tone be present at the two sides of such an intersection. An increase in tone of a certain part of the rectus muscle causes the interior points of this muscle to move in the direction of this part. In this way the fibers of the lateral muscles are pulled out of position and, therefore, exert an oblique pull on the part of the rectus muscle which increased its tone. A difference between the tensions of parts of the rectus muscle will thus result.

SUMMARY

The amplitudes of the respiratory movements of the abdominal wall depend—other things being equal—upon the tension of this wall. By comparing the respiratory amplitudes of symmetrical parts of the abdominal wall while the subject is in an exactly horizontal position, differences between the tensions of the two sides can be demonstrated in an objective manner by using a caliper-like instrument. No significant differences between the tensions of the two sides were observed in 44 out of 50 healthy subjects. In the remaining 6 cases there were marked differences. Differences of a still greater magnitude were observed in various pathologic conditions of the abdominal organs. These observations seem to prove the reality of the palpatory findings of local rigidities of the abdominal wall.

RUBBER PERINEUM*

ARTHUR C. STIRLING, M.D., ROCHESTER, N. Y.

FOR the medical student, when he reaches his course in obstetrics, few new experiences offer so much confusion as when he is first called upon to repair a perineal tear or an episiotomy following a delivery. This is so due to the considerable distortion of structures and the abundance of blood in the field.

It is of value for the student to know how to do this relatively simple and common operation before he actually practices upon a patient; the patient profits in his knowing by having a more comfortable and a more perfect repair; the instructor profits by saving of time and disposition at the time of the student's first attempt on a patient; and the student profits by a sense of knowledge and pride in his exactness of technique. Heretofore, to my knowledge, there have been no methods to facilitate the instruction and the practice of this operative procedure other than on the patient.

The device described and illustrated here is of simple construction, is durable enough for about twenty-five practice trials, and may be easily renewed. The student who is quick to learn a new technique can learn to repair an episiotomy in three trials. The method of repair employed will differ with the medical school or with the individual giving the instructions. It is believed that most ordinary methods may be demonstrated accurately and practiced on this model. The main purpose of the device is to teach the student how to lay the sutures in reference to mucosa, and deep and cutaneous tissues, in order to attain a certain degree of perfection before actually repairing a patient.

The essential feature of the device consists of an air foam type of sponge rubber of such a size that an incision simulating an episiotomy may be made across one edge. The consistency is such that the usual curved round surgical needle may be used without tearing the rubber. An oblong piece of bath sponge purchased for ten cents may be cut into two suitable pieces. The sponge is held firmly to a formed base by a system of prongs and spring arms. The base may be made of wood or cast iron with a thin rubber base to prevent slipping on the table top. The spring arms also serve to separate the edges of the incision, exposing what may be termed the "deeper fascial layers"—thus permitting the student to lay deep figure-of-eight or single interrupted sutures. When worn, the sponge may be easily replaced. There is also mounted on the base an upright peg for holding a spool of moderately heavy cotton thread with which the repair is made.

It has been found satisfactory to use a Bartlett Mayo tapered point curved needle. The needle holder may be a discarded one from the operating room or

*From Department of Obstetrics and Gynecology, Strong Memorial Hospital, Rochester.
Received for publication, March 31, 1942.

any suitable clamp. A pair of scissors or a razor blade completes the essential equipment. With this device one may place sutures simulating deep, mucosal, and subcutaneous stitches with accuracy. By replacing the episiotomy sponge with one in which a simple linear incision has been made, the student may practice ordinary skin closures.

Fig. 1.—Rubber perineum. Scale drawing.

Fig. 2.—Rubber perineum. Photographs illustrating the laying of sutures in the vaginal mucosa, deep structures, and finally the subcutaneous tissues in the repair of a medial episiotomy. Medioloateral episiotomies and tears are very similarly repaired.

Regardless of the amount of material available, this rubber perineum will be of great assistance to the student before he actually attempts a repair on a patient.

A METHOD FOR EXPOSING CULTURES TO CARBON DIOXIDE OR ANAEROBIC ATMOSPHERES IN PETRI DISHES*

EDWARD J. FOLEY, NOTRE DAME, IND.

THE necessity of incubating a few Petri dish cultures under anaerobic conditions or under carbon dioxide tension frequently arises in most bacteriologic laboratories. The need for individual units has been recognized for many years, and two devices of particular merit have been described—the McLeod apparatus¹ and the Spray dish.² Both take advantage of the principle of absorption of oxygen by mixtures of alkali and pyrogallie acid. Two compartments are provided in the bottom chamber by means of a built-in barrier, and alkali and pyrogallie acid are placed in the separate compartments. The half of the Petri dish which contains the inoculated agar medium is inverted over the bottom chamber, and the joints are sealed. After sealing, the dish is tipped, effecting a mixture of the solutions.

The Spray dish has been used successfully for growing cultures in carbon dioxide atmospheres produced by mixing sulfuric acid and potassium or sodium bicarbonate by Joyner and Jones.³

We have found that the Spray dish technique for anaerobic or carbon dioxide cultivations can be made without the use of specially designed apparatus. The only materials required, in addition to the reagents, are modeling clay and 100 by 15 mm. and 75 by 10 mm. Petri dishes.

Anaerobic cultures are prepared as follows: A rather generous roll of modeling clay is fashioned and placed over the lip of the bottom half of a 100 by 15 mm. Petri dish. A shallow bottom half of a 75 by 10 mm. Petri dish is selected and placed open side up in the larger dish. Four cubic centimeters of a 20 per cent solution of pyrogallie acid solution are run into the bottom of the large dish and 5 c.c. of a 20 per cent sodium hydroxide solution (or 7 c.c. of a 20 per cent sodium carbonate) into the small one. The culture is made in a 100 by 15 mm. Petri dish by pouring inoculated cool agar, or by streaking a hardened agar plate followed by pouring a shallow layer of cooled agar over the surface. The tendency of colonies to coalesce is reduced in such cultures. After the medium has hardened, the half containing the culture is inverted and pressed down firmly into the clay roll. Complete sealing is achieved by flattening the excess remaining on the outside surfaces where the lips of the plates approximate. The reagents are mixed by careful tilting and rotating. The smaller plate slides to the edge of the large one mixing the contents.

An approximate 20 per cent carbon dioxide atmosphere is prepared in the same way, except that 2 c.c. of sulfuric acid solution (1 c.c. of concentrated sul-

*From the Laboratories of Bacteriology, University of Notre Dame.
Received for publication, April 7, 1942.

furic acid in 29 c.c. of distilled water) and 2 c.c. of sterile 1 per cent sodium carbonate solution are used.

Effective anaerobiosis produced by this means has been demonstrated consistently to last for ten days, this being the limit of the observation period. Both methylene blue contained in dextrose beef infusion agar and fresh rabbit blood mixed in agar were used as indicators.

Two per cent agar in thioglycollate medium (Baltimore Biological Laboratories) has been used to advantage in this device. More rapid and perhaps more efficient, anaerobiosis is obtained with this medium under the influence of alkaline pyrogallie acid than occurs with ordinary agar.

SUMMARY

A simple method is described by which individual solid media cultures in Petri dishes can be incubated under carbon dioxide tension or under anaerobic conditions.

METHOD FOR DETERMINING THE TOXICITY OF ANTISEPTICS AS MEASURED BY THE DESTRUCTION OF HUMAN LEUCOCYTES*

HENRY WELCH, PH.D., GLENN G. SLOCUM, PH.D., AND ALBERT C. HUNTER, PH.D.
WASHINGTON, D. C.

A METHOD has been presented previously¹ for determining the primary toxicity of antiseptic solutions, as measured by the loss of the phagocytic function of the leucocyte. By comparing loss of phagocytic activity with the bactericidal action of a compound, it is possible to compute a "toxicity index," which is defined as the greatest dilution of the antiseptic that completely inhibits phagocytosis, divided by the greatest dilution which kills the test organism. Later work² indicated that the toxic effect of germicides, when tested by this method on human or guinea pig blood as a tissue, was, in most instances, directed against the humoral elements, in contrast to the cellular elements. However, with mercuric chloride and certain other compounds evidence was presented³ to show that such solutions, when tested by their effect on hemolytic complement, exhibited definite toxicity but, in contrast to iodine, prevented phagocytosis not by an actual destruction of the humoral or cellular elements involved but by a "blocking" of the effective mechanisms. It was apparent in this type of test that concentrations of antiseptic, which brought about cessation of phagocytosis, were not sufficiently great to cause actual destruction (irreversible loss of function) of the cells.

*From the Division of Bacteriology, Food and Drug Administration, Washington, D. C.
Received for publication, April 9, 1942.

It was further apparent from our studies that certain components of the humoral system were sensitive to the toxic action of the majority of antiseptics tested and were thus destroyed by their action, while in those compounds which reacted like mercuric chloride, a "blocking" effect resulted which prevented phagocytosis. This latter effect, however, could be counteracted by dilution of the mixture of plasma and chemical. By testing toxic activity on "naked" cells² (blood centrifuged free of plasma), it was shown that greater concentrations of antiseptic were necessary to inactivate such cells than were found necessary to stop their activity when the toxic effect was directed against the humoral system, an essential cog in the phenomenon of phagocytosis.

Through studies of a variety of techniques for determining the effect of antiseptics on the human cell, it soon became apparent that the use of cells free of plasma was neither an efficient nor an appropriate method. Difficulties were encountered when attempts were made to produce a homogeneous cell suspension which would give uniform results when mixed with increasing dilutions of the compound under test. It appeared that relatively viscous cell suspensions failed to contact evenly the solution tested in the amounts used either through purely mechanical improper mixing during rotation or through absence of sufficient amounts of electrolytic solution in the mixture. For example, when mercuric chloride was tested on whole human blood, the toxic dilution was found to be 1:1,300, while on packed "naked" cells mixed with an equal volume of antiseptic dilution a toxic end point of 1:500 was obtained. Although a dilution of 1:600 or 1:700 showed marked phagocytic activity, dilutions of 1:800 nevertheless showed considerably less activity in spite of the lowered concentration of toxic substance. It was apparent that when the mercury salt was present in high concentrations, destruction of all cells was accomplished in spite of improper mixing of cells and test substance due to an excess of the chemical, while at lower more critical concentrations the effect of poor mixing of ingredients becomes obvious.

In the development of the method presented in these studies, consideration was given also to the fact that under the conditions of use in or on the human body antiseptics do not come into contact with naked cells but with serous exudates as well, and this material offers a certain amount of protection to the cell. Furthermore, it seemed particularly desirable to use whole blood, as a tissue, gauging the toxicity of the compound under test by its toxic effect on an individual cell of that tissue, since such a procedure approaches more closely the conditions met when antiseptics are used on other tissues of the body.

Accordingly, in the present investigation a method has been developed to determine the effect on the leucocytes directly, using whole blood as a tissue. Irreversible loss of phagocytic activity is taken as an indication of lethal action on the leucocyte.

TECHNIQUE OF TEST

The antiseptic dilutions to be tested are pipetted in 0.1 c.c. amounts to the bottom of test tubes measuring 100 by 13 mm. (Wassermann tubes). To the antiseptic is then added 0.4 c.c. of human blood which has been diluted 1:2 with 0.8 per cent citrated salt solution. (The blood is collected in sufficient 20 per

cent sodium citrate in salt solution to give a final concentration of approximately 0.77 per cent citrate. Usually 20 c.c. of blood are mixed with 0.8 c.c. of 20 per cent citrate.) The mixture of citrated blood and antiseptic is then rotated at 37° C. for ten minutes on a serum-leucocyte mixing machine¹ revolving at 4 r.p.m. As soon as the tubes are removed from the rotator, 2.0 c.c. of 0.8 per cent citrated salt solution are added immediately to each tube to stop further action of the antiseptic. The tubes are shaken vigorously, centrifuged at 2,500 r.p.m. for eight minutes, and the supernatant fluid is removed and discarded. Care should be taken not to disturb the buffy coat of leucocytes usually stratified on the red blood cells when removing the supernatant fluid. The cells which have been in contact with the antiseptic under test for a period of ten minutes are now tested for phagocytic activity by the addition of 0.2 c.c. of antigen and 0.1 c.c. of fresh human plasma. The antigen consists of a standardized suspension of artificially opsonized staphylococci, the method of preparation of which has been described¹ previously. Following addition of antigen and plasma in that order, the mixture is rotated on the serum-leucocyte mixing machine again at 37° C. for twenty minutes. Blood smears are prepared, stained for one minute with 1 c.c. of 0.5 per cent methylene blue in absolute alcohol, following which 1 c.c. of distilled water, buffered at pH 7.2, is added and staining continued for four minutes longer. The degree of phagocytosis is then determined.

TABLE I

METHOD I	METHOD II
To show the toxicity of antiseptics as measured by inhibition of mechanism of phagocytosis	To show the toxicity of antiseptics as measured by death of the cell (irreversible loss of function)
1. Mixture: 0.1 c.c. antiseptic 0.2 c.c. antigen 0.2 c.c. human blood	1. Mixture: 0.1 c.c. antiseptic 0.2 c.c. citrated salt solution 0.2 c.c. human blood
2. Rotated on mixing machine for thirty minutes	2. Rotated on mixing machine for ten minutes
3. Smears prepared and stained with methylene blue for five minutes	3. Two cubic centimeters of citrated salt solution added and mixture centrifuged at 2,500 r.p.m. for eight minutes
4. Degree of phagocytosis determined	4. Supernatant fluid removed and activity of cells tested by the addition of: 0.2 c.c. antigen 0.1 c.c. fresh human plasma
	5. Rotated on mixing machine for twenty minutes
	6. Smears prepared and stained with methylene blue for five minutes
	7. Degree of phagocytosis determined

As the concentration of antiseptic is increased, the amount of phagocytosis decreases until a concentration is reached at which no phagocytosis is observed. The degree of phagocytic activity is determined, and complete inhibition of phagocytosis is taken as an end point. The differences between the original method,¹ which measured inhibition of the function of the leucocyte, and the method above, which determines that dilution of antiseptic lethal for the cell,

are shown briefly in Table I. By the use of the two methods described for determining relative toxicity, 26 germicides have been tested. Table II lists the 26 chemical preparations and, wherever possible, the dilution of the active ingredients commonly sold on the market or recommended for use, the dilutions of the active ingredients found toxic by each method, and the corresponding toxic dilutions of the commercial product or recommended concentration.

*This material was obtained from John H. Glynn, M.D. (Armour and Co.) and has been described in the J. Am. Chem. Soc. 63: 1916, 1941; Ibid. 63: 2576, 1941.

†The formulas for these compounds are given in J. Exper. Med. 74: 612, 1941. In a previous publication (J. Immunol. 43: January, 1942) an incorrect interpretation of the chemical make-up of E-605 and E-607 was given.

It will be noted that of the 26 germicides tested, 23 show lower toxicities when toxicity is measured by the direct action on the cells (Method II), while only three show equivalent toxicities by both methods. The marked difference in toxic effect, as measured by the two methods, is brought out particularly with compound "E," which has a toxic end point of 1:1,700 (Table II) when toxicity is measured by the loss of phagocytic function, while a toxic end point of

only 1:60 is obtained when destruction of the leucocyte is taken as an indication of toxic effect. Thus, by the latter method a dilution of only 1:1.2 of the commercial product (2 per cent solution) would represent the toxic dilution of this product, while by the former method a dilution of 1:34 of the commercial product would be toxic. It is of interest that the concentrations of this chemical inhibiting phagocytic function as compared to concentrations which destroy the cell are comparable to those concentrations of this compound which are bacteriostatic and bactericidal.

When destruction of the cell is taken as a measurement of the toxicity of a product such as compound "A," it will be noted that since a 1:3,000 dilution of the active ingredient destroys cells, and the product usually is marketed for use in a 1:3,300 dilution, this product would not be toxic for the cell at the dilution commonly used, although it will be noted that it interferes with the mechanism of phagocytosis at a dilution of 1:5,000. A similar result was obtained with an aqueous solution of potassium mercuric iodide, usually recommended in a 1:5,000 dilution of the active ingredient. As a matter of fact, it will be noted in Table II that besides compound "A" and aqueous potassium mercuric iodide, which are not toxic for the cell in commonly used dilutions, a number of the compounds tested are toxic only at relatively low dilutions of the commonly used strengths when toxicity is measured by direct action on the cell, as exemplified by acriflavine, chloramine-T, and compounds "B₁," "C," "E," "H," and "J."

DISCUSSION

The results obtained by the proposed method, where irreversible loss of function of a human cell is taken as evidence of the toxic activity of antiseptics, indicate that greater concentrations of the compounds tested are required than when reversible loss of function of these same cells is taken as evidence of toxic activity. In the former instance that concentration of antiseptic which destroys the activity of the cell is determined, while in the latter instance the concentration of antiseptic which destroys or interferes with some necessary component of the humoral system is determined.

Where evidence is desired to show the relative toxicity of a group of antiseptics either method may be useful. The method utilized depends upon whether interference with phagocytosis or destruction of tissue cells is the important consideration. In either case the compounds would all be tested under the same set of conditions.

The use of human blood as a tissue and the leucocyte as the test cell seem especially appropriate for measuring toxicity under practical conditions. Human blood is probably the most readily accessible tissue. It is uniform, constant in its pH, reasonably strongly buffered, and in the practical application of antiseptics is the most likely of all the specialized tissues to be encountered. It has been apparent to us in our studies that the leucocyte is relatively resistant to the action of toxic agents and compared to other tissue cells it is unique in its independent nature and its ability to survive for reasonably long periods of time though removed from its natural environment. The resistance of the leucocyte to antagonistic agents, including certain detergents, is rather remarkable and

deserves special comment. With certain dilutions of these compounds it was noted in many instances that where the red blood cells were completely hemolyzed and the plasma coagulated, the leucocytes continued to carry on their phagocytic function undiminished when fresh plasma was added to them. When the resistance of the leucocyte is compared to the resistance of most other body cells in situ, it is generally accepted that the latter are probably less affected by toxic compounds than the former. On the other hand, because of their interdependence on one another, individual tissue cells undoubtedly have less resistance than leucocytes to the action of toxic compounds. It is undoubtedly true, as well, that many tissue cells in their natural habitat are destroyed by the toxic action of antiseptics, although such destruction is difficult to determine and becomes apparent only when such large numbers of cells die that the structure or continuity of the tissue is broken down. Therefore, the toxic effect of an antiseptic on the leucocyte may be taken as evidence of a similar if not greater effect on other individual tissue cells. Furthermore, the mechanism of phagocytosis is manifestly an important one in protection of the host against invading organisms, and since the leucocyte acts as one of the antibacterial agents of the body, chemical antiseptics should augment rather than reduce the activity of these cells.

The results obtained with tincture of iodine, mercuric chloride, and potassium mercuric iodide, all three of which showed the same toxic end point by both methods reported, deserve some comment. As previously reported² all three of these compounds had a lower toxic end point when tested on the naked cell than when tested on whole blood, using inhibition of the mechanism of phagocytosis as an end point. The differences in toxic end points of these compounds appear to be associated with the type of test used to demonstrate cell destruction and are probably caused by inadequate mixing of cells and the chemical under test. In any case, in the method proposed in these studies special care was taken to study microscopically the slides made from dilutions of these compounds which completely inhibited phagocytosis to be assured that at the toxic end point irreversible loss of phagocytosis through destruction of the cell had actually taken place.

The use of tests of the type described, which give accurate and reproducible results, offers a means of interpretation of the relative merits of a group of antiseptics under the conditions of use on or in the human body, since we are using a viable human tissue and estimating toxic effect on the cell upon which nature relies as one of her first lines of defense against invading microorganisms. It is apparent that the use of the method proposed in these studies will result in lower toxic end points than those obtained by the method previously described.¹ However, the former method, which is somewhat easier to perform, is of value in determining relative toxicity of a group of antiseptics designated for a particular purpose, while the method described in these studies may be taken as an indication of absolute toxicity, since actual destruction of a human cell is involved. The greater value in this method rests in its ability to approach more closely conditions of the use of an antiseptic on human tissue. When the actual resistance of human tissue to the action of an antiseptic is compared

with the resistance of pathogenic microorganisms to the same chemical, an evaluation of the efficacy of the antiseptic becomes possible.

SUMMARY

A method for determining the toxicity of antiseptics, which utilizes the destruction of leucocytes as an indication of toxic activity using human blood as a tissue, is presented.

Irreversible loss of the function of phagocytosis following a ten-minute contact with the compound tested is taken as an indication of death of the cell.

The toxicity of 26 antiseptics has been determined by the proposed method, and the results have been compared with those obtained by a method previously described.

CHEMICAL

DETERMINATION OF CHOLESTEROL IN WHOLE BLOOD, SERUM, OR PLASMA*

H. GERSHBERG, M.D., AND J. C. FORBES, PH.D.
RICHMOND, VA.

DURING recent years many modifications of Bloor's procedure for the determination of blood cholesterol have been described. The majority of these do not differentiate ester from free cholesterol. Since the esterified form gives more color with the Liebermann-Burchard reagents, it is evident that the value for total cholesterol, as determined by these methods, must be too high. Other factors often leading to high results are colored substances which may be present originally in the blood, as in jaundice, or produced during the extraction process. Schoenheimer and Sperry,¹ and Kelsey,² avoid these difficulties by saponifying the esters and removing the cholesterol as the digitonide, which is then purified and analyzed. Ireland³ first removes the interfering colors with silica, then saponifies the esters and extracts the cholesterol with chloroform. These procedures are quite long and do not lend themselves readily to the needs of the blood chemistry laboratory.

Some years ago one of us (J. C. F.) described a method⁴ which eliminated interfering colors by use of a synthetic zeolite (Douceil). In this method esters are not saponified before color development, hence the results are necessarily high. In order to overcome this difficulty the method has been modified to obtain the cholesterol in a free state before solution in chloroform and color development. An added advantage is that free cholesterol can be determined on the same extract.

EXPERIMENTAL

Preparation of Extract.—One cubic centimeter of whole blood, serum, or plasma is added with stirring to approximately 17 c.c. of acetone-95 per cent alcohol (1:1) in a 25 c.c. volumetric flask. The extract is brought to a boil in hot water and set aside to cool. It is then adjusted to the 25 c.c. mark, mixed thoroughly, and filtered through a rapid filter paper. Ten cubic centimeters of the filtrate are measured into a 25 c.c. Erlenmeyer flask, and 0.2 c.c. of 15 per cent potassium hydroxide is added. The solution is warmed in hot water and placed in an incubator at approximately 55° C. for about one and one-half hours. The flask is then removed, and the alkali is neutralized with 0.4 c.c. of hydrochloric acid so adjusted that it will assure complete neutralization. The hydrochloric acid concentration is approximately 4.9 per cent. After neutraliza-

Received for publication, February 23, 1942.

tion the flask is placed in water at about 65° to 70° C., and the contents are evaporated to dryness with the aid of a stream of air played upon the surface of the liquid. The flask is removed, allowed to cool, and 0.4 c.c. of distilled water is added. About 1.3 Gm. of neutralized doucil are added and mixed by moderate shaking. Ten cubic centimeters of chloroform are added, and the flask is stoppered immediately with a cork. The mixture is given a whirling motion off and on for five to ten minutes after which it is filtered through a rapid filter paper. In order to prevent concentration of the solution during filtration the funnel should be covered with a watch glass and filtration should be stopped by removal of the filter paper from the funnel as soon as the greater part of the solution has passed through. Five cubic centimeters of the filtrate are pipetted into a test tube standing in a wire rack in a water bath at 21° to 22° C. Five cubic centimeters of a standard cholesterol solution in chloroform (1 c.c. = 0.08 mg. of cholesterol) are pipetted into another test tube placed in the same bath. Two cubic centimeters of acetic anhydride are added to each. The tubes are mixed thoroughly and replaced in the bath for a time sufficient to enable the contents of the tubes to come to the temperature of the bath. This usually does not require more than five minutes, but no harm is done if they are left for a much longer period. Even a two-hour period does not affect the final color development. Four small drops of concentrated sulfuric acid, approximately 0.1 c.c., are added to each tube from a dropping bottle with a ground glass pipette. The tubes are then removed one at a time, the contents mixed thoroughly, and replaced in the bath. The bath is placed immediately into a dark cupboard for twenty minutes, after which the colors are compared in a colorimeter with an Eastman 71A filter in the eyepiece. The temperature of the bath at the time of comparison should not have risen above 23° C.

When free cholesterol is to be determined, 5 c.c. of the filtrate are measured into a 15 c.c. centrifuge tube, the free cholesterol precipitated as the digitonide and determined by the method of Schoenheimer and Sperry.¹ After solution of the cholesterol digitonide in acetic acid, it has been found advisable to control the temperature by using a water bath in the manner already described, except that a temperature of 25° C. is used and at least thirty minutes are allowed for color development.

Recovery of Cholesterol From Standard Solutions.—In order to show the complete extractability of cholesterol, aliquots of the standard were evaporated to dryness in 25 c.c. Erlenmeyer flasks, the residue was dissolved in 1:1 alcohol-acetone mixture and was carried through exactly the same procedures as those described for the unhydrolyzed and hydrolyzed extracts. Complete recovery was obtained in each case. The presence of water was found necessary for complete extraction. The amount of water used can be varied within fairly large limits; any amount between 0.4 and 1 c.c. inclusive allowed complete recovery of the cholesterol. Amounts outside these limits resulted in incomplete recovery. In the case of hydrolyzed extracts or alkali-treated standards, it was found necessary to neutralize the alkali before extracting with chloroform. We prefer to neutralize it before evaporation of the alcohol-acetone extract, but equally satisfactory results were obtained by neutralization immediately after evaporation.

TABLE I
CHOLESTEROL CONTENT OF UNHYDROLYZED BLOOD SERUM AS DETERMINED WITH AND WITHOUT DOUCIL

1 to 12 are normal sera.

13 to 24 are from jaundiced patients with liver disease.

*Free cholesterol was determined by Schoenheimer and Sperry's method and is expressed as percentage of the value obtained for total cholesterol after hydrolysis.

Recovery of Cholesterol From Unhydrolyzed Extracts.—In these experiments 10 c.c. of the alcohol-acetone extract were evaporated to dryness. The apparent cholesterol content was then determined in the manner already described, except that no potassium hydroxide or hydrochloric acid was used. The values obtained for different sera are given in Table I along with those obtained by simply evaporating an aliquot of the alcohol-acetone extract, dissolving the residue in chloroform and developing the color in the usual way. Since no sera containing an abnormal amount of pigment were used, the amount of pigment present was insufficient to interfere with color comparison even in the absence of doucil. It will be seen that the agreement between the two methods is excellent.

Recovery of Cholesterol From Hydrolyzed Extract.—That complete recovery of cholesterol was obtained when a standard was put through the procedure outlined for the hydrolyzed extract has already been mentioned. Evidence for the complete extractability from hydrolyzed serum extracts is shown in Table II. In these experiments comparisons have been made of the color developed by the extract before and after hydrolysis. In 12 normal subjects the ratios varied from 1.18 to 1.32, averaging 1.25. Also included in Table II are a number of typical values on pathologic sera from patients with liver damage in whom a marked increase in the percentage of free cholesterol was obtained. It will be seen that the ratio in all patients is definitely below normal. A ratio of 1 would indicate complete absence of ester cholesterol. Since a slight error in either of the determinations affects the ratio materially, variations in ratio similar to these recorded must be expected.

TABLE III

APPARENT CHOLESTEROL VALUE PER 100 C.C. OF JAUNDICED SERUM DETERMINED WITHOUT HYDROLYSIS, WITH AND WITHOUT DOUCIL

SERUM NO.	APPARENT CHOLESTEROL CONTENT		ICTERIC INDEX (UNITS)
	WITHOUT DOUCIL (MG.)	WITH DOUCIL (MG.)

8	129	114	22
9	125	112	22

Removal of Interfering Substances by Doucil.—It is well known that certain colored substances often present in blood, such as bile pigments, or those produced during the extraction, especially when whole blood is used, will cause high results by interfering with colorimetric readings. This is especially true if a suitable filter is not used in the eyepiece. When doucil is used as described, these interfering substances do not dissolve in the chloroform, and consequently do not interfere with the accuracy of the results. Table III presents values obtained for unhydrolyzed extracts on a number of jaundiced sera with and without the use of doucil. It will be seen that the values for sera of high icteric index are distinctly higher in the absence of doucil. In Table IV are shown a

few typical results showing that doucil will remove the brownish color which forms when whole blood is boiled with alcohol-acetone solution. In these cases three samples of whole blood were taken and added to the alcohol-acetone mixture. One flask was brought just to a boil, another was boiled for five minutes, and the third was boiled for twenty minutes. After cooling, all were diluted to volume and mixed thoroughly. Each was then filtered, and the apparent total cholesterol content was determined without hydrolysis, with and without doucil. It will be seen that when doucil was used, the value obtained for cholesterol was not affected even by long boiling of the blood, but values obtained in the absence of doucil increased progressively as the time of boiling was lengthened, with production of greater amounts of colored products.

TABLE IV

APPARENT CHOLESTEROL VALUE OF WHOLE BLOOD EXTRACTS DETERMINED WITHOUT HYDROLYSIS, WITH AND WITHOUT DOUCIL

Values are expressed in milligrams per 100 c.c. of whole blood

BLOOD NO.	APPARENT CHOLESTEROL VALUE					
	A		B		C	
	WITHOUT DOUCIL	WITH DOUCIL	WITHOUT DOUCIL	WITH DOUCIL	WITHOUT DOUCIL	WITH DOUCIL
1	166	161	189	161	181	164
2	234	225	243	215	249	222
3	128	123	138	124	146	124

A, Brought just to a boil during the alcohol-acetone extraction.

B, Boiled for five minutes during the alcohol-acetone extraction.

C, Boiled for twenty minutes during the alcohol-acetone extraction.

SUMMARY

A relatively simple method for the determination of free and total cholesterol is described. Interfering substances, such as bile pigments or colored substances, produced during the extraction process are removed by means of a commercial synthetic zeolite (doucil).

Commercial doucil is alkaline after drying. Neutralized doucil suitable for use may be obtained from A. H. Taylor & Co., Baltimore, Md.

THE USE OF A NEW DIGESTIVE MIXTURE FOR PROTEIN DETERMINATIONS*

JOSEPH BENOTTI, B.S., M.S., BOSTON, MASS.

THE best clinical nitrogen determinations, whether they be of a protein or nonprotein nature, are measured by acid digestion, and the resulting ammonia is determined by the Kjeldahl method or is nesslerized by direct addition of Nessler's solution.

Several digestion mixtures are available to the technician for nitrogen determinations, all of which have their advantages and disadvantages. The speed with which a certain sample of material will digest, that is, change from organic to inorganic material, depends upon the concentration of phosphoric acid present. Folin's digestive mixture¹ has a rather high concentration of phosphoric acid in comparison to the sulfuric acid present. This makes a very powerful and rapid digestive mixture. However, such a high concentration of phosphoric acid usually attacks glass and produces cloudiness in the resulting solution unless the digestion is stopped at the proper time. Dupray² has reduced the phosphoric acid content of his digestive mixture for nonprotein solutions so as not to produce the above effects. However, by so doing he has also reduced the speed of digestion itself. To overcome this he added an oxidizing agent, perchloric acid. This makes a good mild acid digestive mixture.

Since proteins have such a high nitrogen content, they require a digestive mixture which is very strong. However, it was my intention to make a strong digestive mixture which would not have too high a concentration of phosphoric acid that would attack pyrex glass, and still would digest with some speed. Furthermore, it must produce clear nesslerized solutions.

In all the various acid mixtures tried the phosphoric acid content was kept to a minimum so as to prevent the etching of glass due to overdigestion. Several oxidizing agents were tried to offset the deficiency of phosphoric acid. Some worked very nicely as far as the digestion was concerned, but on later nesslerization gave considerable cloudiness which rendered it impossible for use in this method since the nitrogen is finally measured by direct nesslerization. Finally, a very fine digestive mixture was realized which had the following composition: 54 c.c. of water, 35 c.c. of sulfuric acid concentrated, 10 c.c. of phosphoric acid 85 per cent, and 0.5 c.c. of perchloric acid 20 per cent. This digestive mixture does not attack glass, and on gentle boiling there is no danger of overdigestion. It gives absolutely clear solutions upon the addition of water after partial cooling. The use of digestive mixtures which have high concentrations of phos-

Received for publication, March 6, 1942.

phoric acid force one to add water after digestion while still hot in order to avoid the formation of insoluble precipitates. It is thus possible to lose nitrogen due to spurting.

The digestive mixture herein described has one disadvantage and this is that following digestion and dilution with water the resulting solution must be ice-cooled before nesslerization since the nesslerized solutions sometimes turn cloudy when they are not previously cooled. The resulting digested solutions are nesslerized and read either on a colorimeter or photometer. The nitrogen values obtained by this procedure were checked by the Kjeldahl method and compared very well.

Fig. 1.—Apparatus used for protein digestions.

TOTAL PROTEIN

Dilute 1 c.c. serum to 50 c.c. with water and mix well. Take 1 c.c. of diluted serum in a special digestion tube,^{*} previously described.³ Add 1 c.c. of digestive mixture described above. Digest by boiling gently over a micro chimney burner, as shown in Fig. 1, and cover with a watch glass when charring begins. This takes about fifteen minutes. When it is moderately cool, dilute with distilled water to 35 c.c. Ice cool the latter solution and add 15 c.c. of Nessler's reagent. For comparison in a colorimeter one must use 2 c.c. of standard ammonium sulfate solution, which contains 0.1 mg. nitrogen per cubic centimeter plus 1 c.c. of acid digestive mixture; dilute to 35 c.c., ice cool, and nesslerize. The

^{*}Special digestion tubes may be purchased from Howe and French, 99 Broad Street, Boston.

nitrogen may also be read in a photometer using instead of the standard a blank which is made up of 1 c.c. of acid mixture; dilute to 35 c.c. with water, ice cool, and nesslerize. Calculation: $S/U \times 0.2 \times \frac{100}{0.02} \times 0.00625 - 0.2 = \text{Gm. of total protein per 100 c.c.}$ (0.2 represents the equivalent amount of protein due to the average nonprotein nitrogen).

ALBUMIN

One cubic centimeter of serum is added to 29 c.c. of 22.2 per cent sodium sulfate. Incubate at 37° C. for three or more hours. Filter and discard the first 10 c.c. of filtrate since it will be low in albumin due to absorption by the filter paper. Take 1 c.c. of clear filtrate, add 1 c.c. of digestive mixture described above, and digest in a special digestion tube³ as described for total protein. Dilute to 35 c.c., ice cool, and nesslerize. The standard is the same as for total protein.

Calculation: $S/U \times 0.2 \times \frac{100}{0.033} \times 0.00625 - 0.2 = \text{Gm. per 100 c.c. of albumin.}$

Total protein minus albumin gives globulin.

SUMMARY

A new digestion mixture is herein described which digests protein and non-protein solutions with the same ease. It does not attack glass, and the digestion does not have to be stopped at the proper moment in order to prevent cloudiness upon the addition of water. A method is described for total protein, albumin, and globulin which is easy, rather rapid, and accurate since there is no loss of material during digestion. This digestion mixture has recently been used for nonprotein nitrogen determinations with great success.

QUALITATIVE STUDIES OF THE BILIRUBIN IN BODY FLUIDS

I. A COMPARISON OF THE DIRECT DIAZO REACTION BY THE PHOTOELECTRIC COLORIMETER, THE THREE TEST TUBE METHOD, AND THE OXIDATION TEST IN SERUM

GEORG LEPEHNE, M.D., BOSTON, MASS.

IN 1918 Hijmans van den Bergh¹ reported that the addition of diazo reagent to the blood serum of a patient with obstructive jaundice was followed by the prompt appearance of a characteristic color. When the same reagent was added to the serum of a patient with hemolytic jaundice, the characteristic color appeared very slowly, and then only after a considerable lapse of time. When 95 per cent alcohol was added to the serum of a patient with hemolytic jaundice along with the diazo reagent, the characteristic color developed promptly. On the basis of these observations van den Bergh classified the reaction as "direct" when no alcohol was needed to obtain a prompt appearance of color, and as "indirect" when alcohol was required. Since then the literature contains such expressions as "bilirubin direct positive," "direct negative," or "bilirubin indirect positive." These terms, when applied to the qualitative (direct)-diazo reaction are confusing.² The logical terms are direct diazo reaction prompt or delayed. In addition to these two types of reaction, Feigl and Querner,³ and others^{4,5} described the biphasic reaction, which is a combination of the prompt and delayed reaction.

Since the existing terminology is confusing and since the diagnostic value of the qualitative van den Bergh test is still a matter of dispute, the direct diazo reaction was studied by the photoelectric colorimeter and compared with the three test tube method.⁷ The results reported herein will show the comparative value and usefulness of these two methods, and they will also indicate the advantages of using a uniform terminology. In addition, an oxidation test for further differentiation of the various types of bilirubin in blood serum will be described.

METHODS

Photoelectric Colorimeter.—The technique described by Malloy and Evelyn⁶ was used. Readings were made at ten, twenty, and forty seconds, and at one, two, three, four, five, ten, and thirty minutes after the diazo reagent had been added to serum. It seemed advisable to obtain colorimetric determinations during the first minute of the reaction, since the qualitative difference between the prompt and delayed type is most striking during this interval. Since Malloy and Evelyn found that the prompt direct diazo reaction attained a maximum of color in thirty minutes, subsequent readings were not considered to be essential.

*From the Department of Medicine, Boston University School of Medicine.
Received for publication, March 7, 1942.

Three Test Tube Method.—This method originally described by the author⁷ in 1923 makes use of the fact that caffeine salts (caffeine sodium benzoate or caffeine sodium salicylate) convert a delayed direct diazo reaction into one which is more or less prompt (Adler and Strauss⁸). Three small test tubes are used. One contains serum and diazo reagent; the second contains serum, diazo reagent, and caffeine salt; the third, serum diluted with water. Using the second and third tubes for purposes of comparison, the nature of the reaction in the first tube can be determined very easily.

TABLE I
COMPARISON OF QUALITATIVE AND QUANTITATIVE REACTIONS
CASES WITH PROMPT DIRECT DIAZO REACTION

DISEASE	TOTAL BILIRUBIN (MG. PER 100 C.C.)	1 MIN. DIRECT/30 MIN. INDI- RECT (%)	1 MIN. DIRECT/ 1 MIN. INDI- RECT (%)	1 MIN. DIRECT/30 MIN. DIRECT (%)	30 MIN. DIRECT/30 MIN. INDI- RECT (%)

Cirrhosis of the liver with jaundice	7.8	46.9	65.9	66.6	70.4
Average		51.3	72.7	66.5	75.9

RESULTS

Prompt reactions were obtained in sera from 6 patients with obstructive jaundice caused by either cancer or stone, one patient with so-called catarrhal jaundice, one patient with liver cirrhosis with jaundice and ascites, and one patient with mild cardiac jaundice. The curves obtained by the photoelectric method showed a steep ascent, a high level in ten to twenty seconds (0.9 to 9 mg. per 100 c.c.), reaching a still higher level within one minute (1.5 to 14 mg. per 100 c.c.). Qualitatively, similar curves were obtained in the patients with obstructive, catarrhal, and cardiac jaundice, even though in the last case the total bilirubin content was only 3.2 mg. per 100 c.c. (Charts 1 and 2). These curves were almost parallel to the curves of the indirect (quantitative) diazo reaction, but, as a rule, they did not reach the same level. There always remained a small amount of bilirubin which reacted with the diazo reagent only after the addition of alcohol. The total bilirubin content of the blood in these cases ranged from 3.25 to 32 mg. per 100 c.c. (see Table I). In order to determine the significance of the various direct curves and their clinical value the figures, as obtained at the beginning of the reaction (one minute) and at the end (thirty minutes), were correlated with each other and with indirect (quantitative) photoelectric curves at one and thirty minutes. Table I shows that in the prompt direct curves, the one minute value reaches on the average 51.30 per cent of the total bilirubin content, 72.73 per cent of the indirect first minute value, and 66.51 per cent of the thirty minute direct readings. When the thirty minute values were

compared with each other, it appears that about 25 per cent of the total bilirubin is usually revealed by the indirect method only.

Further investigation must show whether differences can be determined between the 'prompt diazo reactions in hepatic and obstructive jaundice. Cantarow, Wirts, and Hollander⁹ were unable to find any differences, but Varela and his co-workers,¹⁰ and recently Heilbrun and Hubbard,¹¹ demonstrated that differences between these types of jaundice exist when they separated the "prompt" and the "delayed" bilirubin quantitatively by the method of chloroform extraction.

Chart 1.—Comparison of the "prompt direct diazo reaction" in a case of obstructive jaundice with the "delayed direct diazo reaction" in a case of jaundice of the newborn.

In using the three test tube method, a prompt direct diazo reaction was characterized by the appearance of a color immediately after the addition of the diazo reagent. One has the impression that the redness reaches a maximum in one minute (van den Bergh and many other authors). The photoelectric curves, however, reveal that the maximum is reached in about thirty minutes, and Table I shows that the one-minute value of the direct curves is on the average only 66.5 per cent of the thirty-minute direct readings. This fact is due to the accuracy of the photoelectric colorimeter method for detection of the depth of color.

In the three test tube method a new observation was made which may be helpful in the classification of the different types of the direct diazo reaction. In the prompt direct diazo reaction the first orange-red color of the test tube containing the caffeine salts changes to purple in one to two seconds, while in

the tubes containing only serum and reagent the change appears in thirty to ninety seconds. In the delayed and biphasic reactions the appearance of the purple color is much more delayed.

To the *group of delayed direct diazo reaction* belong the serum of a patient with familial nonhemolytic jaundice, 4 patients with jaundice of the newborn, and one patient with healing hepatic jaundice. Furthermore, the following cases of latent jaundice belong in this group: 4 cases of pernicious anemia, 3 specimens of blood from the umbilical cord (placenta blood), one sulfanilamide jaundice (mild case, jaundice of hemolytic origin), one case of possible hemolytic anemia before and after splenectomy. The photoelectric direct curves show a striking contrast to the curves of the prompt group (see Charts 1 and 2). Not only in the first minute but also in the first five minutes a very slow ascent of the curves takes place, and after thirty minutes a low peak is reached. No difference was observed between the curves in the jaundiced cases and those with latent jaundice. But in the cases of jaundice of the newborn and in the case of healing hepatic jaundice the one minute values and the thirty minute values were relatively higher than in the other cases. Apparently the higher total bilirubin content in the jaundice of the newborn and in the healing hepatic jaundice causes the higher readings of the direct curves of these cases.

Chart 2.—Comparison of the "prompt direct diazo reaction" in a case of cardiac jaundice with the "delayed direct diazo reaction" in a case of sulfanilamide jaundice.

When the values obtained at various time intervals are correlated with each other, as was done in the cases of the prompt reaction, some striking results were obtained (Table II). In the delayed cases the value at one minute reaches only 9.5 per cent of the total bilirubin in contrast to 51.3 per cent in the prompt group. The other correlations show similar marked differences between the prompt and the delayed direct reaction. The thirty minute direct value reaches only 30.05 per cent of the total bilirubin (75.9 per cent in the prompt cases).

The three test tube method (direct diazo reaction) also shows that the redness in the delayed group develops slowly. The first trace of the orange-red coloring appears five to ninety seconds after the addition of the diazo reagent,

with an average of thirty-nine seconds. Then the color deepens slowly within one to twenty minutes (average five minutes) to a distinct orange red-color. It is of clinical interest that in this group the change to purple color occurs in about ten minutes to two and one-half hours, on the average in about one hour.

In the cases of jaundice of the newborn the development of the color after the addition of the diazo reagent is slower than in the other delayed cases. A distinct orange-red color could be noted only after ten minutes in Case 1 with 6 mg. total bilirubin; after twenty minutes in Case 2 with 7.25 mg.; after twenty-five minutes in Case 3 with 10.7 mg.; and after three hours in Case 4 with a total bilirubin of 23.36 mg. per 100 c.c. In the test tube method the speed with which the redness develops in jaundice of the newborn is apparently in inverse proportion to the total bilirubin content present. The change to purple color, which appears in the tube containing caffeine, does not occur at all in the other tube. Even twenty-four hours, thirty-six hours, and forty-eight hours after the addition of the diazo reagent, a dark orange-red or brownish-red color was present but no purple color. When a few grains of caffeine sodium benzoate were added to an orange-red twenty-four-hour specimen, a change to purple occurred two hours later.

TABLE II
COMPARISON OF QUALITATIVE AND QUANTITATIVE REACTIONS
CASES WITH DELAYED DIRECT DIAZO REACTION

DISEASE	TOTAL BILIRUBIN (MG. PER 100 C.C.)	1 MIN. DIRECT/30 MIN. INDI- RECT (%)	1 MIN. DIRECT/1 MIN. INDI- RECT (%)	1 MIN. DIRECT/30 MIN. DIRECT (%)	30 MIN. DIRECT/30 MIN. INDI- RECT (%)
Pernicious anemia	1.3	8.2	10.0	16.2	51.4

Hemolytic anemia after splenectomy	1.6	16.5	18.3	38.8	42.5
Sulfanilamide jaundice	1.8	7.2	10.5	23.7	30.3
Placental blood	0.9	18.4	26.4	41.9	46.2
Healing hepatic jaundice	1.9	8.4	9.0	24.1	35.0
	2.2	11.4	13.6	52.3	22.8
	5.2	11.3	16.7	43.7	26.0
	7.5	10.4	16.0	56.1	18.5
	6.0	4.3	3.1	13.2	33.0
	10.7	7.9	12.7	38.8	18.0
Jaundice of newborn	23.3	2.3	5.5	37.0	6.8
Average		9.5	13.4	33.4	30.5

This very delayed direct diazo test tube reaction in the cases of jaundice of the newborn seems to be in a certain contrast with the development of color obtained by the direct photoelectric method (average 0.618 mg. per 100 c.c. in one minute, and 1.5 mg. per 100 c.c. in thirty minutes). To explain this discrepancy it may be considered that the deep yellow color of these jaundiced sera may disguise the development of the red coloring in the test tube method.

Biphasic reactions were obtained in the sera from the following cases: one of liver cirrhosis, 2 of cholelithiasis with decreasing jaundice, and one of jaundice caused by metastases in the liver. In these cases the direct curves

ranged between the steep ascending curves of the prompt group and the low curves of the delayed group (see Chart 3 and Table III).

In this group the three test tube methods showed two variations which I described in 1921:⁵ "biphasic prompt" and "biphasic delayed." In three cases (cholelithiasis with jaundice, liver metastases with jaundice) the reaction was biphasic prompt; immediately after the addition of the diazo reagent a slight red color appeared. The redness deepened more slowly than in the prompt cases but more rapidly than in the delayed cases. The maximum amount of color seemed to be reached after one to two minutes. The change to purple color

TABLE III
COMPARISON OF QUALITATIVE AND QUANTITATIVE REACTIONS
CASES WITH BIPHASIC DIRECT DIAZO REACTION

DISEASE	TOTAL BILIRUBIN (MG. PER 100 C.C.)	1 MIN. DIRECT/30 MIN. INDI- RECT (%)	1 MIN. DIRECT/1 MIN. INDI- RECT (%)	1 MIN. DIRECT/30 MIN. DIRECT (%)	30 MIN. DIRECT/30 MIN. INDI- RECT (%)

Jaundice caused by cancer metastases	6.1	28.8	35.4	65.9	43.7
Cirrhosis of the liver	2.2	34.0	47.9	60.4	55.4
Cholelithiasis	1.1	35.7	56.8	58.0	61.6
Average		22.9	39.9	62.5	46.8

appeared in about one and one-half to four minutes, that is, a little later than in the prompt group. The total bilirubin content in these cases was high (see Table III). In the other cases (2 of liver cirrhosis, 2 of cholelithiasis) the biphasic-delayed direct diazo reaction was present: immediately after the addition of the reagent a very slight red color appeared, but the further development of the color was very slow, similar to the delayed reaction. The maximum color seemed to be reached in two minutes or later. The change to purple in 2 cases with a total bilirubin content of 1.1 mg. and 2.2 mg. per 100 c.c. required twenty and forty-five minutes, respectively.

Besides the differences which can be shown with the direct diazo reaction, van den Bergh¹ reported that the "prompt" bilirubin can be rapidly oxidized to biliverdin, while the "delayed" bilirubin is oxidized slowly. In 1914 Beneke¹² reported that the bilirubin present in blood of jaundice of the newborn, after being treated with formalin, remained yellow, while the bilirubin of cases with obstructive jaundice became green. In 1922 I⁵ proposed an easy oxidation test, and as a result of accumulated experience with this test found that it is of value in differentiating the various forms of bilirubin.

METHOD

The reagent is made by adding 1 c.c. of 0.5 per cent sodium nitrite solution to 9 c.c. of 1 per cent nitric acid solution. The reagent is prepared freshly each time it is used. The test is performed as follows: 0.2 to 0.3 c.c. of the serum is placed in each of two small test tubes. One tube is diluted with the same amount of water. To the other tube is added 0.2 to 0.3 c.c. of the reagent. Both tubes are held in front of a white paper against the daylight, and the rapidity with which a green color develops is noted during a five to ten minute period.

RESULTS

In a series of 80 examinations 3 different reactions were observed: (1) "Prompt oxidation test": immediately after the addition of the reagent, a definite green color develops and reaches its maximum intensity in ten to fifteen seconds. The depth of the color depends on the amount of bilirubin present, but it is always green. (2) "Diminished-delayed oxidation test": either a very slight yellow-greenish color develops immediately and changes to a grayish color within two to three minutes, or a rather slight yellow-greenish color develops in thirty seconds to fifteen minutes after the addition of the reagent. (3) "Negative oxidation test": after the addition of the reagent the color of the serum does not change at all or only becomes lighter. Within the next one to three minutes the color changes gradually to a grayish or straw color. No green color is present at any time. Addition of alcohol or of caffeine salts has no influence on the diminished-delayed or on the negative oxidation test.

Chart 3.—"Biphaseic-delayed direct diazo reaction" in a case of liver cirrhosis.

The *prompt oxidation test* occurred in all cases of obstructive and hepatic jaundice and corresponded to the prompt direct diazo reaction. In one case of mild cardiac jaundice with the low total bilirubin content (3.25 mg.) and in 2 cases with a biphaseic-prompt direct diazo reaction (cholelithiasis with 6.7 mg. and cancer metastases in the liver with 6.10 mg. per 100 c.c.) a prompt oxidation test was present. In serum of obstructive jaundice diluted to a bilirubin content of less than 2 mg. per 100 c.c., the prompt oxidation test changed in the majority of the cases to a diminished-delayed reaction.

The *diminished-delayed oxidation test* was observed in cases with delayed or with biphaseic-delayed direct diazo reaction (2 cases of liver cirrhosis with total bilirubin of 1.5 mg. and 2.3 mg.; one case of pernicious anemia with a total bilirubin of 1.36 mg.; one case of nonhemolytic familial jaundice with a total bilirubin of 4.06 mg.; one case of sulfanilamide jaundice with a total bilirubin of 1.82 mg.; and one case of healing hepatic jaundice with 5.22 mg. bilirubin per 100 c.c.). The time between the addition of the reagent and the

appearance of the yellow-greenish color did not depend on the amount of the total bilirubin. No case with a prompt or biphasic-prompt direct diazo reaction showed an oxidation test of this type.

The *negative oxidation test* was present in cases with delayed direct diazo-reaction only: pernicious anemia, hemolytic anemia before and after splenectomy, liver cirrhosis, in all specimens of cord blood of the newborn and in the cases of icterus neonatorum. The high total bilirubin content in the cases of jaundice of the newborn (6 mg. to 23.3 mg. per 100 c.c.) shows that also the negative oxidation test was independent of the bilirubin content of the serum. In one exceptional case of cholelithiasis with a total bilirubin content of 1.1 mg. a negative oxidation test was found in the presence of a biphasic-delayed direct diazo reaction.

Chart 4.—“Delayed direct diazo reaction” in a case of familial nonhemolytic jaundice.

Photoelectric curves of the different types of this oxidation reaction could not be obtained even though different filters (620, 630, 635) were used. Some examinations with Fouchet's reagent (trichloroacetic acid) and with the oxidation reagent of Malloy and Evelyn¹³ (hydrogenium peroxide, concentrated hydrochloric acid, and alcohol) did not show consistent results. Andrewes¹⁴ states that tincture of iodine gives a green color when added to a serum of obstructive jaundice, but an uncertain color when added to a serum of hemolytic jaundice. He obtained similar results with Fouchet's reagent.

DISCUSSION

The results presented in this paper show that a real negative direct diazo reaction does not exist. In all cases a positive direct diazo reaction can be obtained by the photoelectric method as well as by the test tube method, but the time necessary for the development of the color and its intensity vary markedly

in the different types of sera. When alcohol and diazo reagent are added to the serum ("indirect" or quantitative reaction), the color appears promptly in every serum. Therefore, it is fair to say that, as far as the qualitative test is concerned, it is not absolutely accurate to differentiate between "direct bilirubin" and "indirect bilirubin" or to speak of "bilirubin direct negative" or "bilirubin indirect positive." It is also confusing that Malloy and Evelyn⁶ used the word "promptness" in describing the direct photoelectric curves in cases of hemolytic jaundice which give a definite delayed direct diazo reaction. Bilirubin in the blood serum, when tested by the direct method, is either "prompt," "delayed," or "biphasic."

Chart 5.—"Delayed direct diazo reaction" in a case of healing hepatic jaundice.

The qualitative van den Bergh test is believed to be of diagnostic value. When the incline of the photoelectric curves is studied, definite differences appear between the direct prompt, direct delayed, and direct biphasic reaction. By correlating the values at one minute with those obtained after thirty minutes, the difference between the three types of curves is striking. By means of the three test tube method, the prompt, the biphasic prompt, the biphasic delayed, and the delayed types can be distinguished, especially when one takes into consideration the time at which the orange-red color changes to purple. In addition to the direct diazo reaction the oxidation test may be of aid in classifying the different forms of jaundice.

The presence of a prompt or biphasic-prompt direct diazo reaction and a prompt oxidation test exclude an hemolytic jaundice or a jaundice caused by decreased functional ability of the liver cells to excrete bilirubin to the normal

amount (e.g., familial nonhemolytic jaundice) (see Chart 4). These types of the direct diazo reaction and of the oxidation test indicate liver cell damage or an obstruction of the bile ducts. This fact is of particular clinical importance in cases of latent jaundice with a relatively low total bilirubin content. In such cases as cholelithiasis, cardiac failure, liver metastases, and arsphenamine intoxication the direct test tube diazo reaction, if prompt or biphasic prompt, and the oxidation test can reveal the presence of liver cell damage at once. On the other hand, a definite delayed direct diazo reaction and a negative oxidation test (more rarely a diminished-delayed oxidation test) demonstrate the presence of a hemolytic jaundice or jaundice due to functional inability of the liver cells to excrete bilirubin in normal amount or a combination of both. The delayed (sometimes biphasic delayed) diazo reaction and the negative oxidation test exclude hepatic or obstructive jaundice. Only in the early stages and in the healing stages of hepatic or obstructive jaundice a biphasic delayed or even a delayed direct diazo reaction and a diminished-delayed or even negative oxidation test can occur (see Chart 5). In such cases the clinical picture and repeated qualitative examinations of the blood bilirubin in combination with quantitative examinations (icterus index) may help in arriving at the correct diagnosis.

SUMMARY

A study of the direct diazo reaction was made with the photoelectric colorimetric method, the three test tube method, and a qualitative oxidation test. The following facts emerged:

1. A prompt, a delayed, and a biphasic type of the direct diazo reaction can be distinguished.
2. The oxidation test can be prompt, negative, or diminished-delayed in various types of jaundice.
3. These methods are of diagnostic value, the most important being the photoelectric colorimetric method.

STUDIES ON THE CLINICAL SIGNIFICANCE OF THE SERUM PROTEINS*

I. THE PROTEIN CONTENT OF NORMAL HUMAN VENOUS AND CAPILLARY SERUM AND FACTORS AFFECTING THE ACCURACY OF ITS DETERMINATION

BENJAMIN M. KAGAN, M.D., RICHMOND, VA.

CHEMICAL changes in the blood are becoming increasingly important in our interpretation and treatment of disease. In order for us either to interpret our clinical data in terms of physiologic or chemical changes or to interpret laboratory data in terms of clinical significance, it is necessary that we study thoroughly the changes of each chemical substance in the body under all circumstances.

To do this we must first of all have laboratory techniques available which are accurate and particularly simple and rapid enough to allow extensive investigation and general use. The methods for hemoglobin, sugar, urine albumin, etc., are simple, rapid, and sufficiently accurate for clinical purposes. They are, therefore, widely done, and their significance is generally appreciated.

In the case of blood protein concentration there has until recently been no test which met all these requirements, and largely for this reason the importance of the blood proteins has been widely underestimated.

It is proposed in this report and in subsequent reports to show the importance of the blood proteins in disease. Herein we shall discuss the normal concentration of blood protein and its two constituents, albumin and globulin, the methods available for determining these concentrations, and details regarding the collection, preparation, and handling of the specimen so as to insure maximum accuracy and greatest ease in obtaining the result.

METHODS

The most accurate method for determining the concentration of total protein and its constituents, albumin and globulin, is the Kjeldahl. Unfortunately,

*From the Johns Hopkins and Sinai Hospitals, Baltimore.
Received for publication, April 13, 1942.

it is relatively difficult, expensive, and time-consuming. It is, therefore, not generally available nor useful in the sense that the hemoglobin and urinalysis tests are.

There are in existence several colorimetric methods which, while less difficult to use, do not approach the simplicity of usual routine tests, some of which are subject to errors up to 10 per cent.

In 1937 I described a falling-drop technique,^{1, 2} which is probably the most rapid and simple method for determining the total serum protein concentration.³ Duplicate samples of the same specimen analyzed by this method check well within 0.1 Gm. per 100 c.c., and the mean deviation of 107 different specimens of serum when determined by this method and by the macro-Kjeldahl was ± 0.16 Gm. per 100 c.c. This determination can be done with as little as 0.1 c.c. of blood obtained from finger tip or vein and compares in simplicity with the hemoglobinometer.

It is regrettable that there is no simple test for determining accurately the absolute concentration of albumin alone.* There are, however, several simple tests which indicate whether or not the globulin concentration is above normal. To mention only two: the globulin precipitation test† and the formol gel test‡. If by means of one of these tests it is determined that the globulin concentration is not elevated, then changes in the total protein concentration may be safely attributed to change in the albumin concentration. This will be discussed in detail in subsequent papers on the behavior of albumin and globulin in disease. First, however, let us consider the effect of the manner of collecting, preparing, and handling the specimen on the accuracy of any blood protein determination by any method.

DETAILS REGARDING COLLECTION, PREPARATION, AND HANDLING OF SPECIMEN

Rowe⁴ and others have found that the protein content of a specimen is increased almost 0.2 Gm. per 100 c.c. for each minute that venous stasis is maintained by a cuff around the arm. This is due to loss of water from the vascular bed. It is, therefore, advisable that blood should be collected within one minute of the application of the tourniquet.

Peters and Van Slyke⁵ have reviewed the physiologic factors which may affect the normal concentration of serum proteins. Hyperventilation (when sufficient to produce tetany), vigorous muscular exercise, and stasis of the blood caused by chilling are all capable of increasing the protein concentration. When the body temperature is raised above normal, a lowering of the protein concentration occurs; and when sweating causes sufficient loss of fluid, the opposite obtains. In cases where they are present, these factors need to be kept in mind.

When blood proteins are determined by any of the present colorimetric methods, it is necessary to use blood collected after a twelve-hour fast because

*The falling-drop principle has been applied for the determination of albumin and globulin, but the necessary precautions are too rigorous for routine use. Since only 27 determinations have been correlated with the Kjeldahl, this method cannot at this time be generally recommended.⁴

†Globulin precipitation test (Naumann⁶): Add 0.1 c.c. of serum to 1.0 c.c. of distilled water in a 10 mm. wide test tube. Saturate with alveolar air and read after fifteen minutes. If definite cloudiness appears, globulin concentration is said to be more than 3.0 Gm. per 100 c.c.

‡Formol-gel (Bing⁷): Add 2 drops of 40 per cent formalin to 1 ml. of serum and read after three hours' standing at room temperature. Globulin concentration is elevated if tube can be inverted without losing contents.

the change in amino acids in blood following food intake affects this method. Such changes in the amino acids do not affect the Kjeldahl or drop methods. In four patients on regular hospital diets, from whom blood was drawn every three hours during the day and hourly after the noonday meal for four hours, there was no change in the serum proteins greater than 0.2 Gm. per 100 c.c. when the determinations were done by the drop method.

The following two experiments done by the falling-drop method suggest that it is advisable that no amount of fluid greater than 500 c.c. be ingested at any one time within four hours of the sampling: (1) Each of 3 persons was given between 600 c.c. and 750 c.c. of water, and their blood proteins were followed at half-hour intervals. All 3 showed decreases in protein concentration which averaged for the 3 a value of 0.15 Gm. per 100 c.c. (2) Each of 3 persons with minor surgical ailments was given 1,500 c.c. of tap water by mouth within five minutes. Their blood changes were similar. The serum protein level fell gradually over the first hour after ingestion of the water to an average of 0.5 Gm. per 100 c.c. less than its original value and returned to the previous level two hours after ingestion. On a subsequent day the same persons were given 1,500 c.c. of normal saline solution in similar manner. The serum proteins fell gradually over a two-hour period to an average of 0.9 Gm. per 100 c.c. less than the original value and were still in 2 cases 0.1 Gm. per 100 c.c. below the original value four hours after the ingestion. Following the ingestion of 500 c.c. of tap water or normal saline, changes in protein concentration are definitely within the experimental error. In view of the foregoing experiments, therefore, it is recommended that no amounts greater than this be ingested within four hours of sampling.

TABLE I

COMPARISON OF THE PROTEIN CONTENT OF SERUM WITH HEPARINIZED AND OXALATED PLASMA

SUBJECT	PATIENT 1	PATIENT 2	PATIENT 3
METHOD	KJELDAHL	KJELDAHL	KJELDAHL
Serum	4.66	6.11	7.21
Oxalated plasma	4.63	6.06	7.12
Heparinized plasma	4.82	6.71	7.56

In many previous investigations and in a number of modern texts no distinction is made between protein values for plasma or serum. The following experiment shows that such a distinction is necessary. Blood was drawn from 3 patients. From blood drawn into a single syringe, serum, oxalated plasma, and heparinized plasma were prepared. The proteins were determined by the macro-Kjeldahl method. The results are shown in Table I. Oxalated plasma may contain the same or lower concentration of protein than serum, even though it would logically be expected to contain about 0.3 Gm. more per 100 c.c. because it contains fibrinogen. Furthermore, the values obtained for oxalated plasma are not as reliable as those for serum, probably because the amount of water withdrawn from the red blood cells varies with the amount of oxalate used as well as with the varying effect that oxalate has on the cells of different persons. The values obtained for oxalated plasma would correspond to those obtained for serum only if the same amount of blood were always mixed together with the same amount of oxalate with an accuracy not usual in the laboratory, and also if it were

true that the cells of every person responded in exactly the same manner to changes in surrounding osmotic pressure. Heparinized plasma may contain as much as 0.65 Gm. per 100 c.c. more protein than oxalated plasma because of a combination of these reasons. In a previous report² we found that values obtained for serum protein were definitely more consistent than those for plasma. For these reasons, serum should be preferred to oxalated plasma for use in determining the blood protein concentration.

A series of experiments were done to determine the effect of the age of the specimen on serum protein concentration. These experiments were done by the falling-drop method. A few specimens kept in rubber-stoppered tubes and in an icebox showed increases of over 0.2 Gm. per 100 c.c. when more than twenty-four hours old. Tubes containing the same bloods, but sealed with wax and kept in the icebox, showed no change even after three days. Specimens which were kept in rubber-stoppered tubes at room temperature for twenty-four hours occasionally showed changes as great as 0.7 Gm. per 100 c.c. When cotton-stoppered tubes, such as used in some hospitals, were left at room temperature, increases as high as 1.6 Gm. per 100 c.c. were noted in twenty-four hours. In view of these findings, it would appear safest to do the determinations within twenty-four hours and to keep the specimen in a well-stoppered tube in the icebox.

When a tube of blood is centrifuged without a cork, the concentration of serum protein may rise as much as 0.5 Gm. per 100 c.c. when spun at 3,000 r.p.m. for only fifteen minutes. Although a more detailed analysis of this factor was not attempted, the changes seemed to be directly proportional to the amount of exposed surface relative to the total volume of serum in the tube. When well corked, a tube of blood may be spun at this speed for half an hour without change in concentration.

When the blood was properly stored, there was no difference in the serum protein concentration whether the blood was centrifuged four or twelve hours after its collection or whether or not the serum was separated from the clot before it was stored.

Hemolysis, brought about by shaking a tube of blood vigorously, produced in general an increase of the protein concentration—occasionally of 0.5 Gm. per 100 c.c. Occasionally hemolysis resulted in slight lowering of protein concentration. Apparently the effect depends on the proportion of water and hemoglobin lost from the red blood cells in the procedure. Since it is impossible to judge how great an effect hemolysis will have on an individual specimen, it is considered safer never to use a hemolyzed specimen for this analysis.

In some cases where venous blood is difficult to obtain, it would be very useful to be able to determine the serum protein of blood obtained from the finger tip or heel. This is especially true in pediatrics. Since the amount of blood so obtainable is not adequate for the macro-Kjeldahl technique nor for sufficient accuracy by the colorimetric methods, no comparison of the serum protein concentration of venous and capillary blood has been heretofore reported.

With 0.2 c.c. of blood, which is easily obtainable from the finger tip, about three to five determinations of serum protein can be done by the drop method. It was found most convenient to collect this blood in small test tubes which

measure 35 mm. by 6 mm. and have round bottoms and no lip. A rubber cap fits over the mouth to prevent evaporation. If the finger be placed in warm water for a few minutes prior to being stuck, a free flow is obtained without squeezing tissue fluid into the wound. Capillary blood collected in this manner was compared with venous blood collected from the same arm at the same time. The venous blood was collected without the use of a tourniquet. In tests on 14 adults and 2 children the difference in serum protein concentration between venous and capillary blood was never more than 0.2 Gm. per 100 c.c., and the average difference was 0.07 Gm. per 100 c.c. It is concluded from this experiment that capillary blood is a satisfactory substitute for venous blood and for clinical purposes the results may be considered identical.

NORMAL VALUES OF TOTAL SERUM PROTEIN AND OF ALBUMIN AND GLOBULIN

In 1933 Peters and Eisenman⁹ reported the value for serum proteins on 52 normal persons. They found that 90 per cent of the values were between 6.3 Gm. and 7.7 Gm. per 100 c.c. This is the largest series reported to date which is based on persons who were known to be normal. Larger series have been reported but not on normal subjects. The purpose of the present report is to add to the data already collected with determinations done by the falling-drop method on 150 ambulatory persons who were normal by examination.

Our analysis was done on the blood of 75 medical students, 25 student nurses, and 50 blood donors. On each student a physical examination, Wassermann test, and urinalysis were done. One student had had a recent appendectomy, one had inactive rheumatic heart disease, and two had orthostatic albuminuria. Their ages ranged from 17 to 35 years. Their physical status was considered good in 52 per cent, robust in 26 per cent, fair in 20 per cent, and asthenic* in 2 per cent.

The donors were not examined. They had never given blood before and were selected for the most part from men accustomed to hard manual labor in steel and tin plate mills. The results on their blood differ in no respect from that of the others.

The range of serum protein concentration in these 150 persons was 6.1 Gm. to 7.6 Gm. per 100 c.c. The average value was 6.7 Gm. per 100 c.c. The individual male whose serum protein level was 6.1 Gm. per 100 c.c. had had a severe, continuous nosebleed over the previous three days, which finally required cauterization. One month later his serum protein level was 7.0 Gm. per 100 c.c. The female whose protein level was 7.6 Gm. per 100 c.c. was in good health except for being 20 pounds under average weight for her age and height. Another analysis one month later gave a value of 7.5 Gm. per 100 c.c.

Bruckman and associates¹⁰ report an average value of 6.93 Gm. per 100 c.c. for 13 males and 7.6 Gm. per 100 c.c. for 8 females. Peters and Eisenman found no sex difference in their series. The range for the 36 females in this series was 6.3 Gm. to 7.6 Gm. per 100 c.c., with an average of 6.7 Gm. per 100 c.c. The range for the 114 males was 6.1 Gm. to 7.5 Gm. per 100 c.c., with an average of 6.7 Gm. per 100 c.c.

*For the medical data on these students I am indebted to Dr. Warde B. Allan and Dr. N. B. Herman.

It will be noted that most of the possible deviations from the standard technique used here cause an increase in the serum protein concentration. This may explain why previous investigators have had a few more values between 7.5 Gm. and 8.0 Gm. per 100 c.c. than are found in this report. Many investigations reporting higher values than those reported by Peters and Eisenman and by us have been done on persons who were not normal but who had diseases of various sorts which were assumed at the time not to affect the serum protein concentration. That values above 7.5 Gm. per 100 c.c. are unusual in normal persons is further confirmed by the fact that of 995 determinations of total plasma and serum protein by the macro-Kjeldahl method on 576 patients at the Johns Hopkins Hospital only 24 determinations on 20 patients gave values between 7.5 Gm. and 8.0 Gm. per 100 c.c. Of these 20 patients 15 had diseases which would be expected to cause an increase in the serum protein concentration. This will be discussed in more detail in a subsequent report.

Throughout our work we have accepted the values for normal concentration of serum albumin and globulin to be those given by Peters and Eisenman. They were based upon 50 Kjeldahl determinations on specimens from 34 normal persons. They are for albumin 4.0 Gm. to 5.5 Gm. per 100 c.c. and for globulin 1.4 Gm. to 3.0 Gm. per 100 c.c.

SUMMARY

In order to minimize inaccuracies in the determination of blood protein which may arise during collection and handling of the specimen, it is advisable to proceed as follows:

1. Blood should be collected within one minute after the application of the tourniquet.
2. Serum gives more accurate results than oxalated plasma and should, therefore, be preferred.
3. Only nonhemolyzed serum should be used.
4. The blood should be kept in a well-stoppered tube in an icebox, and the analysis should be done within twenty-four hours after collection of the blood.
5. The tube containing the blood sample must also be well stoppered during centrifugation.
6. It is advisable that no amount of fluid greater than 500 c.c. be ingested at any one time within four hours of the sampling. When all the conditions stated are maintained, a difference of protein content of 0.2 Gm. per 100 c.c. from sample to sample in following the course of a disease may be considered quantitatively significant when either the falling drop or the Kjeldahl method is used for all the determinations. This, of course, does not apply when one determination is done by one method and another determination by another method.

Serum from capillary blood obtained from the finger contains for clinical purposes the same amount of protein as venous blood; and the same normal values, therefore, may be applied. Our technique for collecting capillary blood is given.

The range of concentration of serum protein in 150 normal persons was found to be 6.1 Gm. to 7.6 Gm. per 100 c.c., and the average 6.7 Gm. per 100 c.c. Values greater than 7.5 Gm. or less than 6.0 Gm. per 100 c.c. should be con-

sidered abnormal until proved otherwise. There is no difference between the normal values for total serum protein in males and females.

RICHMOND, VA.

THE RELATION BETWEEN SPECIFIC GRAVITY OF BLOOD SERUM AND ITS PROTEIN CONCENTRATION*

JOSEPH M. LOONEY, M.D., WORCESTER, MASS.

THE application of the falling-drop method for the determination of specific gravity of blood plasma or serum proposed by Barbour and Hamilton¹ has stimulated the adoption of this technique in many hospitals for the estimation of serum proteins. Because the method for the determination of specific gravity is very precise and accurate, many investigators have been led to the belief that the estimation of serum protein from specific gravity figures by the formula of Moore and Van Slyke² is just as reliable. The formula

$$\text{Total Protein} = 343 (\text{sp. gr.} - 1.007),$$

proposed by Moore and Van Slyke, was subsequently confirmed by Weech and his co-workers.^{3, 4} These investigators found that the correlation coefficient between specific gravity and total protein had the remarkably high value of 0.994 for serum and 0.991 for plasma. They gave the following equations for the regression line between the two factors:

For Plasma:

$$P = 340.1 (\text{sp. gr.} - 1.00687) \pm 0.103.$$

*From the Memorial Foundation for Neuro-Endocrine Research and the Research Service of the Worcester State Hospital, Worcester.

Received for publication, April 30, 1942.

For Serum:

$$P = 347.9 \text{ (sp. gr. - 1.00726)} \pm 0.076.$$

However, Zozaya,⁵ in a study on the physicochemical characteristics of blood sera, found a correlation coefficient of only 0.28 ± 0.062 between total serum protein and specific gravity. He thought that his failure to obtain better results might have been due to the use of serum rather than plasma. Against this interpretation, however, is the finding of Nugent and Towle⁶ that the specific gravity of synthetic solutions of serum albumin and serum globulin was a function of the total concentration of protein regardless of the distributions between the two substances. A recalculation of their data gives the following regression equation:

$$\text{Total Protein} = 366 \text{ (sp. gr. - 1.0067)}.$$

For several years we have been accumulating data on the relationship between the protein content and the specific gravity of blood sera. We have not been able to confirm the findings of Moore and Van Slyke² or of Weech and his collaborators^{3, 4} that there is a high correlation between specific gravity and serum protein, and that the percentage of protein in a given serum can be predicted with a high degree of accuracy.

METHODS

The material for our study has been drawn from three sources: first, from a group of 14 schizophrenic patients who were studied under basal conditions at four different times; second, from a group of 10 normal persons who were studied under basal conditions on two different days; and third, from a group of 12 patients undergoing diathermy therapy who were tested on two different days, before the treatment was begun, at the time that the temperature reached the maximum desired, and finally after the temperature was held at this point for three hours. The specific gravity was determined by the falling-drop method of Barbour,¹ using a solution of potassium chloride of density 1.0343 as the standard of comparison. The total protein was determined by the turbidimetric method of Looney.^{7, 8} All determinations were made in duplicate.

The use of the turbidimetric method for the determination of the total protein in our hands has given results which statistically show less variation in duplicate determinations than the standard Kjeldahl method. In a series of 20 sera analyzed for total protein in duplicate by both methods, the following results were obtained: The Howe method gave a mean difference between duplicates of 0.052 mg., with a standard deviation of 0.051 mg. The Looney method gave the values of 0.046 and 0.034 mg. The mean of the differences between means of the duplicates of both series was 0.096 mg., and the standard deviation was 0.069 mg. It is evident, therefore, that there is no significant difference between the methods, and that the variance of the Looney method is somewhat lower than that of the Howe method. In this connection it may be pointed out that only the colorless drops of ghatti gum should be used in the preparation of solutions. If difficulty is experienced in obtaining a good quality of gum, then 2 per cent duponol can be used as a dispersive reagent.

RESULTS

In Fig. 1 the specific gravity of the sera of the patients on four different days was plotted against the total protein. The values for each person are connected by lines, and the order in which the tests were run is indicated by different symbols.

Fig. 1.—Correlation between specific gravity and serum protein in patients. Lines connect readings for individual patients on four different days.

It is evident from an examination of the graph that neither the specific gravity nor the total protein values for any person remain constant. It is also apparent that there is no consistent relationship between the specific gravity and the protein content of the blood serum. The group means for the specific gravity remained practically unchanged from day to day, the values being 1.0248, 1.0246, 1.0247, and 1.0248 for the successive days. The means for the total protein, however, showed considerable variability. The values in grams per 100 ml. of serum were 6.18, 5.87, 5.94, and 5.61. The correlation coefficients for each of these days also showed marked variation, as shown by the following values: 0.22, 0.04, 0.58, and 0.16. The coefficient of correlation for *all* the readings was 0.143.

The means of the total protein for the normal persons were more consistent, giving a value of 6.83 Gm. for the first day and 6.77 Gm. for the second. The specific gravity values gave the same mean 1.0269 for both days. Despite this constancy for the means, the coefficient of correlation was only 0.18. This lack of relationship is clearly shown in Fig. 2.

It was felt that a determination of the relationship between the two variables during diathermy would offer an ideal situation for a conclusive test of the

hypothesis. Marked hemoconcentration takes place during the period of fever despite the administration of copious amounts of water. The protein content of the blood would not be expected to change during the period of the experiment and should furnish a reliable measurement of the amount of fluid loss. If the specific gravity furnishes a reliable index of the total protein content of the blood, then a high degree of correlation should be found in each person tested.

Fig. 2.—Correlation between specific gravity and serum protein in normal subjects.

The results of these experiments are plotted in Fig. 3. It will be noted that in some cases there is such a relationship and the three points can be connected by a line which is straight, or nearly so. In other instances, however, no such relationship occurs, and in one case a fall in specific gravity is associated with an increase in total protein. Moreover, in those cases in which a straight-line relationship was found between the specific gravity and total protein of the serum, the slopes of the lines were not the same. This fact makes the use of any single formula unsuited for the calculation of protein from specific gravity. An inspection of the figure will show that there is a wide spread in the values for specific gravity for the same value of total protein and an even greater spread of total protein for given values of specific gravity. The correlation coefficient for all the values is 0.563 and the regression equation is:

$$\text{Total Protein} = 315 (\text{sp. gr.} - 1.0046).$$

The means for the total protein for the three periods were 6.60, 6.97, and 7.58. The corresponding values for the specific gravity were 1.0258, 1.0267, and 1.0283, and for the hematocrit readings were 40.01, 41.42, and 43.04. The correlation between the serum protein and the hematocrit reading was very low, since the coefficient was only 0.134 and there was no correlation between the specific gravity and the hematocrit reading.

DISCUSSION

The results of our investigations show that the specific gravity of blood serum is not a simple function of the concentration of protein and that the degree of error in calculating the protein value from the specific gravity in any individual case may be very large. This finding is not unexpected, since the amount of salts and fat in the serum should have considerable influence on the final density of the serum.

Fig. 3.—Correlation between specific gravity and serum protein during diathermy. Lines connect readings of individual patients.

Our experiments on the changes in protein concentration and specific gravity during the course of diathermic therapy indicate that the concentration of the serum proteins serves as a better indicator of fluid changes in the blood than either specific gravity or hematocrit value. This type of experiment should provide a crucial test of the relationship between density and protein concentration, since the total amount of circulating protein should remain virtually unchanged during the course of the experiment and the concentration should vary directly with the amount of fluid lost from the blood vessels. As a result the study of a smaller number of cases should provide as much information as that of a larger number of unrelated tests on a group of persons selected at random.

It is also evident that, although the amount of change in specific gravity produced by a given change in the concentration of serum protein may be fairly constant in a single person, it is not the same for all persons. The regression equation for a group would give a fair indication of the mean relationship

between the density and the protein concentration, but this would not hold for any single person.

These results are in agreement with the conclusions reached by Zozaya already quoted,⁵ and also with the findings given by him in a later paper.⁹ He gave figures showing that 12 samples of sera, each having a total protein concentration of 6.59 Gm. per 100 c.c., had specific gravities ranging from 1.0251 to 1.0277. The protein concentration calculated from these specific gravities by the formula of Moore and Van Slyke ranged from 6.21 to 7.10 Gm. per 100 c.c., or using the formula obtained from the data in this paper, from 6.46 to 7.28. In another group of 9 persons, all having a specific gravity of 1.0272 or 1.0273, the total protein values varied from 6.70 to 7.36 Gm. per 100 c.c. The calculated protein for these specific gravities would be 6.93 or 6.96 Gm. per 100 c.c. by Moore's formula and 7.12 or 7.15 Gm. per 100 c.c. by mine. The agreement between the mean protein value of 7.01 Gm. per 100 c.c. and those calculated from the foregoing formulas is good, but the variation from individual readings is rather high.

Similar findings were obtained by Moon and his collaborators¹⁰ in a recent article on shock and hemorrhage. They found that during shock the specific gravity increased while the serum proteins decreased. In hemorrhage, however, both variables were diminished. In these experiments a decrease in the concentration of protein occurred during the period of hemoconcentration following shock, but this loss of protein was not indicated by the specific gravity which increased because of the action of other factors, such as the increased concentration of nonprotein nitrogen and salts except chlorides.

Barbour¹¹ has adopted the method for the estimation of serum albumin by determining the specific gravity of the supernatant solution from an equal mixture of serum and saturated ammonium sulfate and comparing it with a standard solution of ammonium sulfate. Although the standard deviation for the serum albumin estimated from the specific gravity differed from that obtained by Howe-Kjeldahl method by only 0.32 Gm. per 100 c.c., a study of the graph indicates that for any single case much larger differences may be found. Thus, for a serum albumin value of approximately 3.70 Gm. per 100 c.c., the specific gravity varies from 1.0245 to 1.0268, and for a specific gravity of 1.0245 the serum albumin varies from 2.30 to 3.70 Gm. per 100 c.c. While the method can be used for the determination of the mean value of the serum albumin for any given group within the accuracy indicated by the author, the application to any specific case is fraught with considerable danger since this may involve errors in such instances as great as 50 per cent.

A consideration of the data given in this paper, as well as those obtained from other authors, indicates that the correlation between serum proteins and specific gravity is not sufficiently close to permit accurate estimations of the former variable by a determination of the latter.

SUMMARY

The relationship between the specific gravity of serum and its protein concentration was determined repeatedly in a group of schizophrenic patients and also in a group of normal subjects. During diathermy the effect of prolonged

fever on the serum proteins and specific gravity was studied in a third group of paretic patients. The correlation between the two variables was found to be too low to permit accurate estimation of the serum proteins of persons from the specific gravity values.

MEDICAL ILLUSTRATION

Editorial Comment

In consideration of the fact that physicians often speak during the showing of motion pictures that are neither titled nor recorded in sound, the following article should prove of considerable value as a guide to judging word spacing and timing between sequences. This article should also be of value to the scientific worker who plans to have sound recorded on a previously prepared film. In such a case exact timing is of utmost importance. It is logical to reason that with the development of sound recording devices and the obvious reduction in price that has rapidly taken place in the last few years, the sound motion picture for technical use, as in teaching and reporting at scientific meetings, will eventually replace silent films entirely.

It is worth bringing to the attention of the illustrator and physician the fact that sound can be dubbed in on practically any silent motion picture. Sound projectors and projectionists are usually supplied for the use of speakers at most of the larger meetings. The average sound projector costs about twice as much as a silent projector.

For those persons wishing to study the picture along with the text, prints of the picture may be obtained from the author at a nominal cost.

TEXT OF THE MOTION PICTURE: A LECTURE ON THE SPIROCHETES*

THEODOR ROSEBURY, D.D.S., NEW YORK, N. Y.

PHOTOMICROGRAPHS OF SOME OF THE PARASITIC AND PATHOGENIC SPIROCHETES AND SPIRILLA AS THEY APPEAR UNDER THE DARK-FIELD MICROSCOPE

(Magnification is uniform throughout, about 160 diameters on the film.

An approximate scale in microns is given.)

Note.—The text is prepared to be read as the film is shown at standard silent speed, 16 frames per second. Numerals in parentheses, e.g., (150), indicate the approximate rate of reading in words per minute. Other directions for reading are also given in italics in parentheses. Titles are given in capitals as section headings.

(*Begin reading on the first dark-field scene*) (150) The spirochetes are distinctive microorganisms, characterized as unicellular spiral filaments with a flexible body, motile without flagella. They are classified among the bacteria as a separate order, but they are sometimes considered intermediate between bacteria and protozoa. (*Wait 5 seconds*) We are going to examine the parasitic spirochetes individually and look into their relationships in disease. Before we do so let us make some general observations on the group as a whole.

*From the Department of Bacteriology, College of Physicians and Surgeons, and the School of Dental and Oral Surgery, Columbia University, New York City.

This film was shown at the Forty-Third General Meeting of the Society of American Bacteriologists, Baltimore, December 30, 1941. It was made to be used as a general lecture for medical and dental students. Copies of the film may be obtained at the cost of printing from the negative.

MORPHOLOGY AND CLASSIFICATION OF SPIROCHETES AND SPIRILLA

(On chart) (120) We recognize five genera of spirochetes, shown here diagrammatically with a group of spirilla for comparison. Let us look at them individually. (Chart builds progressively; time to animation) (150) The genus *Spirochaeta* properly includes only certain large spirochetes. Part of one is shown here. They occur as free-living forms in water and are not pathogenic. They have a spiral axial filament and regularly disposed granules. The genus *Cristispira* is likewise of no medical importance. These spirochetes usually occur as parasites in the alimentary canal of shellfish. They are large forms with a crest or crista, a flexible membrane wound spirally around the spiral organism. They have granules and a chambered structure. The genus *Saprospira*, also not important medically, consists of spirochetes free-living in foraminiferous sand. They resemble *cristispiras*, but have no crest.

Fig. 1.—Chart of morphology and classification of spirochetes and spirilla. Numbers correspond with those given in the text.

(130) The generic name *Treponema* is used here to include most of the spirochetal species which are parasitic and pathogenic for man and animals. The treponemas usually show no details of internal structure. They are spiral filaments differing in width and in the number and shape of their spirals. These five forms, with their differences exaggerated in the drawings, are all represented in the photomicrographs: (time to animation) 1, the relapsing fever spirochete, intermediate in thickness and winding; 2 and 3, the large spirochetes of mucous membranes, loosely wound, thin, or thick enough to show double contours; 4, the small spirochete of mucous membranes, thin, tightly wound, with shallow spirals; and 5, of which the spirochete of syphilis is the type, thin, tightly wound, with somewhat deeper spirals.

(130) The fifth and last genus of spirochetes is *Leptospira*, which includes both saprophytic and pathogenic species, all of which look somewhat like this.

The leptospiras are much more closely wound than the treponemas, and characteristically one or both ends is bent to form a hook.

(130) The genus *Spirillum* belongs with the true bacteria, not with the spirochetes. The spirilla are flagellated and more or less rigid bacteria. The two forms shown at 6 are typical spirals or portions of a spiral, with flagella peritrichous or polar. Other spirilla, as shown at 7, are curved rods with pointed ends. The rat-bite fever spirillum is 8, short, thick, with rather closely set spirals, and with a tuft of flagella at each end. All these spirilla appear in the photomicrographs.

THE DARK-FIELD MICROSCOPE

(On diagram) (120) Dark-field examination at high magnification requires a substage reflecting condenser. This is a bicentric condenser, one of several kinds available, shown in place under a slide with the objective in position. The condenser has two reflecting surfaces, one concave and one convex. The whole condenser-slide-objective system must be made uniform in refractive index; therefore, oil is placed both above and below the slide.

PATHWAY OF LIGHT

(150) A narrow pencil of light passes from the mirror to fill the convex reflecting surface, which reflects it so as to fill the concave reflecting surface, and this concentrates the light to form a hollow cone. The cone is focused and centered in the plane of the specimen and in the optical axis. Incident light is stopped by a diaphragm in the objective, and only light reflected off particles in the field reaches the eye. The particles or microorganisms are thus illuminated like dust in a beam of sunlight entering a darkened room: they appear bright against a black background, and look larger or thicker than they really are because we see a halo of light around them.

(On preparation of the slide) (120) In preparing a slide for use under the dark field it is best to use a vaseline seal on the coverslip. Here vaseline is applied from a test tube with a wooden applicator. The seal prevents drying of the film and precludes drifts in the field which result from evaporation at the free edge of the film. (Wait 5 seconds) Both coverslip and slide must be scrupulously clean; bubbles should be avoided in the film since they reflect much more light than do microorganisms. The coverslip is pressed down to make a perfect seal.

(At microscope) (135) A small drop of oil is placed on the cover slip, and a larger drop on the under surface of the slide. A strong light source is used, such as an arc or a concentrated filament lamp. The light is focused through a collecting lens to a bright spot on the plane mirror, and the mirror is adjusted so that a concentrated beam of light fills the convex reflecting surface of the condenser. The objective diaphragm is stopped down, and the condenser is centered and focused so that the apex of the hollow cone of light falls in the optical axis and in the plane of the object. When this is done we see under low magnification (*bright spot appears*) a spot of light like this, which changes symmetrically to a ring of light as the condenser is racked either above or below the focus.

TREPONEMA RECURRENTIS FROM THE BLOOD OF AN INFECTED RAT

(*Clipping tail*) (120) A drop of blood from a rat infected with relapsing fever spirochetes is obtained by clipping the tail. The blood must be diluted for dark-field examination in order to separate the cells. The coverslip has previously been prepared with vaseline and a suitable diluting fluid, such as broth.

(*On dark field*) (150) Here we see red blood cells and *Treponema recurrentis* in a diluted rat blood film under dark field. (*Wait 2 seconds*) The discovery of these organisms, reported by Obermeier in 1873, brought out not only the first pathogenic spirochete but also one of the first microorganisms of any kind to be associated with disease in man.

(*Wait 3 seconds*) The motion of all spirochetes can be analyzed into three components: rotation around the long axis, flexion, or bending of the body, and translation or movement from place to place. The relative prominence of these components is a species characteristic, but varies considerably even in a single preparation. These spirochetes show active rotary movements and moderate flexion, but little translation. Others, taken from the same animal, which you will see a little later, show active movements of translation.

(*Wait 3 seconds*) Relapsing fever in man, as the name implies, is characterized by several sharp paroxysms of fever separated by irregular periods during which the symptoms are absent.

(*Progressive movement begins*) (150) There are two general types of relapsing fever. One, the so-called European type, is spread from man to man by the body louse, has occurred in severe epidemics, and often accompanies typhus fever. Both diseases are spread by lice, and, as the louse vector suggests, they are associated with poverty and crowding. Louse-borne relapsing fever is caused by *Treponema recurrentis*, a strain of which you see here. (*Wait 3 seconds*) The other type of relapsing fever is spread by ticks, which parasitize ground squirrels and other wild rodents. This type of the disease in man is sporadic rather than epidemic. It occurs in Africa and in South and Central America. Scattered cases have been reported in several parts of this country. Spirochetes have been recovered on numerous occasions from ticks taken in rodent burrows, especially in the western and southwestern states. The spirochetes of tick-borne relapsing fever are morphologically identical with the louse-borne strain you see here.

(*Wait 3 seconds*) (150) In relapsing fever in man, spirochetes occur in the blood during the onset phase of each paroxysm and diminish in numbers with its decline. They may be absent or difficult to find during the afebrile intervals. Diagnosis in man is best made by dark-field examination of a diluted blood film such as this, although staining methods can likewise be used on fixed films. The patient's blood should also be injected intraperitoneally into mice or rats, which are then examined for spirochetes in the blood after twenty-four to forty-eight hours. (*Elapsed time 12 minutes, 25 seconds*)

THE MOUTH SPIROCHETES AND ASSOCIATED BACTERIA IN EXUDATES FROM FUSO-SPIROCHETAL ANGINA AND GINGIVITIS, AND FROM OTHER MOUTH DISEASES

(*On patient*) (150) Here we see the method of removing exudate from a case of Vincent's or fusospirochetal gingivitis. To provide enough material for

cultures and animal inoculation, as well as for smears and dark-field examination, (*making suspension*) a heavy suspension is made in 1 c.c. of broth.

(*On dark-field*) (135) Spirochetes similar to those of the mouth may also be found on the genitourinary and intestinal mucous membranes, and in a group of pathologic processes known collectively as the fusospirochetal infections. Several kinds of bacteria always accompany the spirochetes from any of these areas or disease processes. Among these bacteria (*fusiform bacilli appear*) are fusiform bacilli, of which one of several types is shown here; (*motile rod*) various motile bacteria, such as this small organism traveling in a circle, and filaments, as seen at the left; (*vibrio*) also vibrios, sometimes showing one or more polar flagella. Various cocci are always present. (*Spirillum*) Here is a spirillum, a characteristic mouth organism. Note the flagella. (*Motile spirillum*) And here is an actively motile spirillum of a different type.

THE MOUTH SPIROCHETES: *TREPONEMA VINCENTI* AND *TREPONEMA BUCCALE*

(*On dark field*) (150) These large loosely wound spirochetes of mucous membranes are easily distinguished from the smaller tightly wound forms, particularly when they are in active motion. Notice how these organisms (*spurts*) move forward in spurts, spinning rapidly and stretching their spirals almost taut as they spin, then stopping momentarily, relaxing, and reforming their spirals. This is a characteristic picture.

(*Wait 2 seconds*) (140) The names *Treponema vincenti* and *Treponema buccale* are applied to long loosely wound spirochetes which differ only in thickness. *Treponema vincenti* is the thin form, which appears as a single white line, or, as we say, is single contoured. *Treponema buccale* is thick enough so that light reflected off its opposite surfaces is resolved separately. It, therefore, appears as two white lines separated by a dark line; in other words, it shows double contours. Both spirochetes appear in these preparations, along with smaller spirochetes and various bacteria.

(150) These microorganisms can be demonstrated in small numbers in almost any mouth in which teeth are present, in material taken from the gingival crevice. They are not easy to find on really clean and healthy tissues, and never occur on such tissues profusely. Large quantities are indicative of a pathologic process.

(*On heavy field*) (150) Enormous numbers, like these, may, nevertheless, be found in a wide variety of pathologic conditions, and the number is not an index of severity. The condition may vary from a mild, localized inflammatory or ulcerative process all the way to fatal fusospirochetal gangrene, without any significant difference in the dark-field picture.

(*Double contoured form*) Note the double contours on the spirochete moving vertically. This is *Treponema buccale*.

(*Wait 5 seconds*) (150) Spirochetes found normally or in fusospirochetal lesions, in the anogenital region, have been given distinctive names, although they closely resemble the mouth spirochetes. For example, a genital spirochete called *Treponema refringens* looks like the large spirochetes of the mouth. It is important to distinguish these organisms from the spirochete of syphilis. This is

not hard to do if you remember that these larger nonspecific spirochetes are more loosely wound than the syphilis organism; these spirochetes rotate more actively and move forward much more rapidly when they move. Their spirals are more elastic, being lost and reformed during active rotation. It is worth remembering that *any* spirochete that shows double contours is *not* the spirochete of syphilis. This subject will be discussed more fully later.

(Wait 5 seconds) (150) Another differential feature of these large spirochetes is that they stain fairly well with aniline dyes, whereas the more tightly wound spirochetes, like *Treponema microdentium* and *Treponema pallidum*, do not. The large forms may, therefore, be prominent in stained films; the smaller spirochetes are best seen under dark field, although they can be stained by the Giemsa method or by silver impregnation. Films stained with aniline dyes often are used for the diagnosis of fusospirochetal infections, such as Vincent's angina, the diagnosis being based on the occurrence of these large loosely wound spirochetes and of large granular fusiform bacilli. This procedure may be useful in differential diagnosis, for example, in distinguishing between Vincent's angina and diphtheria; however, its positive value is doubtful because these organisms can be found in large numbers in conditions clinically distinct from Vincent's infection. In lung abscesses and other internal fusospirochetal infections, moreover, these larger organisms may be absent even though smaller spirochetes, small fusiform bacilli, and other bacteria can be demonstrated under the dark field. (End of reel 1; elapsed time 19 minutes)

TREPONEMA MICRODENTUM AND OTHER SMALL MOUTH SPIROCHETES

(On dark field) (150) These tightly wound spirochetes of the mouth and other mucous membranes, commonly found along with the larger ones, are interesting for two general reasons. First, the small spirochete called *Treponema microdentium* is morphologically similar to *Treponema pallidum*, so that differentiation of the two forms is important in the microscopic diagnosis of syphilis. Second, the small spirochetes of the mouth seem to be essential members of the fusospirochetal flora, perhaps the most important of the group of microorganisms which appear to be responsible for Vincent's infection. We will consider both points in greater detail as we proceed.

MOUTH SPIROCHETES IN EXUDATE FROM INFECTED GUINEA PIGS

(On guinea pig) (150) Material containing the fusospirochetal flora, for instance, the exudate from Vincent's infection, pyorrhea or a lung abscess, when inoculated subcutaneously into the groin of a guinea pig, produces transmissible lesions which may take the form of a large necrotic abscess like this (120) or appear as a fatal diffuse gangrene of the subcutaneous tissues. In either case an abundant exudate, foul and usually fluid, can be aspirated from the lesion with a syringe, as shown here. (Wait 5 seconds) This abscess easily yielded about 5 c.c. of pus; some lesions contain 50 c.c. or even more. (Wait 3 seconds) The pus is frequently greenish, but may be cream colored. (Wait 3 seconds) In this instance it was bloody and dark in color. (On tube) It always has the foul odor characteristic of all fusospirochetal infections.

(On dark field) (120) Examined microscopically, the exudate from a guinea pig lesion usually shows fewer of the large spirochetes, particularly after several passages through guinea pigs. *Treponema microdentium* and other small spirochetes predominate, accompanied by bacteria of fewer varieties than are seen in the original human lesion material. Guinea pig passage eventually eliminates aerobic and gas-forming bacteria and many nonpathogenic anaerobes. The more limited flora that persists seems to represent the more pathogenic types: the smaller spirochetes, smaller nonmotile fusiform bacilli, and gram-negative rods of the *Bacteroides* group, as well as vibrios, streptococci, and other cocci. The whole flora in a stabilized guinea pig strain is anaerobic so that although the exudate contains myriads of living microorganisms, aerobic cultures made from it remain sterile.

(*Pallidum-like spirochete appears*) (150) Here is a form of *Treponema microdentium* which closely resembles *Treponema pallidum*. The two can be distinguished by their motility with some difficulty, as we shall see. When these spirochetes are not actively motile, as in this instance, the distinction becomes extremely difficult, if not impossible.

TREPONEMA MICRODENTIUM AND OTHER SMALL SPIROCHETES FROM CULTURES

(On plate) (150) *Treponema microdentium* and the other small spirochetes of the mouth can be cultivated without great difficulty. Here we see a culture of spirochetes in a small Petri plate being sampled with a capillary pipette by removing a portion of the medium containing spirochetes to a cover slip. The spirochetes grow in the depths of the medium, which is a solid nutrient agar containing ascitic fluid or serum ultrafiltrate and minced fresh sterile tissue, inoculated by a special technique and incubated in an anaerobic jar.

(On dark field) (120) *Treponema microdentium* is a small spirochete with regular closely wound coils. Some of the spirochetes seen here are small loosely wound forms, probably distinct from *Treponema microdentium* but as yet of uncertain nature. (Wait 2 seconds) The motility of *Treponema microdentium* is characterized by rapid rotation, often with active movements of translation. When movements of flexion are present, they frequently appear jerky or awkward, thus suggesting that the organism is relatively stiff.

(Wait 5 seconds) (120) These are the spirochetes which appear to be the contributing pathogens in fusospirochetal infections. They predominate in experimental lesions in guinea pigs and in internal fusospirochetal processes in man. Moreover, it has been reported that typical and transmissible fusospirochetal lesions could be produced in guinea pigs with combinations of pure cultures of four species: *Treponema microdentium*, a small fusiform bacillus, a vibrio, and a streptococcus, all anaerobes. Typical lesions could not be produced with any other or any lesser combination of species.

TREPONEMA PALLIDUM FROM THE TISSUES OF INFECTED RABBITS

(On rabbit) (160) The testicle of this rabbit, which is infected with *Treponema pallidum*, shows a large chancre. The chancre in rabbits, as in man, is an indurated swelling with surface ulceration that becomes encrusted. Material taken from the indurated tissue under the crust by aspiration with a capillary shows the characteristic spirochetes.

(On dark field) (120) *Treponema pallidum*, sometimes called *Spirochaeta pallida*, varies considerably in length, as do all spirochetes. Otherwise this organism is uniform in morphology, whether taken from the rabbit or from human lesions. Its coils are closely and regularly wound, often a little deeper than those of *Treponema microdentium*. *Treponema pallidum* is delicate; it never shows double contours under dark field. When it is not motile it resembles *Treponema microdentium* so closely that it is difficult, if not impossible, to tell them apart; but the two can be distinguished on the basis of motility. (Wait 2 seconds) *Treponema microdentium*, as we have seen, shows rapid rotation, frequently with active progressive movements. Its movements of flexion, when present at all, are rather awkward and give an impression of stiffness. (Wait 2 seconds) *Treponema pallidum* shows slower, more deliberate movements of rotation. Progressive movement is usually absent. The organism does not dart rapidly across the field. If it moves at all, it usually moves rather slowly and not far. (Wait 2 seconds) The spirochete of syphilis is characterized especially by its flexibility. It appears soft and its movements are, on the whole, graceful. It often looks like a streamer floating gently in the breeze. It has a certain dignity and elegance, befitting the aristocrat of spirochetes. *Treponema microdentium*, on the other hand, is the upstart, nervous and awkward in its movements. *Treponema pallidum* often exhibits a shimmering effect because of the combination of rather slow rotation with soft bending movements.

(Wait 3 seconds) (120) A demonstration of *Treponema pallidum* under the dark field is essential for the diagnosis of primary syphilis, and is also useful for rapid diagnosis in the secondary stage. In either instance, and particularly when the lesion is on or near a mucous membrane, contamination with nonspecific spirochetes should be avoided by expressing or aspirating fluid for dark-field examination from the depths of the lesion after carefully cleaning the surface. When the occurrence of *Treponema microdentium* or similar nonspecific organisms cannot be avoided and positive differentiation cannot be made, it is best to aspirate from a lymph node draining the area of the lesion.

(Sperm appears. Wait 5 seconds) (150) *Treponema pallidum* was not discovered until 1905, when Schaudinn and Hoffmann described it, along with *Treponema refringens*, in preparations made from syphilitic lesions. *Treponema pallidum* cannot be identified by ordinary methods. It cannot be cultivated by any of the methods used to grow bacteria; it does not stain with aniline dyes; and it is so delicate that it can hardly be seen at all in unstained preparations by direct illumination. Schaudinn and Hoffmann, nevertheless, discovered it without the use of dark-field illumination in fresh and in Giemsa-stained preparations.

(Wait 5 seconds) (150) The in vitro cultivation of virulent *Treponema pallidum* remains an unsolved problem. Noguchi and a few others have reported the cultivation of virulent spirochetes; other workers have either failed completely to grow them, or have obtained only avirulent spirochetes in culture which may not have been true pallidum at the beginning. Virulent *Treponema pallidum* is best grown and maintained for study in living tissues, commonly in the testicles of rabbits. In the rabbit testicle it produces a syphiloma or in-

durated swelling which may or may not ulcerate and form a chancre. This lesion usually appears in about three weeks, which is also the average incubation period of the chancre in man. The passage from rabbit to rabbit can be made in indefinite series. This is the Nichols strain of pallidum. It has been passed from rabbit to rabbit for about thirty years. In 1925 it was found pathogenic for man after accidental inoculation.

(Wait 5 seconds) (150) Experimental syphilis has been produced in chimpanzees and in some species of monkeys, as well as in rabbits. In the famous experiments of Metchnikoff and Roux on chimpanzees in 1903, two years before the discovery of the organism, all of twenty-two apes inoculated with human lesion material developed chancres and lymphadenitis, and some had secondary lesions. Most of the animals died of bronchopneumonia and no tertiary lesions developed. (135) Lower monkeys show only primary lesions. Rabbits are easier to infect than apes, and are the animals of choice for in vivo culture and for study of the experimental disease. In addition to the primary lesion they may develop generalized syphilis, with lesions that resemble both secondary and tertiary phenomena in man.

(Wait 5 seconds) (135) Mice, rats, and guinea pigs also can be infected with *Treponema pallidum*, but they usually show no lesions and spirochetes may not be demonstrable in their tissues. Their lymph nodes, spleen, and brain may, nevertheless, remain capable of infecting rabbits.

(On active movement) (120) The spirochetes shown in these preparations are as active as *Treponema pallidum* is ever likely to be. Notice that some of them show progressive movements, but that they move more slowly than *Treponema microdentium*, and much more slowly than the larger loosely wound spirochetes.

TREPONEMA PALLIDUM FROM LESIONS IN MAN

(On dark field) (120) These preparations were made from penile chancres. (Wait 2 seconds) Primary lesions in man often yield no more than one or two spirochetes per microscopic field; in fact, it may be necessary to search for the organisms and to make a diagnosis on seeing only one or two typical spirochetes. (Wait 2 seconds) Secondary lesions of the skin also show few spirochetes, as a rule, whereas secondary lesions on or near mucous membranes, mucous patches or condylomas, may show large numbers of pallidum. Skin lesions may, nevertheless, be more suitable for microscopic diagnosis, particularly by the inexperienced worker, because they are much less likely to be contaminated with nonspecific spirochetes. In any case, the surface of the lesion first should be cleaned carefully and fluid for microscopic examination expressed from the depths of the lesion.

(Wait 5 seconds) With a well-adjusted dark field, look carefully for double contours or for active progressive movements. Spirochetes showing either of these are not *Treponema pallidum*.

(Wait 2 seconds) (100) The spirochete of syphilis, as shown here, and this is worth repeating, is delicate, single contoured, and regularly wound with rather deep coils. It is flexible and graceful in its movements, rotates but does not spin rapidly, seldom moves from place to place, and if it does so generally moves rather slowly and not far.

Fig. 2.—All figures are enlargements directly from 16 mm. negative frames. Magnification as reproduced is about 1,100 diameters. 1, *T. recurrentis* (novyi strain) in rat blood; 2 and 3, *T. buccale* and other microorganisms in gingival scrapings; 4, A mouth spirillum (*Sp. sputigenum*!) in gingival scrapings, showing flagella; 5, *T. microdentium*, probably mixed with other small mouth spirochetes, from a culture; 6, *T. pallidum*, from a penile chancre in man; 7 and 8, *T. pallidum* (Nichols strain) from rabbit testicular syphilomas; 9, 10, and 11, *Spirillum minus* in mouse blood and peritoneal washings; 12, *L. canicola* (strain D95) from a culture.

(Wait 5 seconds) (130) While different strains of pallidum are known to vary somewhat in thickness, even under uniform conditions, the organism sometimes appears exceptionally delicate, apparently through an artifact. This may happen if the exudate is kept for some time before microscopic examination, or if only a small amount of exudate is obtained and the film is exceptionally thin (*thin form appears*), particularly if it is made without a vaseline seal. The spirochetes may then look so delicate as to be barely visible, even with the best dark-field equipment. Here you see a preparation of this kind.

TREPONEMA CUNICULI FROM AN INFECTED RABBIT

(On dark field) (120) *Treponema cuniculi*, which is shown here, is the causative agent of a naturally occurring venereal disease of rabbits, sometimes called rabbit syphilis, but not to be confused with experimental syphilis produced in rabbits by the inoculation of *Treponema pallidum*. *Treponema cuniculi* and another tissue spirochete, *Treponema pertenuis*, the causative agent of yaws in man, are both morphologically indistinguishable from the spirochete of human syphilis. Like pallidum, they cannot be cultivated successfully and hence much remains to be learned about their biologic characteristics.

(Wait 3 seconds) (120) Yaws is a nonvenereal disease of man in tropical areas and occurs chiefly in children, with lesions confined mainly to the skin. The lesions of rabbit syphilis usually occur on the skin in the anogenital region, and are much smaller and softer than lesions of true syphilis. The syphilis and yaws spirochetes are immunologically related, but *Treponema cuniculi* is distinct. (End of reel 2; elapsed time 37 minutes, 30 seconds.)

LEPTOSPIRA BIFLEXA FROM A CULTURE

(On dark field) (130) This is *Leptospira biflexa*, a nonpathogenic spirochete found in water that contains decomposing organic matter. The several species of *Leptospiras* do not differ in morphology among themselves, but they are easily distinguished from the other spirochetes. They are much more closely wound than any of the treponemas, so that the individual spirals do not always show clearly; and they have the characteristic hook at one or both ends. Their movements are erratic and mercurial, they are the clowns among spirochetes. They rotate rapidly and often dart forward or to and fro; they may show quick lashing movements of flexion, or they may bend into crazy contorted figures.

LEPTOSPIRA ICTEROHAEMORRHAGIAE FROM A CULTURE

(On dark field) (120) *Leptospira icterohaemorrhagiae* is the spirochete of Weil's disease or spirochetel jaundice in man. The disease occurs throughout the world and has been reported in several parts of the United States. The organism was first isolated by Inada and Ido in 1915, and independently by Uhlenhuth and Fromme in the same year.

(Wait 5 seconds) (120) Weil's disease, in its more severe form, has a sudden onset with fever which may reach 105° F., and symptoms of acute intoxication. Jaundice may appear after about a week. The mortality may be as high as 50 per cent; but milder cases also occur, more chronic in character, often without jaundice.

(Wait 5 seconds) (120) Whereas all the treponemas appear to be more or less strictly anaerobic and can be cultivated with difficulty, if at all, the leptospiras are aerobic and grow readily in suitable media. They grow at room temperature in the upper centimeter or so of a column of serum or other organic fluid diluted with salt solution and containing a small amount of agar. Actively motile leptospiras like these are easily demonstrated in a loopful of culture removed from the upper portion of the medium and examined under dark field. Like the smaller treponemas, the leptospiras do not stain well with aniline dyes.

(Wait 4 seconds) (120) A characteristic feature of culture leptospiras in active motion is that they rotate so rapidly that their hooked ends look like closed eyelets, as shown by some of these organisms.

LEPTOSPIRA ICTERHAEMORRHAGIAE FROM THE LIVER OF AN INFECTED GUINEA PIG

(On dark field) (150) Guinea pigs are exceptionally susceptible to Weil's disease; they usually die about seven to nine days after subcutaneous or intraperitoneal inoculation, and show intense jaundice of the skin and conjunctiva, with leptospiras demonstrable especially in the liver, kidneys, and adrenals.

(Wait 2 seconds) (150) In the diagnosis of Weil's disease a dark-field examination should be made of the blood early in the disease, or of the urine in the later stages, and 2 or 3 c.c. of blood or urine should be inoculated intraperitoneally into guinea pigs. At autopsy, or on about the ninth day after inoculation, dark-field examination of a suspension of the liver should show this picture. Young white mice may be used for inoculation, but older mice are resistant. Species of deer mice have also been used successfully.

(Wait 2 seconds) (150) As we shall see later, certain filaments which appear normally under dark field in blood or tissue suspensions may be mistaken for leptospiras. A true leptospira should show the characteristic hooked ends and at least some degree of rotary motion. These two characteristics justify a diagnosis of leptospira infection even though only a few organisms are found. The movements of flexion are unreliable, as is the apparent demonstration of spirals, since the filament artifacts bend in Brownian movement and may show irregularities that can be mistaken for spirals.

(Wait 2 seconds) (150) The leptospiras are sometimes called the water spirochetes, not only because *Leptospira biflexa* is found in water, but also because contaminated water is directly concerned in the transmission of Weil's disease. The infection has been common in Japan in wet mines in which the miners worked barefoot; elsewhere it has been associated with marshy or muddy soil, or with unsanitary bathing places; and cases have been reported both in Europe and in this country among sewer workers, fish handlers, and others who come into contact with wild rats or rat-infested water. Wild rats are frequently found infected with this organism and excrete leptospiras in their urine. Rats evidently serve as reservoirs of infection and disseminate it by the contamination of water. Transmission to man seems to occur mainly through the skin, the leptospiras being able to penetrate slight abrasions if not the intact skin itself.

TABLE I
DIFFERENTIAL DATA ON PARASITIC SPIROCHETES AND *Spirillum minus*

NAME OF ORGANISM	GENERAL CHARACTERISTICS	COILS*			TYPICAL ACTIVE MOTILITY			HABITAT OR SOURCE	ANIMALS USEFUL IN DIAGNOSIS, ETC.	NAME OF ORGANISM
		NUMBER	PITCH μ	OVER-ALL WIDTH μ	ROTATION	FLEXION	TRANSLATION			
<i>T. recurrentis</i> type	Intermediate in length, thickness, and winding; usually single contoured; may be double under critical illumination	6-10	2.5	1.5	Moderately active	Moderate	Moderately active; may be absent	Blood in relapsing fever during onset of paroxysm; rosette clumps during decline	Mice or rats; blood in <i>frappe</i> tonically; spirochetes in animal blood in 24 to 48 hours (stain with aniline dyes)	<i>T. recurrentis</i> type
<i>T. vincenti</i> type (<i>T. refringens</i>) <i>T. buccale</i> type	Long, thin; loose shallow coils; single contoured Long, thick; loose shallow coils; double contoured	3-6	4 or more	1-3†	Very active; spinning, with heart loss of coils during progression, reformation on stopping	Not marked in fully active form	Very active, intermittent spurts in one direction or reversing	Mouth, between gums and teeth; tonsillar crypts; anogenital mucocutaneous areas; fusospirochetal surface lesions	(Stain with aniline dyes)	<i>T. vincenti</i> type (<i>T. refringens</i>) <i>T. buccale</i> type
<i>T. microdentium</i> type	Short, thin; tight shallow coils; single contoured	6-12	1.2	1 or less	Very active; coils untorted	May be active, jerky, stiff, or absent	Active, darting; may reverse repeatedly	As above; also in internal fusospirochetal lesions (e.g., lung abscess)	Guinea pigs; exudate subcutaneous in groin; spirochetes in pus aspirated after 4 to 10 days	<i>T. microdentium</i> type

<i>T. pallidum</i> type	Medium length, thin to very thin, tight deep coils; always single contoured	8-12	1.2	about 1	Rather slow, deliberate	Active, soft, graceful	Usually ab- sent; never darting	Lesions of primary and secondary syphilis; <i>T. per-</i> <i>tenuis</i> ; skin le- sions of yaws; <i>T.</i> <i>cuniculi</i> ; anogeni- tal lesions of rab- bit syphilis)	Rabbits (not for <i>T. pallidum</i> type)
<i>Leptospiras</i> (all species)	Short to long; thin, single con- toured; very tightly wound; one or both ends hooked (easily cultivated, mor- bide)	15 or more	about 0.6	about 0.5	Very active, spinning; hooks look like eyelets	Marked, with erratic dash- ing move- ments	Active; may be absent	<i>L. biflexa</i> ; stag- nant water; <i>L. ic- terohaemorrhagiae</i> ; wild rats and rat-infested water; blood (early), urine (late) in Weil's disease; <i>L. can- icola</i> ; dogs	Guinea pigs; blood or urine intraperi- toneally; spiro- chetes in liver, kidneys, adrenals in about 9 days (also cultivation, serologic tests)
<i>Spirillum</i> <i>minus</i>	Short, thick, but barely double contoured; coils appear closely set under dark field; bipolar flagella	2-5	1 or more	about 1	?	Slight or ab- sent	Typical very rapid, dart- ing	Mice intraperi- toneally (but spon- taneous infec- tion); guinea pigs; blood, ex- udate or excised tissue intraperi- toneally or suben- taneously; spirilla in blood or peri- toneal washings in 5 to 10 days	<i>Spirillum</i> <i>minus</i>

*These approximate measurements are based on the film. "Pitch" equals the distance between two coils as measured from crest to crest on one side. Length measurements are omitted because with variation makes them of little differential value. The shortest *T. microdentatum* may be 44, the longest *T. Vincenti* about 26 μ , but some specimens of *T. microdentatum* are longer than some *T. Vincenti*. Descriptions of motility apply to typical, fully active forms; all species lose motility more or less gradually in slide cover slip preparations; dying forms may show erratic movements.

†Over-all width decreases during active rotation and progression because of stretching of spirals.

(Wait 2 seconds) (150) Weil's disease, unlike other spirochetal infections, confers lasting immunity. Agglutinins and lysins develop during the disease and persist for many years after recovery.

(Wait 2 seconds) (150) Noguchi, who made many outstanding contributions to our knowledge of spirochetes, particularly in the difficult problem of their cultivation, reported in 1919 that yellow fever is caused by a leptospira. The evidence for this view was gathered with Noguchi's usual thoroughness and it was widely accepted until 1928, when Stokes, Bauer, and Hudson showed that yellow fever is caused by a filtrable virus. Noguchi had apparently worked in 1919 with cases of Weil's disease mistakenly diagnosed as yellow fever. He later went to Africa to check his own findings. This time he worked with yellow fever and did not find leptospiras. While there Noguchi contracted yellow fever and died.

LEPTOSPIRA CANICOLA FROM A CULTURE

(On dark field) (160) *Leptospira canicola*, the leptospira of dogs, is morphologically identical with the other leptospiras. It can be distinguished serologically. It is less pathogenic for guinea pigs, but may infect both dogs and man. The prevalence of canicola infection in dogs is suggested by the finding of Meyer and his co-workers that agglutinins to *Leptospira canicola* occurred in a high percentage of normal dogs in urban areas of California. The *canicola* infection in man, contracted from dogs, is milder than Weil's disease, and may be so mild as to escape detection. Jaundice is usually absent; meningeal symptoms may be present. Leptospiras may be found in the spinal fluid or blood, later in the urine. By the seventh to the tenth day of illness or later, a diagnosis can be made by the agglutination of culture *Leptospira canicola* with the patient's serum.

SPIROCHETE-LIKE FILAMENTS: ARTIFACTS WHICH MAY BE MISTAKEN FOR LEPTOSPIRAS

(On dark field) (120) These filaments, seen here as delicate waving threads, sometimes attached to cells and sometimes free, are of no importance in themselves. They are not microorganisms. They are shown because they may resemble microorganisms, especially leptospiras, and thus give rise to errors in diagnosis. Although they are often homogeneous, they may show irregular swellings, clubbed ends, or beading. Occasionally they have a regular beaded structure, as shown here, which may give a false impression of spirals. Filaments occur frequently in dark-field preparations made from blood or tissue emulsions, particularly but not only when a hot loop has been used in preparing the slide. They may be extremely delicate and pale, or coarser and brighter, and vary from short rods to long waving threads. They have no independent motility, do not rotate or move progressively; but they may wave and bend actively in Brownian movement. The two features that best distinguish them from leptospiras are the absence of hooked ends and the lack of rotary movement. (Elapsed time 48 minutes, 25 seconds)

SPIRILLUM MINUS FROM THE BLOOD OF AN INFECTED MOUSE

(On dark field) (140) This organism, seen lying still among red blood cells, is a spirillum, not a spirochete. The difference, as we have seen, is that a

spirillum is a curved or spiral organism motile by means of flagella, while a spirochete moves, as far as we know, by means of the undulations of the body of the organism itself. Flagella have never been demonstrated on true spirochetes. They appear on these organisms, and you will see a tuft at each end in later sequences if you watch for them.

Spirillum minus appears under dark field as a short thick rodlike form, just barely double contoured, with rather closely set stiff spirals which are not always clearly visible.

(Wait 5 seconds) (110) This organism is generally regarded as the cause of rat-bite fever or Sodoku. Since its cultivation has not been successful, it has not been possible to fulfill Koch's postulates for *Spirillum minus* as the etiologic agent of rat-bite fever; however, inoculation experiments with unpurified animal blood or exudate have been successful in animals and in man. The relationship of this organism to rat-bite fever has been challenged in favor of a distinct bacterium called *Streptobacillus moniliformis*, which may also occur in the human lesions and in infected rats and mice, and which can be cultivated independently.

(Wait for flagellated form) Flagella can be seen on this organism and in several of these sequences. (Wait for another flagellated form) Note the tuft of flagella at each end (and another), and here again.

SPIRILLUM MINUS IN PERITONEAL WASHINGS FROM AN INFECTED MOUSE

(On dark field) (120) When *Spirillum minus* moves, it darts rapidly across the field. You will see these darting movements in a little while.

(Wait 5 seconds) (130) Whether or not this organism is the cause of rat-bite fever, diagnosis can be made if it can be demonstrated under the dark field in exudate expressed from the bite wound or from the skin papules which accompany the paroxysms of fever. The bite wound usually heals during the incubation period, and later ulcerates and looks like an extragenital chancre. The demonstration of spirilla in the blood or peritoneal fluid of mice or rats after inoculation with the patient's blood is less reliable for diagnosis, since these animals may harbor the organism normally without showing symptoms. The subcutaneous inoculation of guinea pigs is probably a better procedure. Numerous instances of clinically typical rat-bite fever fail to yield spirilla. *Streptobacillus moniliformis* has been isolated from some of these. It seems likely that the streptobacillus is responsible for some cases, at least, of rat-bite fever. Recent findings suggest that there may be two types of the disease, clinically similar, although perhaps not identical, but caused by distinct organisms. (Elapsed time 52 minutes, 25 seconds)

(On apparatus) (120) The apparatus includes a rigid stand supporting the camera independently of the microscope, the two being joined without contact by a light-tight coupling. A prism side ocular permits visual examination of the field being photographed. In order to allow one-man operation, a solenoid mounted beside the camera release is actuated by a foot switch, as shown here.

Pure strains of spirochetes were provided through the courtesy of:

A SIMPLIFIED APPARATUS FOR DARK-FIELD CINEMICROGRAPHY*

FRED ROSEBURY AND THEODOR ROSEBURY
NEW YORK, N. Y.

THE apparatus described is that used for the preparation of the 16 mm. film "A Lecture on the Spirochetes."¹ Except for the microscope and camera, it comprises few and inexpensive items. It is designed to be operated by one person, and is arranged so that with a minimum of inconvenience records on motion-picture film may be made of specimens observed during routine visual microscopy. The apparatus is adaptable to bright-field, histologic or other microscopy, as well as to dark-field microscopy with the oil-immersion objective, although it was designed primarily for the purpose last mentioned.

The optical system used comprises a Leitz AT microscope with the fluorite oil-immersion objective, 1.95 mm., N.A. 1.32, fitted with an iris diaphragm, and the Leitz bicentric dark-field condenser, N.A. 1.20. The focusing prism side ocular (Fig. 1 A) is similar to that supplied as the optical portion of a Leitz Makam camera, the camera box and ground glass having been removed, and the lower element of a 10× ocular, convex surface upward, having been fastened immediately above the prism in the optical axis to shorten the focal length of the system. A celluloid shield, blackened and lined at the outer edge with black felt fitted to the eye, is attached to the end of the lateral member of the side ocular so that when the operator's eye is pressed against it extraneous light is excluded. No camera lens is used. The camera, which is supported independently of the microscope, as will be noted below, is joined to the optical system without contact by means of a light-tight brass baffle coupling (Fig. 2H), threaded to fit into the camera in place of a lens. The inner surface of the brass coupling must be dead black. A cylinder projecting upward from the top of the side ocular unit (Fig. 2J) fits into the coupling without contact, so as to make the light-tight baffle connection between the microscope and camera.

The whole assembly is fastened to a large heavy draftsman's board, which in turn stands on four No. 7 live rubber stoppers to absorb vibration (Fig. 3). The microscope is mounted on a steel plate which is bolted to the board and cushioned with live rubber washers $\frac{1}{4}$ inch thick. The holes in the plate through which the bolts pass are large enough so that the bolts do not touch the steel plate itself, but are held by rubber washers above and below the plate. The plate is fitted with three steel pegs which mate accurately in shallow holes in the base of the microscope.

The stand upon which the camera is mounted consists of a heavy cast iron base, a tubular steel post (Fig. 1B), and an adjustable bracket with ball crank (C), which are available as parts of a standard drill press. Firmly attached to the bracket is a carriage (D) bearing a tripod screw and its bushing, and with side guides made to support the camera with a snug fit. At the outer end of

*From the Departments of Biochemistry and Bacteriology, College of Physicians and Surgeons, and the School of Dental and Oral Surgery, Columbia University, New York City.
Received for publication, April 14, 1942.

Fig. 1.—A, Prism side ocular; B, post supporting camera; C, adjustable bracket; D, camera carriage; E, electric solenoid camera release; F, collar; G, pin; F and G serve respectively as vertical and horizontal stops for the bracket and camera carriage.

Fig. 2.—Detail of light-tight baffle joint between the camera and the prism side ocular, with the brass coupling (H) shown raised out of position above the cylinder (J).

the carriage is mounted an electric solenoid (*E*), the magnetic plunger of which is normally retained in a position on the outer side of the coil by means of an adjustable spring. When current is applied by means of a foot switch the plunger presses the release button of the camera. The end of the plunger carries a rubber bumper.

Fig. 3.—Photograph of the entire assembly.

A collar (Fig. 1*F*) is fastened to the post with a setscrew to serve as a vertical stop for the camera assembly and its bracket on the post. Horizontal locating is determined by means of a spring pin (*G*) in the collar, which fits accurately into a hole in the adjustable bracket. The spring pin is released by drawing down the chain attached to it. By this means the camera assembly can be lowered quickly into its proper position over the microscope and prism side ocular.

Two light sources are used, one for visual microscopy by bright or dark field and for bright-field photomicrography, the other for dark-field photomicrography. The former is a 6 volt automobile headlight lamp in a parabolic mirror reflector, operated on 110 volts A. C. through a variable voltage transformer (Bausch & Lomb). The stronger light source is a clockwork are adapted to take National Projector carbons Nos. 698 or 722, ($\frac{7}{16}$ ") and 168 ($\frac{5}{16}$ "). The arc is operated on 110 volts D.C. through four 660 watt cone heater elements connected in series parallel with a switch in each parallel branch so that the arc current, which is read on an ammeter, may be conveniently adjusted in four steps. The resistances, switches, and ammeter are mounted on a transite and metal stand.

Both lamps are fastened in position on the draftsman's board so that their rays, condensed and cooled in each instance through a 250 c.c. flask of water,

are focused on the mirror of the microscope when the latter is in position on its steel plate. This provides a convenient arrangement for visual microscopy with the 6 volt lamp. When a specimen is seen which it is desired to photograph, the split prism with its ocular is substituted for the visual ocular of the microscope. The camera, with coupling attached, is swung and lowered into position with the aid of the collar and pin on the post and clamped tight, and the arc is turned on. With these operations, which require less than one minute, the apparatus is converted from a visual to a cinemicrographic assembly.

Fig. 4.—Focusing calibrator. *K*, Turned collar fitting into cylinder *J* in Fig. 2; *L*, cover slip ruled to 16 mm. frame size and placed in the focal plane.

The calibration of focus for the visual arm of the split prism ocular and the film was accomplished by means of the device shown in Fig. 4. A fiber cylinder 2 inches high was fitted with a turned wood collar (*K*) so as to set snugly into the baffle cylinder (Fig. 2*J*) of the split prism ocular. A clear circular cover slip (Fig. 4*L*) was then ruled with hydrofluoric acid to approximate a 16 mm. frame, and fastened in position in the cylinder at the level which would be occupied by the film when the camera was in place, as determined by measurement. A focusing magnifier could then be set into the cylinder from above so as to focus on the ruled cover slip. With this device the focus at the film plane could be matched with that in the visual arm of the split prism by varying the length of the latter. This calibration was checked by exposing and developing short lengths of film.

The film "A Lecture on the Spirochetes" was made chiefly on Agfa Superpan Supreme negative, which provided sufficient speed with maximum amperage of the arc (15 to 20 amperes). Photographs of specimens containing large numbers of cells, e.g., red blood cells, were in fact overexposed, although printable; and several sequences were made successfully with a slower film, DuPont 314 Pan. The film was developed, using Stineman tanks, in Agfa 17M at 18 C. for sixteen minutes with continuous agitation ($\gamma = 0.9$). Under these conditions no objectionable grain appeared. Resolution on the negative seems remarkably good at the low magnification used (160 diameters), and, although slightly impaired in printing, it is considered satisfactory in the finished film.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

DIPHTHERIA, Studies on the Antibacterial Property in, Huang, C. H. *Am. J. Hyg.* 35: 317, 1942.

Evidence pointing to the presence of antibacterial property in the diphtheria antitoxic serum is presented, based on the finding of the rapid disappearance of type D₂ organisms in the throats of patients during the first two weeks after treatment with antitoxic serum as compared with the slow disappearance of the organisms in the throats of patients infected by the other S types. Type D₂ organism is serologically the same as Park S strain which is universally used for the preparation of diphtheria antitoxin.

Specific agglutinins were found in the blood of diphtheria patients during the convalescent stage. In the acute stage such agglutinins were not found. A negative agglutination test with the blood of a diphtheria patient at the early stage of the disease and the appearance of specific agglutinins in the convalescent stage may, therefore, serve as a diagnostic method.

TARRY STOOL: Observations on the Oral Administration of Citrated Blood in Man. II. The Effect on the Stools. Schiff, L., Stevens, B. J., Shapiro, N., and Goodman, S. *Am. J. M. Sc.* 203: 409, 1942.

A tarry stool may result from the ingestion of 100 c.c. or more of citrated human blood. Following the intragastric administration of 1,000 to 2,000 c.c. of citrated human blood, gross blood may appear in the stools, and tarry stools may continue for five days and may number as many as 8. Positive chemical tests for occult blood in the stools may persist for as long as ten days after ingestion of 250 c.c. of citrated human blood or for twelve days after intragastric administration of 2,000 c.c.

The passage of a tarry stool does not necessarily indicate the occurrence of a severe hemorrhage into the digestive tract. The persistence of tarry stools or occult blood in the stools does not necessarily indicate the continuation of such hemorrhage.

CULTURES, A Note on the Preservation of Certain Bacteria Under Paraffin Oil. Simons, R. T. *M. J. Australia* 1: 283, 1942.

Overnight slope cultures were completely covered with sterile liquid paraffin (heavy mineral oil; Parke, Davis Company) and stored in a dark cupboard at room temperature. The slopes should be moist, and they should be inoculated to the bottom of the slope so that some bacteria are suspended in the water of condensation which remains at the bottom of the slope under the paraffin. The paraffin was sterilized by dry heat at 160° C. in amounts of 15 milliliters heated for one hour, or in amounts of two liters heated for two hours. Autoclaving or the presence of moisture in the container caused turbidity. Paraffin from discarded cultures may be strained through gauze, sterilized and used again.

The top of the culture slope must be covered by the paraffin (preferably half an inch above) in order to prevent drying. A long, stiff, platinum loop was used to remove the growth from the bottom of the slope, where the organisms remained viable longer than at the top. After one year it was occasionally necessary to replace the paraffin with broth in order to obtain growth, but it was generally sufficient merely to transfer a loopful of organisms to broth.

PLASMA COAGULATION TIME, The Normal, Cheney, G. Am. J. M. Sc. 203: 325, 1942.

The plasma coagulation time is a satisfactory test for vitamin K deficiency, as previously noted.

The test has been carried out by a standardized technique in 340 normal persons and in 107 patients with nonhemorrhagic conditions.

The importance of a constant speed and time in centrifuging the blood has been emphasized.

The effect of changes in temperature upon the results of the test has been pointed out. Room temperature is satisfactory under ordinary conditions.

Standards have been set up for laboratory temperatures which may be encountered and for 37° C.

The constancy of the results obtained warrants the use of the plasma coagulation time as a simple laboratory test, provided the physical conditions of the procedure are adhered to closely.

The test of plasma coagulation time is routinely carried out as follows:

1. A clean venipuncture must be performed, obtaining the required amount of blood in a dry syringe.

2. The blood must be rapidly transferred to a test tube containing a weighed amount of dry potassium oxalate. A number of these tubes may be prepared at one time by adding 2 per cent potassium oxalate and evaporating the solution so that the tube will contain oxalate in the ratio of 10 mg. to 5 c.c. of blood. Centrifuge tubes are usually prepared with 5 mg. of oxalate for 2.5 c.c. of blood (0.25 c.c. of the 2 per cent solution per tube). The oxalate must be thoroughly mixed with the blood by inverting the corked tube ten or fifteen times.

3. The oxalated blood is centrifuged in a constant speed centrifuge at 3,500 r.p.m. for five minutes and the plasma is pipetted off.

4. Two-tenths cubic centimeter of plasma is pipetted into each of two small chemically clean test tubes, and 0.2 c.c. of 0.4 per cent calcium chloride is added to the first tube and 0.1 c.c. to the second. The tubes should be gently shaken five to ten times to secure thorough mixing. They need not be inverted.

A liter of the 0.4 per cent calcium solution may be made up at a time, using chemically pure calcium chloride.

5. The coagulation time of the plasma should be read in minutes. The end point is taken when the solution no longer flows when the test tube is held horizontal. The shortest time of coagulation for the two tubes is the plasma coagulation time.

6. The room temperature at which the test is carried out should be recorded. A variation between 23° and 26° causes no gross variation in the test.

7. The test should be completed within the first hour after the venipuncture.

CLOT RETRACTION TIME, A Method for Measuring, Hirschboeck, J. S., and Coffey, W. L. Arch. Path. 33: 380, 1942.

The equipment needed is a clean, dry syringe with needle and two dry test tubes, 1 cm. in diameter, one of which serves as a control. The tubes should be of soft glass and must be free of scratch marks. In addition they must be chemically clean. With the syringe and needle 4 c.c. of venous blood are removed, and 2 c.c. are placed in each of the test tubes. The tubes are closed with rubber stoppers, and the blood is shaken for a few seconds in order to create an equal amount of foam in each tube. The coagulation time is then determined by measuring the interval of time between the complete withdrawal of the blood from the vein into the syringe and the point at which the blood fails to flow when the tubes are completely inverted. The tubes are held in the same hand and are tilted every half minute in order to test for the end point. The end point of coagulation then becomes zero for the measurement of the retraction time. The tubes are placed in a rack kept at room temperature and are observed for the beginning of retraction.

The normal clot retraction time with this method is usually between twenty-five and thirty minutes. Some normal bloods may have a retraction time as short as twenty minutes; others, as long as forty-five minutes. The clot retraction time becomes shortened postoperatively, and if it is less than ten minutes, the patient may be considered a possible candidate for pulmonary embolism.

ANTITHROMBIN, Quantitative Studies on, Wilson, S. J. Arch. Int. Med. 69: 647, 1942.

A quantitative test has been devised for the determination of the antithrombin of serum and plasma. One unit of antithrombin is defined as that amount which will inactivate 1 unit of thrombin in four minutes at 28° C.

Normal human plasma or serum contains an average of 90 units of antithrombin per cubic centimeter, which is as much as a thousand times the amount revealed by many previous methods.

There is little or no difference in the antithrombic activity of serum and that of plasma.

During the actual process of blood coagulation only a small portion of the thrombin is adsorbed onto fibrin, the remainder being inactivated or neutralized by the normal antithrombic activity of the serum.

The hemorrhagic tendency in hypoprothrombinemia is not, therefore, fully explained on the basis of decreased prothrombin and the variations in the conversion rate of prothrombin to thrombin. The hemorrhagic diathesis usually occurs when the prothrombin unitage approximates or is lower than the antithrombin unitage.

The method follows:

The prothrombin-free fibrinogen was prepared by the method of Warner, Brinkhous, and Smith, all procedures being carried out at 5° C. and the materials stored at -35° C. The thrombin was prepared by the method of Seegers, Brinkhous, Smith, and Warner and standardized by either the pipette or the dropper method. The standardization tests should be repeated just before any critical observations are made.

The following method was devised to determine accurately fractions of 1 unit of thrombin: Fifteen drops of physiologic solution of sodium chloride were added to each of 9 test tubes. A series of 9 dilutions, containing 0.2 to 1.0 unit of thrombin in each drop, was then prepared, and portions of a single drop were added in sequence to the tubes of saline solution. To each test tube was then added 5 drops of fibrinogen (a total of 21 drops), and the appearance of the fibrin strands was timed with a stop watch. The following clotting times were observed:

Units of Thrombin	Clotting Time, Seconds
1.0	20
0.9	21.5
0.8	23.5
0.7	25.5
0.6	27.5
0.5	31
0.4	35.5
0.3	40.5
0.2	46.5

A curve to be used in the studies on quantitative antithrombic activity was then plotted. One unit of thrombin was used in the studies. If the figures for the thrombin are reversed, the curve will indicate the amount of thrombin inactivated or neutralized.

HEPATIC DEFICIENCY, The Value of the Hippuric Acid Test and Takata-Ara Reaction in the Investigation of, Henderson, M., and Splatt, B. M. J. Australia 1: 185, 1942.

A series of cases is reported of 313 hippuric acid excretion tests performed on 240 adult subjects.

The serum of 143 patients and of 50 normal subjects has been tested by the Takata-Ara reaction.

Quick's hippuric acid excretion test is both a reliable and a sensitive index of liver function, and is a valuable aid in estimating clinical progress, response to treatment, and prognosis.

It is simple to perform and is devoid of danger to the patient, but is not applicable to patients with poor renal function.

The Takata-Ara test is practically valueless as a test of liver function and is not a specific test for liver disease. It is, however, a useful confirmatory test for parenchymatous liver disease.

PREGNANCY, Colostrum Cutaneous Test for, Goldmann, L. M., Kessler, H. B., and Wilder, M. E. J. A. M. A. 119: 130, 1942.

In 500 tests of cutaneous sensitivity to colostrum there were tested approximately 70 per cent correct reactions in all groups, both male and female.

There was apparently no greater or less efficiency of the test among endocrine cases.

In our hands the colostrum cutaneous test does not appear to offer a valuable diagnostic procedure for pregnancy.

AMINO-ACID, Plasma Levels in Health and in Measles, Scarlet Fever and Pneumonia, Farr, L. E., McCarthy, W. C., and Francis, T., Jr. Am. J. M. Sc. 203: 668, 1942.

Thirty-one determinations of the plasma amino acid concentration of 30 normal, apparently healthy persons averaged 4.50 mg. per 100 c.c. by the ninhydrin- CO_2 method. The standard deviation was 0.46, and the observed range was 3.75 to 5.56 mg. per 100 c.c.

In patients with pneumococcus pneumonia the plasma amino acid nitrogen concentration was found to be low at the time of onset. With recovery from pneumonia the plasma amino acid concentration returned to the normal range. Patients admitted to the hospital after the fourth day of disease failed to show significant plasma hypo-amino-acidemia.

In patients with scarlet fever and measles the plasma amino acid nitrogen concentration was usually within the normal range. However, because of the difficulty of ascertaining the time of onset of these diseases, the data do not exclude the possibility of a plasma hypo-amino-acidemia during the pre-eruptive phase of these diseases.

PLASMA PROTHROMBIN Concentration, Clinico-Pathologic Correlation Between Hepatic Damage and, Sweet, N. J., Lucia, S. P., and Aggeler, P. M. Am. J. M. Sc. 203: 665, 1942.

The prothrombin concentration was determined in 42 patients in whom the liver was examined at operation or at autopsy. Vitamin K was administered in adequate dosage to all those patients who had suffered from extrahepatic biliary obstruction. In general, the prothrombin concentration was normal when there was little or no destruction of the parenchymal tissue, and it was diminished when there was moderate or marked destruction of tissue. Exceptions to this rule are noted.

TUBERCLE BACILLI, Rapid Method for Concentration of, Oliver, J., and Reusser, T. R. Am. Rev. Tuberc. 45: 450, 1942.

Five to 10 c.c. of sputum are mixed in a flask or widemouthed bottle, with approximately an equal amount of commercial chlorox, and shaken two or three times over a two-minute period and kept at room temperature for ten minutes. Then the mixture is centrifuged at 3,000 r.p.m. for ten minutes in a 15 c.c. conical tube. A creamy white sediment forms in the bottom of the test tube; the supernatant fluid is poured off and the tube is drained for two minutes. No neutralization is necessary. With an applicator a small drop of sediment is transferred to a slide. The slide dries at once and needs no fixing. Staining is done by the usual methods.

CLINICAL AND EXPERIMENTAL

PREVENTION OF PORPHYRIN INCRUSTATIONS ON PANTOTHENIC ACID-DEFICIENT RATS BY HARDERIAN GLAND ABLATION*

FRANK H. J. FIGGET, PH.D., AND KURT SALOMON, M.D., PH.D.
BALTIMORE, MD.

ONE of the most conspicuous symptoms observed in rats fed a diet deficient in pantothenic acid was the accumulation on the nose of an incrustated material that superficially resembled dried blood. This material appeared to emanate from the nostrils and was, therefore, observed most abundantly on the nose, whiskers, and fore paws, but it was sometimes spread to the fur of other parts of the body. The fur on the back of the neck region frequently appeared red or rusty. Because of the strong resemblance to dried blood and the apparent origin from the nose, this symptom had been described variously as "nosebleed,"^{7,8} "blood-caked whiskers,"¹¹ "rusty spots on fur,"^{9,12} and "inflamed noses."¹²

Several months before the initiation of the work to be reported in this paper, it was observed in collaboration with others¹⁰ that the red material on the rats exhibited a brilliant red fluorescence when illuminated with near ultraviolet light. Since blood is not fluorescent, an attempt was made to characterize this incrustated red fluorescent exudate chemically, and to discover its origin.

The red fluorescence made it appear probable that the incrustated material was a porphyrin (see Plate I, page 1608). Chemical and spectroscopic examination proved this to be the case. Other chemical tests indicated that very little, if any, of the fluorescent material was blood.¹⁰ A survey of the literature re-

*From the Departments of Anatomy, Yale University School of Medicine and University of Maryland Medical School, and the Department of Physiological Chemistry, Yale University School of Medicine.

This work was aided by a grant from the Anna Fuller Fund for Cancer Research. The illustration for this article will be found in the section on Medical Illustration of this number of the JOURNAL, Plate I, page 1608.

†Rockefeller Foundation Fellow, 1940-1941.

Received for publication, March 1, 1941.

vealed that the reddish incrustated exudate which appears on rats maintained on a filtrate factor deficient diet had been identified spectroscopically and described as protoporphyrin. The tests for blood were also negative.² Our own independent observations and more exhaustive investigation confirm this observation in some respects.¹⁰

At this stage of the investigation a short abstract appeared describing the harderian gland as a porphyrin-secreting gland.⁶ The fact that the harderian gland was fluorescent and contained protoporphyrin had been known for some time.^{4, 16} It thus appeared likely that the material was secreted by the harderian gland and passed to the nose via the nasolacrimal duct. In order to test this hypothesis, the harderian gland was completely removed from a number of rats to see if this operation would prevent the accumulation of the porphyrin-containing incrustations (*see* Plate I, page 1608). These operated animals and an equal number of controls were maintained on a diet deficient in pantothenic acid. This experiment demonstrated convincingly that harderian gland ablation prevents the porphyrin incrustations in albino rats maintained on a diet deficient in pantothenic acid. It is the purpose of this paper to present the details of this experiment.

METHODS AND MATERIALS

The 24 albino rats used in the experiment were weaned at the age of 22 to 24 days. They were from three litters³ and, in so far as possible, the animals from each litter were uniformly distributed in four groups. There were 12 females and 12 males so that 3 of each sex were placed in each group of 6 rats (*see* Table I). The males and females were separated and placed three in a cage. The cages were made of pyrex glass and prevented contact of the animals or their excreta with metal. The feces, urine, and spilled food fell between the glass bars to pyrex glass plates and could not be retrieved by the rats. The feces were examined periodically to see whether they contained a red fluorescent material. The weights of the rats and other observations were recorded bi-weekly.

All rats were fed a basic diet of cerelese, 68 per cent; vitamin-free casein, 18 per cent; erisco, 8 per cent; salt mixture, 4 per cent; cod-liver oil, 2 per cent. This basic diet was supplemented for all rats by the addition of choline chloride (1 Gm. per kilogram) and the following vitamins: thiamine† (4 mg. per kilogram), riboflavin† (5 mg. per kilogram), pyridoxine† (4 mg. per kilogram), and nicotinic acid† (50 mg. per kilogram).¹⁸ Twenty milligrams of pantothenic acid per kilogram were added to this for 12 animals maintained on a nondeficient diet. These mixtures were pounded compactly into the food cups to prevent excessive spilling. During the experiment special care was exercised to keep the water bottles filled at all times. This is an important requirement when investigating the porphyrin-containing incrustations.⁵

The harderian gland was removed from 11 rats (*see* Table I); five of these in one group were fed a diet deficient in pantothenic acid and 6 rats in another

†These vitamins were very kindly supplied by Dr. Robertson of Merck & Co.

group were fed the diet containing pantothenic acid. Rat 7 was not operated upon because at the time of operation it was thought that the animal would not survive the anesthesia. This unoperated animal did survive and was later regarded as a control for the two operated animals kept in the same cage.

The harderian gland in rodents is very large, occupying in the case of the rat about one-half of the total volume of the orbital cavity. This gland is a lacrimal gland. It is associated with the nictitating membrane and, therefore, is located on the medial side of the orbit. The location appears to be the chief characteristic used to distinguish it from the true lacrimal gland which is either extra-orbital or on the lateral side of the orbit. The harderian gland is horse-shoe-shaped and almost completely surrounds the optic nerve and bulbus oculi.

*Nonoperated.

The operations were performed with sodium amytal anesthesia (0.1 mg. per gram of rat weight). If necessary, this was supplemented with ether, but this practice has little to recommend it. The ether caused some animals to develop mucous plugs which gave rise to respiratory difficulties. In the first 3 animals two incisions were made between the eyes near the medial angles. The lateral edge was pulled laterally to expose the medial margin of the orbit. After the fascia attached to the medial margin of the orbit was cut, the gland was exposed. A suction pipette was applied to pull the gland out of the orbit and at the same time the blood vessels were cauterized. The blood vessels and other connections were then cut with scissors. During the operation the field was illuminated alternately with visible and near-ultraviolet light. This not only facilitated

locating the gland, but also insured the complete removal, because even a tiny bit of gland was so highly fluorescent that it was very conspicuous in near-ultraviolet light. A small portion of a harderian gland was found in the orbit on only one operated animal when the rats were killed and examined at the end of the experiment.

During the first few operations it was found that in order to remove completely the gland, the nictitating membrane and conjunctiva were frequently cut and damaged. In view of this, it appeared superfluous to make an incision in the skin. The last sixteen glands were removed by cutting the conjunctiva near the medial angle of the eye with an iridectome. The nictitating membrane and attached harderian gland were removed together. The other connections of the gland were cut with scissors, but no attempt was made to use a cautery. With this method the animals lost a drop or two of blood, but the eyes soon returned to normal. Since no incision was made in the skin, and no suturing was required, this was a much more rapid method. Examinations at the end of the experiment revealed only one eye damaged, and this was in one of the first animals operated upon. This injury was thought to have been caused by the cautery. Only one animal (No. 24) was blinded by the operation; the eyes of the other operated animals were normal. It was thought that all the animals would be blind from conjunctivitis caused by drying of the conjunctiva. The eyes of the operated animals were apparently kept sufficiently moist by the secretions from the extra-orbital lacrimal gland. This extra-orbital gland, located just in front of the ear, was found to exhibit a slight red fluorescence in only 6 of 50 rats examined specifically for this. No mention of the variable red fluorescence which was observed in this extra-orbital lacrimal gland was found in the literature. Even though there may have been some porphyrin in the secretion of some of these glands, it was never observed on the nose or fur of any of the animals with the harderian gland removed.

RESULTS

The experimental conditions for the different groups of animals and the observations regarding the porphyrin incrustations and condition of the fur were tabulated (see Table I). No fluorescent porphyrin-containing incrustations were observed at any time on animals in which the harderian gland had been removed. This was true regardless of the diet (group 1B, 2B). All non-operated animals maintained on a diet deficient in pantothenic acid showed fluctuating, but marked, porphyrin incrustations (group 1A). These incrustations were red fluorescent and were most abundant on the nose, whiskers, and near the medial angle of the eye (see Plate I, page 1608). These symptoms required about four to five weeks to appear, and after this time varied from time to time, but in general became increasingly severe. Some of the nonoperated animals, maintained on a diet not deficient in pantothenic acid, exhibited slight and variable porphyrin incrustations. The slight porphyrin incrustations in this group were observed most frequently on the females. Operated animals maintained on a similar diet not deficient in pantothenic acid appeared unusually white and clean (group 2B) throughout the experiment. These very clear-cut

results indicate that the harderian gland is the source of the porphyrin-containing red fluorescent incrustations.

In addition to these observations several others were also recorded. An intense red fluorescence was observed in the feces of all nonoperated animals. In the feces of operated animals no red fluorescence was observed. The weight curves for the animals on the deficient diet were considerably below those on the nondeficient diet. Since these weights were found to agree with those of other investigators,¹⁵ they have not been reproduced. The fur on all animals fed a diet deficient in pantothenic acid appeared matted. Depilation of body fur and bald head also occurred in some animals. The removal of the harderian gland did not influence these symptoms.

DISCUSSION

Previous investigations^{4, 6, 16} had established the fact that the harderian gland contained and secreted porphyrin. The physiologic significance of the porphyrin in this fluid, which bathes the conjunctiva, has not been discovered. The anatomical pathway of this harderian gland secretion was followed by observing the red fluorescence. Under normal conditions the secretion was found to collect in the sacculus lacrimalis and pass to the nasal cavity by way of the nasolacrimal duct. A fluorescent nasolacrimal duct was found in several cases. From the nose it may pass either to the alimentary tract directly via the nasopharynx or to the nose and whiskers through the external nares. In a normal rat on an adequate diet some of this red pigment was seen occasionally in visible light on the fur. When these normal rats were irradiated with near-ultraviolet light, a small amount of this red fluorescent material was frequently seen near the external nares. It was usually not very conspicuous, however, as healthy rats keep it cleaned off by washing and licking.

In some rats porphyrin incrustations were induced by water deprivation. When these rats were given water, they drank it and soon cleaned the incrustated material off by licking and washing. The rats were killed two to four hours later. A red fluorescent band was observed in the intestine. It was assumed that this band was caused by the unusually heavy dose of concentrated porphyrin cleaned off the nose and fur by washing. This may account for the presence of large amounts of porphyrin which had been observed in the excreta of rats.¹³ The red fluorescence of the feces was not observed in the case of the operated animals. This is no proof, but it suggests that the harderian gland may elaborate the porphyrin which it secretes.

In the case of nonoperated rats, maintained on diets deficient in pantothenic acid, this porphyrin-containing secretion accumulated and became incrustated on the nose, whiskers, and face. The infrequent and feeble attempts to remove this by washing and licking were unsuccessful and usually the material was merely smeared around to other areas, notably the fore paws and back of the neck. This smearing and unsuccessful cleaning, while partly caused by the lethargy of the rat, was also thought to be related to a change in the physical nature and the amount of the saliva. It appeared to function like a liquid glue that did not dissolve or remove the material, but acted as an adhesive base for the smeared porphyrin-containing excretion.

Much evidence was found to support this concept of the mechanism of the accumulation of porphyrin incrustations. Water deprivation and limitation induced porphyrin incrustations in rats.⁵ This had been observed previously, but the red exudate was not only mistaken for blood, but the tests for blood were positive.¹⁵ Pantothenic acid deficiency may influence water metabolism indirectly through its effect on the adrenals. A deficiency of this vitamin in the diet caused adrenal cortical damage and necrosis.^{1, 3, 11, 14} Experimental adrenal cortical insufficiency resulted in the loss of water from the plasma and general dehydration as indicated by hemoconcentration in cats and decreased plasma volume in dogs.⁸ The rats fed a deficient diet sneezed more frequently and drank less water (approximately one-half as much) than the animals on a nondeficient diet. It was thought that this sneezing might be an indication of a relatively dry nasal mucous membrane.

The porphyrin-containing exudate which was seen to come from the nose was doubtless a mixture of the harderian gland and nasal secretions. Any changes in physical properties of these secretions that would result from a general dehydration would also have to be regarded as an important factor in the control of the adhesive properties of this exudate. From these bits of evidence gathered from various sources, it may be seen that pantothenic acid deficiency caused adrenal necrosis^{1, 3, 11, 14} which, according to the work of Lewis,⁸ caused a loss of water from the plasma and general dehydration. Water deprivation and consequent dehydration caused a marked decrease in salivary flow in man and dogs,⁷ and both pantothenic acid deficiency and water deprivation induced the porphyrin incrustation symptom in rats.⁵ These facts indicate that pantothenic acid deficiency regulates water metabolism; it suggests the mechanism by which it does this, and influences the accumulation of porphyrin incrustations.

SUMMARY

Ablation of the harderian glands prevents the accumulation and incrustation of a red fluorescent porphyrin-containing exudate in rats fed a diet deficient in pantothenic acid. This indicates that the harderian gland is the immediate glandular source of the porphyrin in the incrustated material observed on the nose, whiskers, and fur of rats fed a diet deficient in pantothenic acid.

DUODENAL BULB ("ULCER-BEARING AREA") ACIDITY IN FASTING NORMAL PEOPLE*

J. EDWARD BERK, M.D., M.Sc. (MED.),† MARTIN E. REHFUSS, M.D., AND
J. EARL THOMAS, M.D., PHILADELPHIA, PA.

IN THE present-day concept of the problem of chronic peptic ulcer the acid gastric juice occupies a position of acknowledged prominence. Since the gastric acid is important only because of its effects, direct and indirect, either on the ulcer proper or on some area susceptible to ulcer, one wonders why attention has been directed so exclusively to acidity in the stomach when most clinical ulcers occur in the duodenum.⁴ Simultaneous determinations of gastric and duodenal acidity would serve better to evaluate the accepted importance of the acid gastric juice in duodenal ulcer. However, our knowledge of the changes in acidity which occur in the "ulcer-bearing" duodenal bulb is very limited.^{16, 26} We particularly need more extensive information concerning the situation which normally exists in the duodenal bulb before we can hope to interpret the findings in ulcer patients.

In a previous study⁵ we found, in agreement with Morton,²⁶ that the contents of the duodenal bulb in normal people following an Ewald meal were endowed with a considerable capacity to neutralize, buffer, and dilute the gastric chyme. Several investigators,^{13-15, 19, 25-27} using men as subjects, had commented on the apparent lack of close relationship between gastric and duo-

denal acidity and we were able to demonstrate a similar lack of sharp parallelism between the acidity in the stomach and that present at the same moment in the first part of the duodenum of normal persons after an Ewald meal.

The present study was undertaken to determine whether a neutralizing efficiency of equal magnitude and relationships of like nature obtained in the duodenal bulb during fasting in normal people studied under the same experimental conditions.

MATERIAL

The subjects utilized for the purposes of this study were drawn largely from the Out-Patient Gastro-Intestinal Clinic of the Jefferson Hospital. Although a number of them presented symptoms referable to the digestive tract, none gave evidence of fever or of any acute, chronic, infectious, metabolic or cachectic disease, and x-ray examination revealed no abnormality of the stomach and duodenum. Achlorhydries were not excluded, since a lack of free acid in the stomach is expected in a certain percentage of "normal" persons.^{2, 3, 20, 23, 24, 29, 30, 35}

We could not hope to standardize all the variables which are known to affect gastric secretory behavior even in "normal" people⁸ and, inasmuch as our primary concern was with the changes in acidity in the duodenal bulb which might be associated with changes in gastric acidity, we felt that variations in gastric acidity were actually desirable for our purpose.

Twenty-two subjects were studied, of which 14 were males and 8 were females. The age of the entire group ranged from 22 to 51 years, with an average age of 35.5 years. The males ranged from 22 to 51 years of age, with an average age of 32.5 years; the females from 29 to 49 years of age, with an average age of 40.9 years.

METHOD

Each subject was examined in the morning before breakfast, following a period of alimentary rest of at least twelve hours. A specially constructed double lumen tube was employed, and a method was utilized which permitted more or less fluoroscopic control as well as radiographic proof of the position of the tube.⁵ Most of the subjects had swallowed tubes before for other purposes so that the element of fright was minimal. If much difficulty was encountered in swallowing the tube, if nausea or vomiting occurred, or if the subject complained of any other distress of any moment, the experiment was discontinued, and the results were disregarded. After ascertaining the location of the tube in the stomach with the aid of the fluoroscope, we were able, in some instances, to manipulate the tube into position in the duodenum. When we failed in this attempt, the subject was placed on his right side, the room was darkened, and the person was exhorted to relax and slowly swallow about 6 inches of the tube over a period of half an hour; not uncommonly the subject was asleep when we returned to the room at the end of that period.

Once the tube was determined by fluoroscopic examination to be in the desired position, the person was placed at rest on his right side, and the aspiration apparatus was assembled. Specimens were collected simultaneously from

the pars pylorica and the duodenal bulb at ten-minute intervals for one-half hour. At each of the four-interval aspirations all the material which could be obtained was collected.

The pH of each specimen was determined at once by means of a Leeds-Northrup pH indicator, which uses a glass electrode. After filtration the free and total acidity of each specimen was estimated using Töpfer's reagent and phenolphthalein as the respective color indicators.⁶ In addition, on each duodenal specimen, we determined what was called the excess neutralizing ability.^{4, 6} This consisted of the amount of N/10 hydrochloric acid necessary to lower the pH to the point at which Töpfer's reagent evidenced a positive reaction for free acid.⁶

Out of 29 experiments 25 were accepted as being satisfactory with respect to technique. These involved 558 separate determinations made up of 156 pH readings, 163 estimations of free acid, 163 estimations of total acidity, and 76 determinations of excess neutralizing ability of the duodenal contents.

RESULTS

Acidity in pH Units (Fig. 1).—Stomach. The average gastric acidity in terms of pH in fasting normal subjects (pH 3.51) was less than that observed after an Ewald meal (pH 2.78),⁸ even though the range of the individual pH values in both the fasting and digestive states was about equal. It is interesting to note that even the average gastric acidity expressed in pH units of those subjects who had some free acid in their fasting stomach contents (pH 2.37) was less than that in fasting normal dogs (pH 1.90).⁷

Duodenum. The efficient neutralizing ability of the contents of the duodenal bulb during fasting was evidenced by the constant maintenance of a difference in pH in the samples collected at the same moment from areas just above and just below the pylorus. Throughout the period of observation in the fasting state this difference averaged 2.09 pH units. Further evidence of the effectiveness of duodenal neutralization in the fasting state was found in the relative infrequency of occurrence of free acid in the duodenum. Under fasting conditions only 26 per cent of all the samples had a pH less than 3.5, the critical value we had adopted for free acid,⁶ compared with 31.7 per cent during the observation period following an Ewald meal.

A peculiar feature, which was seen in the entire group as well as in those members of this group who were able to secrete free acid, was a progressive elevation in the average duodenal pH during the period of observation. As a result, the character of the line representing the plotted values for average duodenal pH was distinctly different in pattern from the corresponding one for average gastric pH.

The over-all average duodenal pH was 5.60, which was about equal to that we found in fasting normal dogs (5.56),⁷ despite a much greater acidity in terms of pH in the stomach of dogs as compared with men. The much more efficient duodenal bulb neutralization in fasting dogs was also seen in the fact that only 17.2 per cent of the duodenal samples in these animals showed free acid (a pH less than the critical value of 3.5).

Free Acid (Fig. 2).—Stomach. The average gastric free acid in fasting normal subjects was 15 clinical units. This was less than that after an Ewald

meal^s (21 clinical units), and the maximal values attained were not as great. The average gastric free acid was also much less than that in fasting normal dogs.⁷ There was a contrast between the configuration of the line representing the plotted values of average gastric free acid and that representing average duodenal pH (Fig. 1).

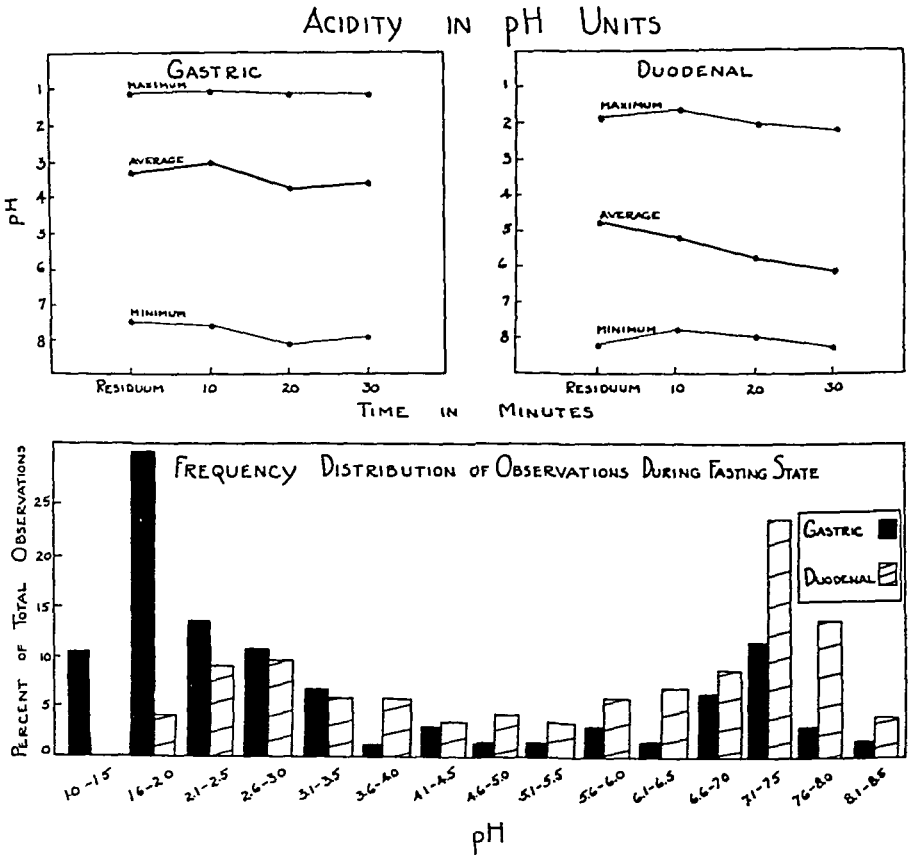

Fig. 1.—Acidity in pH units of samples collected simultaneously from just above and just below the pylorus in fasting normal people.

Duodenum. In the vast majority of instances the contents of the duodenal bulb under fasting conditions showed an absence of free acid; only 10 per cent of all the specimens yielded a colorimetric reaction with Töpfer's reagent, such as was considered positive for free acid. A greater percentage of these samples (26 per cent), it will be recalled, were thought to contain free acid as judged by their pH values (Fig. 1). The apparent discrepancy between these percentages may be attributed to our method of filtration and dilution preparatory to colorimetric titration which results in a number of false negative readings.⁶ Our end point with Töpfer's reagent was about pH 3.5,⁶ so that a more accurate figure is the one based upon the assumption that all specimens whose pH in the unfiltered, undiluted state is 3.5 or less contain free acid.

The percentage of duodenal samples positive for free acid was less than in normal people after an Ewald meal in whom free acid was found col-

orimetrically in 15.2 per cent, and electrometrically in 31.7 per cent of the samples.⁸ An added contrast indicating the very effective neutralizing power of the contents of the duodenal bulb during fasting was the smaller percentage of subjects who had free acid in the contents of their bulb at some time during the period of observation. The comparative values are: fasting, 22.7 per cent of the subjects (colorimetrically), 40.9 per cent (electrometrically); Ewald

FREE ACID

Fig. 2.—Free acid as determined on samples collected simultaneously from just above and just below the pylorus in fasting normal people.

meal, 66.6 per cent of the subjects (colorimetrically), 75 per cent (electrometrically). On the other hand, duodenal neutralization in fasting normal persons was less effective than in normal fasting dogs: despite a greater gastric acidity in the latter animals; colorimetrically, only 6.3 per cent, and electrometrically, only 17.2 per cent of the duodenal samples were positive for free acid in fasting dogs.

What little free acid was contained in the duodenal bulb contents during fasting showed the same tendency toward a diminution in average values with each successive aspiration, as had been noted in the case of duodenal pH (Fig. 1).

Total Acidity (Fig. 3).—Stomach. Average gastric total acidity, as with average gastric free acid, was distinctly less than that in normal people following an Ewald meal.⁸ It was also less than in normal fasting dogs.⁷ A differ-

ence in configuration of the graphic curves of average gastric total acidity and average duodenal pH was evident (Fig. 1).

Duodenum. The average value for duodenal total acidity was 18 clinical units. This and the narrower range of distribution of the individual values under fasting conditions indicate a neutralizing capacity at least equal to that observed in normal people after an Ewald meal.⁸ The average value and the range of values, however, were not much less than those in fasting normal dogs in spite of the greater gastric acidity in the latter.⁷

Fig. 3.—Total acidity of samples collected simultaneously from just above and just below the pylorus in fasting normal people.

Here again the contents of the duodenal bulb during fasting displayed the rather characteristic trend toward progressive decrease in acidity values. The line representing the plotted values for average duodenal total acidity assumed a form which was quite dissimilar in pattern from the corresponding curve for average gastric total acidity.

*Neutralizing Ability of the Duodenal Contents (Fig. 4).—*We previously defined excess neutralizing ability as a measure of the reserve capacity which the contents of the first part of the duodenum possess to neutralize, buffer, and dilute the secretions received from the stomach above that necessary to offset the free acid content.^{4, 6}

The contents of the duodenal bulb in the fasting state slightly surpassed those in the digestive state, as measured by this index of neutralizing capacity. The over-all average was 17 clinical units, which was a little higher than after an Ewald meal (14 clinical units).⁵ Only 14.5 per cent of all the samples had no excess neutralizing ability, as compared with 20 per cent of those after an Ewald meal. As measured by the same index, however, the neutralizing capacity was inferior to that in fasting normal dogs;⁷ in the latter the over-all average value was greater (28 clinical units), the range of distribution of the individual values was wider, and the percentage of specimens negative, for excess neutralizing ability was less (8 per cent).

Fig. 4.—Excess neutralizing ability of the duodenal contents in fasting normal people.

The fairly typical trend toward a progressive decrease in acidity in the duodenal bulb with each succeeding aspiration was seen here in the slight but definite increase in values for average excess neutralizing ability.

DISCUSSION

The figures we obtained in the course of this study are not submitted with the thought that they establish an ultimate standard for the acidity in the duodenal bulb in all fasting normal people. Despite our efforts to control the origin of the specimens, undoubtedly some of them *must* have been drawn from portions of the stomach and duodenum other than those which were designated.

The existence of a true fasting gastric secretion in men is still a moot question.^{1, 9, 11, 23, 31-33} Even though we made an attempt to avoid all extraneous influences and to secure a true resting state, it is unlikely that all normal and abnormal stimuli sufficient to influence gastric secretion were thoroughly excluded.¹ The values for fasting gastric acidity which we obtained, while in agreement with those observed by others with respect to both pH^{10, 16, 21, 22} and titrable acidity,^{2, 3, 17, 18, 32, 33, 34} are not advanced as necessarily characteristic of the normal fasting stomach. The findings, however, are useful for comparison with like values simultaneously obtained in the duodenal bulb or with corresponding values obtained under similar experimental conditions during the course of digestion.

Under our experimental conditions the reaction in the first part of the duodenum in man is acid during the fasting state, just as it is during the digestive state. In a thirty-minute observation period the contents of the duodenal bulb displayed a more or less characteristic tendency toward a progressive decrease in average acidity values, and a concomitant progressive increase in neutralizing ability. This feature was all the more interesting because it occurred independently of any similar trend in gastric acidity.

The contents of the "ulcer-bearing" duodenal bulb in fasting normal people are able to neutralize, buffer, and dilute the gastric secretions as well, and possibly even better, than during the course of digestion of an Ewald meal. A difference in reaction is constantly maintained between the adjacent pars pylorica and duodenal bulb which about equals that during digestion. While neutralization is generally effective (measured by the ability to maintain a pH of 3.5 or above), free acid is by no means constantly or consistently absent. Therefore, as in the digestive state so in the fasting state as well, the occasional presence of free acid in the contents of the duodenal bulb cannot be considered as greatly significant from the diagnostic standpoint.^{12, 14, 15, 19, 26}

The frequently noted lack of sharp parallelism between the several indexes of gastric acidity on the one hand, and the duodenal pH as well as the corresponding indexes of duodenal acidity on the other, permits the conclusion that there is no constant relationship between the gastric acidity and that present at the same time in the duodenal bulb.

The fact that neutralization of gastric acid in the duodenal bulb is apparently more efficient in dogs than in man may be related to the fact that dogs rarely, if ever, display a spontaneous duodenal ulcer, whereas, man is very frequently afflicted with this disturbance.

SUMMARY AND CONCLUSIONS

1. The "ulcer-bearing" first portion of the duodenum in fasting normal people is an acid area with an average pH of 5.60.

2. The duodenal bulb in fasting normal people is able to neutralize, buffer, and dilute the gastric secretions with an efficiency which equals and possibly exceeds that during digestion of an Ewald meal.

3. Free acid is generally, but not consistently, absent in the contents of the duodenal bulb in fasting normal persons; its presence cannot be taken as a necessarily abnormal finding.

4. There is no constant relationship maintained between the acidity simultaneously determined in the stomach and in the duodenal bulb.

5. Fasting normal dogs display a greater neutralizing power in the duodenal bulb than do fasting normal men.

We wish to express our thanks to Dr. B. B. Vincent Lyon for his kind permission to use the facilities of the Gastro-Intestinal Clinic, and to Drs. Melvin Dillman and Karl Kornblum for their cooperation in performing the x-ray studies on each subject.

ACUTE POSTOPERATIVE LUNG ABSCESS

REPORT OF A CASE WITH UNUSUAL BACTERIOLOGIC FINDINGS

ALEXANDER STRELINGER, M.D., M.Sc. (MED.)

ELIZABETH, N. J.

INFECTION is one of the prerequisites of the breakdown of lung tissue. The infecting organism in some cases is very specific, as in the case of a tubercular cavity or an amebic abscess of the lung. These are usually not considered under the heading of lung abscesses; however, the primary acute putrid or acute nonputrid abscesses of the lung are those that are grouped under this name.

There are observers of great experience in this field, among them Neuhof,¹ who readily ascribe all nonputrid abscesses to aerobic bacteria, and all putrid abscesses to anaerobic ones. Nevertheless, papers by Bucher,² Cohen,³ and Varney,⁴ with extensive bacteriologic studies, cast some doubt on the truth of this simple classification. Cohen³ reported the results of an exhaustive bacteriologic study of 16 cases; he emphasized that it is highly debatable whether anaerobes are the determinant feature of putrid lung abscess. He showed that gamma streptococcus and diphtheroids were present in each of the 16 examined cases, and *Bacillus melaninogenicum* was observed in 15 of these. A great variety of other bacteria occurred in varying numbers. The findings of Bucher,² in a larger but seemingly not so meticulously studied group, indicated a total incidence of 451 bacteria in 118 cases of lung abscess. Three streptococcus groups described as hemolytic, nonhemolytic, and *viridans*, occurred 93 times. The next in frequency was the *Micrococcus catarrhalis*, occurring 61 times; diphtheroids, on the other hand, were found only 29 times, and the *Bacillus melaninogenicum* is not mentioned in his report. Varney⁴ reported 27 cases in which certain rigid requirements were adhered to in order to obtain

all, but no other organisms than those actually present in the abscess. He stressed the point that anaerobes are found mostly in granules occurring in pus of abscesses. In two instances out of a total of 27 all the growth was anaerobic; in the other 25 there were both aerobes and anaerobes present.

These reports bring out the fact that usually more than one bacterial species is found in a lung abscess and also, that in many cases aerobes and anaerobes occur, irrespective of whether the abscess is putrid or not. A lung abscess harboring only one species of bacterium seems to be rather rare. It is of interest, therefore, to report a case of acute, nonputrid postoperative lung abscess in which two cultures were obtained from the pus aspirated from the lung. The pus was obtained before perforation into the bronchus, or operative drainage would have taken place. Both cultures showed that the only bacterium present was a micro-aerophilic, nonhemolytic, gram-positive streptococcus. The case also presented other interesting features.

G. E., female, married, 24 years of age, came under observation in November, 1940. Two years prior to this date she underwent an appendectomy for right lower quadrant pain; following this operation, the pain persisted and became her main complaint.

She had one child and had had no miscarriages. Her menstrual periods came every 35 days and were of seven days' duration; usually the pain in the right lower quadrant became more intense during the period. She had a "streptococcic" sore throat in 1939, and as later verified from the physician in charge, this diagnosis was made on clinical bases alone. Her weight was 102 pounds.

On examination the essential findings were as follows: wide diastasis of the recti muscles; small mass on the right side of the pelvis, thought to be due to salpingo-oophoritis, and cervical erosion. Treatment consisted of cauterization of the cervix, followed by biweekly diathermy and aolan injections. This regime was maintained until Jan. 17, 1941. There was no appreciable relief. The patient had an upper respiratory infection from which she apparently recovered clinically.

She was admitted to the Newark Beth Israel Hospital on Feb. 9, 1941, and was operated on, under general anesthesia, the following day. The operation consisted of right salpingo-oophorectomy, resection of the presacral nerve, and reconstruction of the abdominal wall. She stood the procedure well.

On the fourth postoperative day a nonproductive, spastic, and persistent cough developed, the temperature rose to 102° F., but the physical findings were essentially negative. An expectorant was prescribed. The cough continued, became loose and annoyingly persistent. The maximum temperature on the eighth and ninth postoperative days did not exceed 100° F., and the patient was more or less comfortable. On the eleventh postoperative day, however, the cough reappeared, the temperature rose again, and the patient vomited most of her food. The temperature reached 104° F. on the fifteenth day, and dullness, but no râles, developed at the base of the right lung. Sulfathiazole was given by mouth, but the patient did not retain it. On the following day sodium sulfapyridine was given intravenously. The report of the x-ray examination of the chest was: "Pneumonic type infiltration of mesial portion of right base." The patient felt pain at a well-circumscribed point at the base of the right lung; she was tapped here, and about 1 c.c. of heavy pus was obtained; it did not seem to contain any granules. On the following two days the patient was slightly more comfortable, the cough being nonproductive and persistent. The patient was tapped again on the nineteenth postoperative day at the point of greatest pain, and a few cubic centimeters of heavy creamy pus were obtained. The bacteriologic report on the smear and the culture of the pus both times was: gram-positive, micro-aerophilic, nonhemolytic streptococcus. The following day the patient looked cyanotic and toxic, coughed, and vomited continuously, and her temperature remained above 102° F.

Fig. 1.—Roentgenogram taken on Feb. 26, 1941, showing pneumonic type infiltration of right lower portion of the lung.

Fig. 2.—Roentgenogram taken on March 3, 1941, showing a marked spreading of process involving more than two-thirds of right lung area. Note seat of resection shown by arrow.

In view of these alarming symptoms coupled with the physical findings, and of having obtained pus twice by tap, it was felt that a diagnosis of empyema was justified. Dr. Aaron E. Parsonnet saw the patient in consultation. He concurred in this opinion and advised immediate thoracotomy. The patient was transfused and operated upon on the same day. A two-inch part of the ninth and tenth ribs was resected in the scapular line, and the pleural cavity was opened. It was found free of fluid or inflammatory changes; there were no adhesions between the two pleural leaves. The visceral pleura was yellowish and discolored over an area of about an inch. The lung was aspirated at that point, and a few cubic centimeters of creamy pus were obtained. A part of the lung the size of a silver dollar was sutured to the parietal pleura, and iodoform packing was placed in the wound. On the next day the lung was entered at the exposed part by cautery, one finger was inserted, and friable tissue was broken up. The cavity was drained by rubber tube and packed with activated zinc peroxide cream and gauze. None of the pus specimens nor the wound afterwards had a foul odor.

Fig. 3.—Roentgenogram taken one week later, March 10, 1941, showing marked recession of the process.

Within a few hours after pneumonotomy, an impressive change occurred. The general appearance of the patient improved strikingly, the cyanosis and toxicity lessened; never returning to the same degree during the eventful and rather stormy postoperative course.

The appearance of total empyema was feared; it did not occur. At the first change of the dressing, one day after the pneumonotomy, activated zinc peroxide cream (Z.P.O.) was injected through the drain tube into the lung cavity. It resulted in such an exasperating coughing spell, that its use had to be temporarily discontinued, and powdered sulfanilamide substituted for a while. Later Z.P.O. was used again. From the very first day of pneumonotomy a bronchial fistula was present. The temperature throughout the twenty days of hospitalization following pneumonotomy continued to be about 103° F. Jaundice was noticed on the ninth day postoperatively (bilirubin was 2.7 per 100 c.c.); it subsided as the general condition improved. The cough persisted; it was spastic, with very little sputum, and was often followed by vomiting. About two weeks after pneumonotomy, burrowing appeared at the

Fig. 4.—Roentgenogram taken on March 19, 1941. Note marked improvement and aeration of lung.

Fig. 5.—Roentgenogram of final plate on Sept. 9, 1941. Condition practically restored to normal.

upper and inner wound margins. Though the patient was cheerful, the persistent cough, the vomiting, and the high temperature caused further decline. The condition became stationary, and the patient was discharged on March 23, 1941, the forty-first day of hospitalization.

Up to April 15, the burrowing at the inner wound edge persisted, causing further loss of tissue. For a while Z.P.O. was used, followed later by azochloramid in triacetin. On April 13, the overhanging wound edge seemed to melt away at one point; it seemed that some superimposed infection helped to destroy it. By April 15 this melting-down process neatly scooped off all the overhanging edge. From this point on the patient's condition improved rapidly; the daily temperature curve, ranging between 102° and 102.6° F. daily, tapered down, and the vomiting ceased. Her weight, which came down to the dangerous level of 72 pounds, started to come back. The recovery became uneventful. The skin wound and the bronchial fistula closed completely by May 15.

Examination on September 9 found the patient weighing 114¼ pounds, and with no clinical symptoms. Of further interest is the fact that the patient was now completely relieved from right lower quadrant pain.

COMMENT

1. In this case the x-ray examination did not disclose an abscess. Jackson and Judd⁵ reported that an abscess can be demonstrated only after drainage of some kind has been established, thus permitting the access of air into the abscess cavity. The alternative possibility of gas in the abscess would be gas formation by bacteria; such an occurrence, however, does not seem to have been reported in the literature. Palugyai⁶ stated that "closed forms of abscess cannot be differentiated from tumor." Touroff and Neuhof⁷ stated that acute abscess may show either cavity or dense infiltration. In this case, x-ray findings indicated a pneumonic type of infiltration.

2. There were no adhesions between the parietal and visceral leaves of the pleura, though a definite abscess was already present. This refutes the claim made by some that adhesions are always present. The abscess was not near an interlobar fissure, thus excluding the presence of invisible adhesions.

3. Pus was obtained twice, and later the abscess was found at the site of the most intense pain. This fact may be used as a lead in future cases.

4. The improvement within a few hours after draining the abscess was striking.

5. During recovery it was noted that the intercostal spaces were narrowed and that the right half of the chest, harboring the abscess originally, became smaller than the other half. Following complete closure of the wound, the chest re-expanded and the intercostal spaces widened.

6. Pus for culture is rarely obtained prior to the abscess opening into the bronchus. It cannot be obtained by bronchoscopy because the abscess did not perforate. It can hardly be obtained by operation because the examination of an abscess before perforation fails to disclose a cavity, and therefore, an operation is usually not performed. This, in large measure, is also the reason why aspiration is not attempted, the other one being the likelihood of a resultant empyema, following the needling of an abscess at an early stage. Superimposed infections easily occur after the abscess perforates, and therefore, examination will naturally disclose more than one bacterium. In the case reported, an aspiration was done because the physical findings indicated a pleural process. Both through error and lucky coincidence the needle entered the lung. Pus was found

twice, yet the pleural cavity was not infected. Thus the pus of a lung abscess was obtained under sterile conditions before the usual perforation would have occurred. The chief reason for only one bacterium being present may be due to the fact that there was complete absence of superimposed infection. It seems fair to assume that this bacterium caused the infection because the identical organism was obtained both times, and no other bacteria were found in either instance. The bacterium is a nonhemolytic or gamma streptococcus, belonging to the group that was reported by Cohen,³ in each of his 16 cases. This bacterium, though micro-aerophilic, differs from the streptococcus described by Meleney; his being a hemolytic streptococcus not causing any persistent fever. Meleney and Harvey⁸ stated that "there is usually a moderate fever and a moderate pain in the wound. At times the fever may reach 103° F. for a period of days, but usually it remains at a lower level." No cultures were made after pneumonotomy. It seems that this bacterium caused burrowing, high fever, and toxicity, while even the smallest amount of burrowing persisted, though secondary infection might have played a part in this. These features make this bacterium different from the Meleney streptococcus. At least one author, Reicher,⁹ called attention to a streptococcus that was not hemolytic, but burrowing.

7. Finally, this streptococcus was the sole bacteriologic cause of a lung abscess.

SUMMARY

A case of lung abscess is reported. Pus for bacteriologic examination was obtained before the abscess perforated. The bacteriologic examination showed that only one bacterium was present, a micro-aerophilic, nonhemolytic, gram-positive streptococcus.

BENZENE POISONING IN INDUSTRY

REX H. WILSON,* M.D., AKRON, OHIO

AS THE national defense program alters industry to suit its needs, it is placing increasing burdens on the industrial physician. In the rubber industry one of the problems confronting the medical staff is the increasing use of benzol and the physical hazards it presents.

Pure benzene, C_6H_6 , is a coal tar distillate. It is a colorless limpid liquid with a characteristic odor which is rather pleasant. It boils at $80.2^\circ C$. Its specific gravity is 0.879. It is soluble, 0.07 Gm. in 100 c.c. of water. It is somewhat soluble in alcohol. Pure benzene is not used in industry. The commercial varieties contain from 2 to 10 per cent toluene, xylene, olefins, paraffin, and carbon disulfide. It is an excellent solvent for rubber gums, resins, celluloid, and fats of all kinds. It is the best solvent for certain types of synthetic rubber because it dries faster and is cheaper. It is these properties that make its use so prevalent in the rubber industry today.

It is used extensively in the rubber industry, in the leather industry, in varnish and paint removing, in gilding and bronzing, in spray gun paints, coal tar paints, and to a small extent as a motor car fuel.

Benzol poisoning may result from absorption of the benzene by the respiratory tract or the alimentary tract, or through the skin. In the majority of cases absorption through the respiratory tract is the common mode of entrance. Absorption through the skin is slow. A considerable amount of fumes may act as an asphyxiation agent. With the use of animals the United States Public Health Service states that concentrations as low as 5 parts per million may cause symptoms. Cases of poisoning in human beings have been found with concentrations as low as 25 parts per million. Concentrations of 50 to 100 parts per million are considered to be safe for the average person. Individual susceptibility varies. Some are able to withstand much higher concentrations than others. This factor in itself causes a big problem in industry, since ventilation adequate to maintain a concentration within safe limits is still not enough to prevent the person whose tolerance is low from absorbing the chemical.

The following statistics are those of a factory in the rubber industry that has been using benzol in small quantities for years. With the advent of large war orders and the increasing use of synthetic rubber, patients came to the company hospital with complaints of malaise, nausea, and vomiting, and in a few cases, of bleeding. An immediate check was made on all employees using benzol to any extent. Complete blood counts were done on 1,104 people. Of this number 83, or 7.5 per cent, showed mild blood changes and gave symptoms of having some slight absorption of benzol fumes. Twenty-five, or 2.2 per cent, showed severe blood changes with symptoms of severe benzol intoxication. These patients had to be treated over a long period of time. Of the above 25 cases, 9 were confined to the hospital for a period of time and received blood transfusions

*Now Captain in United States Army, Medical Corps.
Received for publication, March 12, 1942.

varying in number from a low of 2 to a high of 50. Three patients of the above 9 died. For absolute certainty in the diagnosis a bone marrow biopsy and study were done on all the severe cases. This degree of fatality of three patients out of 25 with aplastic anemia, or 12 per cent, is low. This low incidence was believed to be due to the extreme amount of treatment received. The treatment given will be explained later.

SYMPTOMS

Individual susceptibility is the governing factor in the appearance of symptoms. Some patients can apparently be exposed to large concentrations of benzol without effect. Others show symptoms when the concentration is as low as 5 parts per million. The United States Public Health Service states that young intelligent girls are the most susceptible.

Acute benzol poisoning is rare. The symptoms of an acute case are referable to the central nervous system. There are muscular tremors, salivation, violent twitchings, exhaustion, paralysis, narcosis, convulsions, and death from paralysis of the respiratory center.

The common cases are those of long exposure to fairly small concentrations of the fumes; that is, concentrations usually below 100 parts per million, with occasional sharp exposures of 500 to 1,000 parts per million, such as occur when fumes are obtained from the opening of a can of benzol or from the heating of material containing benzol. The concentration of fumes to which the patients studied were exposed varied between 50 and 500 parts per million, with the average concentration being about 100 parts per million. Then the symptoms are lassitude, malaise, nausea, vomiting, dizziness, and headaches, usually frontal in character. If there is any skin absorption, a macular dermatitis will appear at the site of exposure. As exposure continues the above symptoms become more severe. Petechiae, scattered over the body, appear. Hemorrhages under the skin and from the body cavities may occur. In one case ecchymoses and petechiae were the first symptoms that appeared. At the time of appearance the count was normal. In five days the white blood cell count was 500. Diplopia, especially for close distances, occurs in some cases. If the person is highly susceptible, or if the exposure has been great and prolonged, he may get physiologic or functional depression of the bone marrow. This varies in degree from a slight hematopoietic suppression to a total bone marrow aplasia.

The symptoms of a total aplasia are those of benzol absorption followed by prostration. On the other hand, it is sometimes strange how well the patient may appear. Aside from fatigue he may have no other complaints.

The best index of benzol absorption is the blood count. All blood counts should be done with pipettes that have been standardized by the United States Bureau of Standards. The improved Newcomer method of hemoglobin determination is preferable. All components of the blood are affected, being lowered. Most important, the total leucocyte count falls. Special reference should be made to the differential count. The ratio of polymorphonuclear cells to monocytes is changed. The number of monocytes increases and the polymorphonuclear cells decrease. The red blood cell count is lowered. If it makes a drop of 25 per cent, the employee should be removed from the fumes. The hemoglobin also falls. It has been reported by some investigators that the blood count

may be raised at first. However, when this occurs it is quickly followed by a general lowering of the count. The platelet count is lowered, dropping to practically zero in severe cases. The reticulocyte count is also lowered. The prothrombin time is normal. The resulting picture is one of aplastic anemia. One of our patients exhibited a count of 125 white blood cells, 1,500,000 red blood cells, and 25 per cent hemoglobin. This man died. The red blood cells exhibit anisocytosis, poikilocytosis, and polychromatophilia. In all patients showing a marked blood reduction a bone marrow biopsy should be done. The degree of aplasia can be determined, and usually an accurate prognosis can be made. Patients with total aplasia always die. Patients with partial aplasia have a prognosis dependent upon the amount of regeneration present.

Urine examinations are usually negative for albumin and sugar. The urinary sulfate test, which is a ratio between the total sulfates and the inorganic sulfates present in the urine, is useful in indicating absorption of fumes. The ratio is lowered when the absorption is great. This is because the inorganic sulfates are increased. This test is useful only at time of exposure, the ratio returning to normal in about four hours when the patient is in fresh air. Normally the ratio is about 0.75. In severe exposures it may be lowered to 0.25. Lowering of the ratio is an indication for removal of the employee from exposure to the fumes.

The blood pressure may be lowered. This test is not significant unless it is accompanied by other positive findings.

DIFFERENTIAL DIAGNOSIS

Aplastic anemia is to be differentiated from agranulocytosis and acute leucemia. The symptoms of both of these diseases are very similar. In agranulocytosis the red blood cell and platelet counts are usually essentially normal. In acute leucemia the white blood cell count may be normal, raised, or lowered. The differential count shows a marked increase in very young white blood cells at the height of the disease of acute leucemia. The liver and spleen are usually enlarged in acute leucemia and are normal in aplastic anemia and agranulocytosis. The lymph nodes are normal in aplastic anemia and are usually enlarged in leucemia. In agranulocytosis the lymph nodes of the neck are usually enlarged and are painful and tender. Hemorrhages are common in aplastic anemia and leucemia, and are rare in agranulocytosis. Sore throat is common in leucemia and especially so in agranulocytosis. It must be recognized that the differential diagnosis between these three diseases may be difficult. Bone marrow studies usually reveal the proper diagnosis.

PROPHYLAXIS

This problem is one of major importance. The cooperation of the management of the company is necessary. Many different ideas have been expressed on the subject. Of course, the ideal situation would be to do away with the use of benzol. Toluene is mentioned as a substitute. This chemical, which is methyl benzene, is not as toxic as benzol because of its higher volatility. However, sufficient concentrations of the fumes of toluene will act in the same manner as benzene.

Adequate ventilation is an important prophylactic measure. A closed system of ventilation where the workman comes in contact with no fumes is ideal. Any other type of ventilation is not entirely safe. So long as any fumes are present it is possible that intoxication may occur.

The health of people working in benzol should be kept under constant supervision. Any illness or symptoms of illness should be investigated. Frequent blood counts should be made. Occasional urinary sulfate tests are of value.

The following program is suggested:

1. The testing of frequent air samples with a combustible gas indicator. Introduce ventilation in an endeavor to keep the concentration of benzol in the air as far below 100 parts per million as possible.
2. All new employees, before being permitted to work, should be given a complete blood count. Any persons with blood dyscrasias should not be permitted to work in benzol departments. No one should be allowed to work in a benzol department with a white blood cell count below 5,000, or above 13,000.
3. After ten days' employment the employee should be given a urinary sulfate test at the end of a working day. If the urinary sulfate ratio is below 50, there is a tendency to absorption, and the employee should be removed from the benzol department.
4. Any employee exhibiting symptoms should be sent to the hospital for blood studies and physical examination. A drop of 25 per cent in any blood components is sufficient reason for removal. An employee who is so removed should be given one week vacation and then placed on another job. During the week off the employee should remain as much as possible in the open air. At the end of the week the blood should be rechecked. If normal, the employee may be permitted to return to work in a nonbenzol department.

An ideal arrangement would be to use a system of repeated blood checks on exposed employees. If this were done at intervals of approximately every two weeks, it would be of benefit, but even then no positive guarantee could be given that poisoning would not occur. This type of test may be prohibitive in large industry because of the number of technicians needed to perform the counts.

TREATMENT

In patients with mild intoxication, with or without a drop in the blood count, the treatment is removal from the fumes and plenty of fresh air. These patients will return to normal in a few days with no medication.

In patients in whom absorption is sufficient to cause a marked change in the blood picture more active treatment is necessary. These patients are placed at absolute bed rest. Multiple small whole blood transfusions (about 250 c.c.) are given. One patient was given 50 transfusions, another 36. The patient is alkalized with sodium or potassium citrate on the possibility that this might prevent a reaction to the transfusions due to acidosis. When severe reactions occur, blood plasma may be used in place of whole blood.

Direct bone marrow transfusions may be given as often as twice weekly. In this procedure 2 to 5 c.c. of bone marrow are removed from the sternum of a compatible donor and introduced directly into the sternum of the patient. From the same donor 250 to 300 c.c. of blood are drawn and transfused into the patient. This is followed by 1,000 c.c. of normal saline solution.

Ten milligrams of liver are given intramuscularly daily. Large daily doses of liver, iron, calcium, phosphorus, yellow bone marrow, and multiple vitamins are given by mouth. A total of 400 to 600 mg. of ascorbic acid are given daily by mouth. This has been claimed by some investigators to be a necessary adjunct in treatment. A full diet is prescribed. The patient's general hygiene is improved as much as possible. Bleeding areas are stopped if at all possible. Pentnucleotide has been used and found to be effective in some cases.

The resistance of these patients is low due to the agranulocytosis. Secondary infection, the most common of which is a Vincent's organism infection of the mouth, is one of the causes of death. For certain types of severe secondary infection sulfadiazine in 4 Gm. daily doses has been used. Sulfanilamide powder was used on one case of secondary streptococcus infection with good effect. However, the sulfone products must be used with care since they are bone marrow depressants.

The response to therapy is slow since a considerable time is necessary for the bone marrow to regenerate. One patient has been under treatment for twelve months. He still has a low hemoglobin and red blood cell count. It has been suggested that a splenectomy be done on patients who do not respond to therapy, the rationale being that the spleen has an inhibiting effect on the bone marrow. This procedure has been reported to be successful in several patients who otherwise would probably have died.

The treatment at best is not wholly satisfactory. In too many patients the disease proves fatal. The problem of the use of benzol has become a large and vital one and as yet is not solved.

Probably the most important fact to remember about the use of benzol for industry is never to sacrifice caution in the use of benzol because the result of carelessness with this chemical is usually death.

SUMMARY

Out of 1,104 people tested who were exposed to concentrations of benzol fumes averaging about 100 parts per million for varying periods of time, 83, or 7.5 per cent, show slight blood changes, indicating slight absorption of the fumes. Twenty-five, or 2.2 per cent, showed marked blood changes. Nine of these 25 patients had a severe enough aplastic anemia to demand hospitalization. Three patients died, a 12 per cent fatality out of all the patients showing absorption, or 0.27 per cent fatality out of all the people exposed to the fumes. This degree of fatality of patients with aplastic anemia is considered to be low. The form of treatment was multiple whole blood and direct bone marrow transfusions as well as liver, iron, calcium, phosphorus, yellow bone marrow, and multiple vitamin therapy.

Prophylactic measures recommended are adequate ventilation and constant medical supervision, which is best done by frequent blood examinations.

THE BLOOD PATTERN AS A CLUE TO THE DIAGNOSIS OF MALIGNANT DISEASE

II. LEONARD BOLEN, M.D., FALL RIVER, MASS.

THE early diagnosis of carcinoma is a goal eagerly sought by science in order that treatment may be undertaken before it is too late. The greatest obstacle to progress in cancer therapy is the vagueness of the early complaints and the obscurity of physical findings. As Fitz remarked in 1939:¹

"Cancer presents a bewildering problem. To me the impressive feature of watching such cases was the apparent suddenness of onset of important symptoms. . . . If this is true, what is badly needed is a test for carcinoma analogous to the tuberculin test for tuberculosis and the Wassermann test for syphilis, so that cancer can be recognized in its preclinical state. Until such a test is discovered, cancer inevitably must continue to be discovered in most cases, when it is already far advanced."

To this end investigators have utilized the laboratory in an effort to discover the presence of cancer cells in the body before the appearance of clinical symptoms and signs. In 1940 these statements appeared² regarding the status of the search for a serologic test for cancer:

"It may be doubted whether it will be possible for science ever to place at our disposal a test so delicate as to indicate the existence of a few cancer cells in the human body; yet this is precisely the type of test most desired."

"Ordinary examination of the blood reveals no condition peculiar to malignant disease. Most observers have found a decrease in red cells, some have found a diminution in hemoglobin, others have noticed an increase in leukocytes. All these findings, however, are present only in the later stages of the disease. In many cases reported, the notation *blood negative* will be found."

According to Stahl,³ the origin of blood and the origin of cancer are very closely interwoven in primal embryologic study. Investigation indicates that there is a specific cancer cellule. This is always an immature, never a mature, cell. In the normal organism a growth-control hormone is present; when this ceases to function, the cancer cells grow, and if this growth is not checked, the neoplasm progresses, causing devastation and death.

In 1935 Boyd⁴ stated that cancer may be regarded in two ways. It may be the expression of a power for unlimited proliferation, which develops in a tissue at a certain age in its genetic life history; or a malignant condition may be imposed on cells from without by a number of carcinogenic agents, such as coal tar or dibenzanthracene. Of the exact mechanism nothing is known, and may never be known.

Does the answer lie in a study of the blood? In a physiologic sense the blood is a part of every tissue, and any change involving the fixed tissues of the body must affect the blood. Thus we have a picture of deformity of the red blood cells in anemias sufficient to clinch the diagnosis even without clinical evidence. Hematopoiesis is the sum total of the integrated functioning of all the tissues of the body.

There is not space to review the various tests which have been proposed to detect the presence of cancer cells in the human body. Fuchs's⁵ test for malignancy appeared in 1925. He examined the blood of 92 persons with cancer and 48 controls without malignant disease. The blood serum from every cancer patient digested heated human fibrin; the blood serum of the controls was invariably negative. This test has furnished the basis for later investigation. Recently Robinson⁶ used a modification of the test in 200 patients in the Vanderbilt University Hospital. Rosenthal⁷ published results with this method at the University of Pennsylvania. Esculies of Buenos Aires⁸ discussed results in 1940.

They stated that they isolated an ether-soluble protein from the serum of cancer patients, which was either the product of abnormal metabolism, or a protective ferment called into being against the invasion of abnormally metabolized protein derivatives. Further investigation is to be carried on to determine whether the protein isolated by these authors possesses fermenting activity in the presence of the same serum from which it was extracted, as well as the precise polarimetric deviation.

This test has the following limitations:

1. The growth must be over six months old.
2. The patient should not have been operated upon or have received radium or roentgen-ray treatment for at least a month.
3. The tumor must be in a period of active growth.

Pfeiffer's⁹ crystallization method for the diagnosis of cancer, which appeared in 1938, has also been widely used. He claimed that the patterns which crystals assumed after the addition of diluted blood to a solution of copper chloride was a method of differentiating between health and disease. A certain cross formation was characteristic of tuberculosis; a wing pattern was indicative of cancer. In cancer, however, the blood picture is decentralized and disorganized. The more numerous and defined the groupings, the more advanced the cancer. The fact that cancerous blood actually produces these differences, which are uniform in kind, is readily established even with a few tests. Rascher of Munich¹⁰ and Gruner of Montreal¹¹ have used Pfeiffer's method with personal modifications and have obtained a high degree of accuracy in diagnosing cancer.

The test is fairly simple. One drop of blood from a finger prick is allowed to fall into 1 c.c. of distilled water; after thirty minutes 2 drops of this are introduced into 10 c.c. of a 20 per cent solution of copper chloride. After thirty seconds the mixture is poured out upon specially prepared plates resting in a chamber. Readings of the crystallizations are made after eighteen hours.

Gruner uses polarized light to read the slides. He secured positive results in 110 of 122 patients, and in 33 normal persons the test was positive only once. Rascher examined 246 persons. In 98 there were no signs of cancer, and the clinical picture agreed in every case. In 148 patients the plates indicated cancer. In 11 the diagnosis was incorrect, three being normal, and eight having sarcoma instead of carcinoma. In nine the clinical diagnosis of cancer was doubtful. In 128 the plates were correct; all these patients had carcinoma.

Fig. 1.

For this test the technique must be extremely exact, and only fresh blood can be used (not later than five hours old). In some instances the test was repeated after excision of the cancer. In some cases the test became negative, which was interpreted as indicating complete removal. If the test was repeatedly positive, the patient was watched carefully, even though no tumor could be located.

Reports from the Lankenau Hospital¹² show an 80 to 85 per cent of reliability in diagnosing early cancer. The test needs simplification and is available only in a large medical center because of the difficult technical procedures. The cancer pattern is described as two wings rising from a straight basis line, both wings extending on the same side of the basis line.

The blood sedimentation rate has been employed for many years as a diagnostic aid. Its use in gynecology, obstetrics, and urology, and the different methods of performing this test are set forth in an excellent article by Hirsh.¹³ He outlines the Schiller modification of this test and its wider application, and analyzes the various theories regarding the factors which influence the speed with which the erythrocytes settle. The most probable explanation is that toxin production involves a breaking down of tissue proteins, and the products of disintegrated tissue proteins stimulate fibrinogen formation. The following statement of Hirsh is significant:

"We believe the sedimentation rate depends on the presence of a foreign protein in the circulation. In pregnancy, this is the protein of fetal catabolism;

Fig. 2.

Fig. 3.

in infection, it is the protein of bacteria, and in malignancy or coronary occlusion, it is the protein of necrotic tissue."

The test, although not specific for any one condition, is of great value in estimating the degree and progress of disease. According to Schiller:

"If a malignant growth be removed operatively, the blood sedimentation rate should return to normal within six weeks if complete removal has been obtained. If the rate returns to normal and remains normal at least six months, one may give a guardedly favorable prognosis. If the rate becomes abnormal within this time, it is suggestive of local recurrence of the growth or metastasis."

Wolfson and his co-workers¹⁴ recently published an article on early diagnosis of malignant metastases to the spine, and discussed the value of the erythrocyte sedimentation rate, which has a definite correlation with metastatic involvement of bone. Malignancy is often associated with an elevated phosphatase level and a rapid sedimentation rate.

In 1939 Goldberger¹⁵ published his report of a rapid bedside test for measuring the blood sedimentation rate. He pricked the finger of the patient and allowed a small drop of blood (about 3 mm. in diameter) to touch the under-surface of a clean glass slide. Since the first drop collected will be thickly rimmed, a second and third drop are touched to the slide. Then the slide is righted and the drops of blood are allowed to clot and dry spontaneously in a horizontal position. When dry, the blood is observed macroscopically by holding the slide up to the light. The criteria for reading the film are as follows:

1. Fineness or coarseness of general detail.
2. Character of meshwork, if present.
3. Presence or absence of central agglutination.
4. Presence or absence of peripheral rings.

With these in mind, four classifications of sedimentation rate can be made:

1. Normal—very fine detail; no meshwork; gradual transition from periphery to dark central agglutinated mass.
2. Moderately rapid—detail somewhat coarse, but uniform throughout; meshwork not particularly noticeable; there may be the beginning of a central agglutinated mass.
3. Rapid—coarse detail; meshwork fine, but easily observed; no central agglutinated mass.
4. Very rapid—very coarse detail; definite meshwork; no central agglutinated mass.

By careful study of a great number of slides, Goldberger found that this method proved to be a simple, rapid, qualitative gauge in the diagnosis of coronary thrombosis, rheumatoid arthritis, salpingitis, etc. He found that the rate at which the red blood cells settle is directly proportional to the degree of their rouleau formation. Moreover, there was no correlation between the red blood count and the character of the drop of blood on the slide.

This problem of the blood sedimentation continues to give rise to much speculation. Rubin and Smith¹⁶ believe that the volume of the erythrocytes

Fig. 4.

Fig. 5.

exerts an important influence on the sedimentation reaction under all conditions, and that probably physiologic changes in the sedimentation rate are also, to a great extent, influenced by the erythrocyte factor.

Davison,¹⁷ in studying the separation of the blood cells from plasma (sedimentation), concludes that the process is dependent on rouleau formation. In normal or slowly sedimenting blood, each rouleau contains few erythrocytes, and the cell aggregates appear evenly distributed. In pathologic blood showing rapid sedimentation, each rouleau contains many corpuscles, and the rouleaux are clustered together, leaving large areas of free plasma between them. The sedimentation rate is directly proportional to the size of the cell aggregates or rouleaux.

Fig. 6.

Impressed with the simplicity of Goldberger's method, the author decided to obtain a similar record of the blood on every patient, to see whether it would afford material aid in diagnosis, prognosis, and therapy. In each case, the finger was pricked, and 3 small drops of blood were collected on a glass slide and allowed to dry after the method of Goldberger. The patterns which the blood assumed, both macroscopically and microscopically, have proved of great value, especially when considered with clinical and laboratory findings.

The most interesting phenomenon was the distinctive pattern of the blood obtained from cancer patients. The pattern characteristic of normal blood

and of blood from patients with ulcer, inflammatory disease, etc., is devoid of meshwork. There is no breaking up of the fibrin; the blood is more compact. In the central part of each drop of blood is a dark agglutinated mass (Fig. 1). Invariably, the pattern formed by cancerous blood is that which I describe as the "dotted curtain" type (Fig. 2). Peripheral rings are absent, and no agglutinated mass can be seen in the center. The blood is broken down into "dots." The microphotograph of normal blood (Fig. 3) and (Fig. 5) is contrasted with the microphotograph of cancerous blood (Fig. 4) and (Fig. 6). Under the microscope the cancerous blood shows numerous three-cornered, tri-asteroid spicules scattered throughout. In no other condition have these spicules or rays been found in such abundance.

In six conditions listed in Table I I have demonstrated that a positive pattern was obtained. In all these, however, the clinical findings have differentiated the condition from cancer. Moreover, the positive reaction gradually changed to negative as the proper treatment was instituted. The laboratory analysis of the blood shed no light on the problem of diagnosing cancer.

TABLE I
CONDITIONS YIELDING TEMPORARY CARCINOMA PATTERN

	POSITIVE	NEGATIVE	TOTAL
Acute rheumatic fever	3	7	10
Rheumatoid arthritis	2	2	4
Active tuberculosis	5	8	13
Pregnancy	3	4	7
Pernicious anemia	2	2	4
Coronary disease	4	6	10
Total	19	29	48

TABLE II
CASES OF APPARENTLY CURED CANCER

	POSITIVE	NEGATIVE	TOTAL
Clinically Cured After Surgery:			
Breast	0	2	2
Stomach	0	1	1
Rectum	1	3	4
Prostate gland		2	3
Clinically Cured After Irradiation or Radium Therapy:			
Epithelioma, face	0	1	1
Hodgkin's disease	0	1	1
Breast	1	3	4
Sarcoma	0	1	1
Total	3	14	17

The same transition from positive to negative blood pattern on the slide occurred when "cures" were obtained in cancer patients, either by total extirpation surgically of the neoplasm, or radium implantation, or deep x-ray therapy.

The cases I have had in this category are noted in Table II.

Although the cases listed in Table II are few, the tendency is for the blood pattern to approach normal with eradication of cancerous elements. In the great majority of cancer cases, whether treated or untreated, the blood shows the

typical carcinoma pattern described above. It is so characteristic that it is usually possible to identify at a glance which of the slides bear the cancer pattern merely by holding them up to the light.

No relation has been found between the blood count and the carcinoma pattern. The similarity of the blood analyses in normal and cancer patients is apparent from a study of 50 unselected cases in each category, as seen in Table III.

TABLE III

TYPE	NO. OF CASES	HEMOGLOBIN	ERYTHROCYTE COUNT	LEUCOCYTE COUNT
Normal	50	70%-92%	3,200,000 to 4,500,000	7,500 to 10,000
Carcinoma	50	40%-90%	3,000,000 to 4,200,000	5,900 to 18,000

Tables IV and VI include analyses of the various conditions encountered in my practice since 1939, and the type of blood patterns which were noted on the slides. In some instances, these tests were made on the same patient weekly or monthly, before and after treatment for the specific condition.

TABLE IV
GROUP OF NONCANCER CASES

DISEASE	POSITIVE	NEGATIVE	TOTAL	% POSITIVE
Appendicitis	0	10	10	0
Diverticulitis	1	4	5	20
Encephalitis	0	1	1	0
Endometriosis	1	1	2	50
Epilepsy	0	6	6	0
Gall bladder disease	0	28	28	0
Hypertension	0	15	15	0
Meningitis, tuberculous	0	2	2	0
Pneumonias	0	5	5	0
Poisoning (methyl alcohol)	0	2	2	0
Tuberculosis (arrested)	0	4	4	0
Ulcer, gastric and duodenal	0	34	34	0
Ulcerative colitis	0	12	12	0
Miscellaneous	0	6	6	0
Total	2	130	132	1.5

Thus in this group of noncancer cases selected at random, there was a positive reaction in the blood in two conditions only; the margin of error was only 1.5 per cent. All readings in cases of appendicitis were normal regardless of the pathology. A case of ruptured appendix with peritonitis, myocardial damage, hypertension, diabetes mellitus, and a high nonprotein nitrogen reading showed a negative blood pattern. There were no positive readings in the gastric and duodenal ulcer patients, even when the hemoglobin was lower than 65 per cent. In the arrested stage of tuberculosis a normal pattern was seen, although a positive pattern was obtained in several patients with active tuberculosis. Also, in cases of coronary occlusion a positive pattern was noted about the second or third day. There was a return to normal as the condition of the patients improved.

Table V contains a classified list of cases of proved cancer. The slides of 140 of these patients were reviewed. In this series the age incidence is indicated.

TABLE V

AGE GROUP	SEX		TOTAL NUMBER OF CASES
	MALE	FEMALE	
Under 40 years	5	4	9
40 to 50 years	5	12	17
50 to 60 years	19	16	35
60 to 70 years	23	18	41
Over 70 years	17	21	38
Total	69	71	140

The results of the blood test for cancer are tabulated in Table VI.

TABLE VI
PROVED CARCINOMA CASES

SITE	POSITIVE	NEGATIVE	NUMBER OF CASES
Adrenal glands	1	0	1
Bladder	3	1	4
Breast	9	0	9
Breast, recurrent	3	0	3
Breast, metastases to lung	4	0	4
Breast, skeletal metastases	6	0	6
Gastrointestinal tract:			
Esophagus	1	0	1
Stomach	35	2	37
Colon	27	0	27
Rectum	11	0	11
Epidermoid carcinoma, cheek	1	0	1
Epidermoid carcinoma, nose	1	0	1
Throat	1	2	3
Larynx	1	0	1
Skin	1	0	1
Pancreas	4	0	4
Prostate gland	5	1	6
Uterus	7	2	9
General carcinomatosis	1	1	2
Hodgkin's disease	2	1	3
Sarcoma, osteogenic	0	2	2
Miscellaneous	4	0	4
Total	128	12	140, or 91.4% positive

A comparison of the noncancer and cancer cases revealed that a positive pattern was often obtained when there was no sign of anemia. The red blood cell count was an unreliable guide as to the state of the patient and the stage of the disease. With decrease in the cell count there was a corresponding decrease in the hemoglobin. A leucopenia was noted in patients with skeletal metastases. Increase in the white blood cell count invariably denoted peritoneal involvement or infection. But the red blood cell count, the white blood cell count, and the hemoglobin were of no help in differentiating between cancer and noncancer cases.

Two representative cases are herewith reported in some detail to illustrate the value of the test in diagnosis and treatment.

CASE 1.—J. C., a white male, aged 47 years, was seen at the office on January 6, 1940. At this time he stated that he had always been well until about two years before. In January, 1938, he began to have attacks of mid-epigastric pain, which occurred an hour after meals. These were relieved, at first, by alkalis or by vomiting. Attacks increased in frequency and severity. In February, 1939, he was x-rayed and told that he had a "growth" in the stomach. He was put on a diet and given "injections."

He continued on this regime for another year. Heartburn, postprandial pain, and vomiting occurred at frequent intervals, and the patient became weaker. He had a good appetite but was afraid to eat because of the subsequent pain and distress. He lost 30 pounds and began to complain of dyspnea on exertion.

Fig. 7.

When first seen at our office in January, 1940, he stated that the pain had increased in severity. However, it never radiated to back or shoulders. He had no cough, hemoptysis, hematemesis, or melena. He was thin, pale, and listless. There was slight tenderness in the epigastric region, but no palpable mass. Three drops of blood on the slide showed a normal pattern. The patient was placed on a Sippy regimen. The following month the blood test was repeated and showed no change.

Because of inability to retain food and continual pain, the patient was seen again at the office on March 10. Another slide of the blood was made. In this the central nucleus was absent and there was definite formation of spicules. Since I felt that he had gastric cancer, patient was immediately referred to the hospital for surgery.

X-ray examination of the gastrointestinal tract was made. The impression of the radiologist was gastric ulcer, prepyloric.

Examination of the blood showed 44 per cent hemoglobin, 3,630,000 erythrocytes, and 8,400 leucocytes. The differential count was normal. There was very slight variation

in the size and shape of the red blood cells. The blood sugar was 95 mg., the nonprotein nitrogen was 33 mg. The benzidine test for occult blood in the stool was positive.

Gastric analysis on March 11, 1940, showed the following:

		<i>Free Acid</i>	<i>Total Acidity</i>
Fasting	68 c.c.	None	8 degrees
1st specimen	3 c.c.	10 degrees	32.5 degrees
2nd specimen diluted with water		10 degrees	16 degrees
3rd specimen	10 c.c.	20 degrees	80 degrees
4th specimen diluted with water		12 degrees	29 degrees
		52 degrees	165.5 degrees

On March 15, 1940, a subtotal gastrectomy was done for what appeared to be a prepyloric ulcer. A regional node was also excised for pathologic examination. The pathologic report, to the surprise of radiologist and surgeon, was gastric ulcer with small focus of carcinoma and metastasis to the regional lymph nodes. Fig. 8 shows a portion of the stomach with neoplasm removed at operation.

Fig. 8.

Except for an upper respiratory infection on the fifth to eighth postoperative days, the patient made a satisfactory convalescence, and was discharged improved April 7, 1940.

Six weeks after operation he was seen at the office. Examination of the blood showed that the pattern on the slide was now that of normal blood. This patient has been seen at frequent intervals since operation. There has been no recurrence of symptoms clinically. He works every day and has gained over 60 pounds. To date, January 15, 1942, the blood pattern on the slides has remained normal.

CASE 2.—D. P., a housewife, 46 years old, was admitted to the General Hospital on January 1, 1941, with the chief complaint of pain in the lower abdomen above the pubis, more severe after the menses. She stated that for the last three months menstrual pain had started about three days before the onset of flow, continued throughout the menstrual period of six or seven days, and persisted for a week after cessation. There was also a watery pinkish discharge for three days following menstruation.

She reported no previous serious illness. Catamenia began at the age of 15, a regular twenty-eight-day cycle, heavy flow, of nine days' duration. She had borne six children, all normal deliveries.

The patient's mother died of cancer of the uterus. One sister had uterine fibroids. There was no family history of tuberculosis, heart disease, allergy, or diabetes mellitus.

Physical examination revealed tenderness in both tubo-ovarian regions and in the suprapubic area. No masses or spasm were noted. The cervix was low near the introitus, large, both lips somewhat firmer than normal, both containing several small cysts. There was slight cystocele and rectocele.

Examination of the blood revealed 70 per cent hemoglobin, 4,100,000 erythrocytes, and 13,000 leucocytes. The differential count was normal. Three drops of blood on the slide, however, showed definitely the carcinoma pattern.

The clinical diagnosis was uterine fibroids.

Fig. 9.

Operation was done on the following day, January 2, 1941. Laparotomy revealed a large tumor mass attached to the sigmoid. The tumor and the adjacent mass were brought out through the incision, and the wound was closed around them. On the ninth day the exteriorized loop of bowel and the tumor were removed (Fig. 9). The pathologic report was as follows:

The segment of sigmoid colon removed measured 18 by 8.5 cm. Protruding into the lumen and causing constriction, but not complete obstruction, was a large cauliflower growth, measuring 8 by 6 by 4 cm. Microscopically, the tumor mass was composed of columnar, glandular, epithelium; several mitotic figures were noted. The tumor invaded the submucosa. Diagnosis: Adenocarcinoma of the sigmoid.

This patient remained in the hospital. On March 15, 1941, rectal examination revealed metastases to the rectum. The patient was discharged on June 28, 1941. She is still alive at home, complaining of pain in the region of the sigmoid and rectum.

CONCLUSION

After a review of over 4,000 of these slides, two dominant blood patterns were noted: the first characterizes that of healthy persons and patients with

a variety of complaints; the second characterizes that of patients with cancer, and also those who have primary pernicious anemia, some with rheumatoid arthritis, and a few in late pregnancy. When treatment was instituted, however, in all but the cancer patients, the blood pattern changed to normal. In the cancer patients the typical "dotted-curtain" pattern persisted, except when total extirpation was achieved. Slides made on cancer patients up to within half an hour before death showed the same honeycombed appearance of the blood pattern. In patients in whom surgery had apparently removed all the tumor, and in some patients treated by radium or deep x-ray therapy, the blood pattern was found to return to normal after an interval of six weeks or more. No blood slides on patients who have remained well after operation for cancer have been made sooner than six weeks after operation. In one case of "cured" cancer of the stomach, the patient has had slides made weekly for a period of twenty-three months, and these have all been normal.

The erythrocyte count, the leucocyte count, and the hemoglobin appear to have no relationship with the carcinoma blood pattern on the slide. In my experience in cancer patients the blood picture changes relatively late. There is often a high red blood cell count and hemoglobin, with no indication of a malignant process. The changes in the blood picture occur only after clinical symptoms and signs have made it apparent that the disease is well advanced. Therefore, I have found this blood pattern test on the slide, when employed routinely, is of great value in suggesting, at least, the presence of carcinoma before it is discovered clinically or by roentgen ray.

Constant familiarity with a long series of slides enables the examiner to obtain a high percentage of correct readings. Erroneous interpretations have resulted, but the margin of error is small. This has happened when the technique has been faulty and the drops of blood have been too thick or have been smeared or not allowed to dry sufficiently; also the blood picture has changed somewhat when patients have had deep x-ray or radium therapy or repeated transfusions. We have already referred to those patients with pernicious anemia, etc. (Table I) in whom the reaction has been positive for a limited period.

The test is simple and can be done in the office by the examiner or his assistant with inexpensive equipment and with no loss of time during the course of a routine office examination. It is not offered as a *sine qua non*, but as an adjunct to be evaluated along with clinical and laboratory findings. In spite of a negative x-ray film, the test, if positive, should be carefully weighed and the patient closely watched. It may be an even more delicate index of the patient's condition than the clinical picture, leucocyte count, temperature curve, blood analysis, or x-ray film. The test is done routinely on every patient along with the general physical examination. Sometimes this cancer pattern has been the sole evidence of the presence of malignancy, and has led to a more thorough study of the patient.

Our results justify the continued use of this test as a detector of early malignant tumor formation.

BLOOD PRESSURE FLUCTUATIONS IN RESPIRATORY OBSTRUCTION*

EXPERIMENTAL OBSERVATIONS

HOWARD OSGOOD, M.D., BUFFALO, N. Y.

WITH THE TECHNICAL ASSISTANCE OF ROBERT S. BERKSON, DONALD W. HALL,
MURL E. KINAL, AND ABIE S. LENZNER

IT HAS long been known that in normal persons and in animals there is a slight fluctuation of the systemic systolic blood pressure during quiet respiration.¹ In asthma patients, when the dyspnea is pronounced, it has been noted that the systolic blood pressure may fluctuate markedly during the respiratory cycle.²⁻⁵ This fluctuation decreases as the asthmatic paroxysm subsides,^{3, 4} and is usually within the normal limits of quiet respiration when the patient is asthma free.⁴

Recent literature reveals some experimental work with animals on the effects of various types of respiratory obstruction.⁶⁻⁹ The reports include data on lung volume, blood changes, and the production of emphysema, but very few observations have been made of the effects of such obstruction on blood pressure.

The following experiments were carried out in order to determine whether blood pressure changes, similar to those observed in asthmatic patients, could be induced at will by obstructing respiration in animals and in man, and to detect a quantitative relationship, if any, between the amplitude of these changes and the degree of respiratory obstruction.

Received for publication, March 16, 1942.

ANIMAL EXPERIMENTS

Cats were used anesthetized by chloralose rectally. Experiments were carried out on a number of animals, all of which responded similarly to the various procedures.

Simultaneous kymograph tracings were made of the carotid blood pressure, the intratracheal air pressure, the intrapleural pressure, and the respiratory movements. The blood pressure manometer was of mercury; the air pressure manometers were of water (see Fig. 1 for details of preparation of the cat). One to 3 c.c. of air were injected into the pleural cavity to prevent closure of the intrathoracic end of the blunted needle.

3mm. TRACHEAL Opening

4mm. TRACHEAL Opening

Chart 1.

Chart 2.

Charts 1-5.—Rest, respiratory rest interval; Insp., inspiration; Exp., expiration. Scale drawings from Figures, bringing all simultaneous moments of time into the same vertical draw through the curves.

The open end of the T-shaped tracheal cannula was provided with a short rubber sleeve into which could be inserted short lengths of glass tubing with various-sized lumina. At the beginning of each experiment a glass tube with the lumen approximately equal to the diameter of the trachea was used, assuring free breathing. Successively smaller tubes were then inserted, introducing increasing obstruction to the respired air. Tracings of sufficient length were made with each size to secure reliable records. None of the cats survived with the 0.5 mm. tube in place. Tracings were continued until death.

The charts are scale drawings from the tracings, corrected so as to bring all points in any vertical line drawn through the tracings into the same moment

of time. The downstroke in the three respiratory tracings represents inspiration; the upstroke, expiration. The time line, with five-second intervals, lies at zero blood pressure level.

The following results are from continuous observations on a single cat, a healthy female, weighing 3.2 kg., anesthetized with 0.32 Gm. of chloralose.

A study of the tracings, and of the charts developed from them, will show several significant things.

With free breathing (4 mm. opening) there was a respiratory fluctuation of the blood pressure, amounting to about 4 mm. Hg. When the 3 mm. and 2 mm. openings were inserted, this fluctuation was increased slightly to about 5 mm. Hg. As would be expected, the fluctuations of the intratracheal and intrapleural pressures during respiration also increased somewhat, the increase being more noticeable in the intratracheal pressure, and with the 2 mm. opening. With the latter opening in place there was moderate respiratory obstruction.

The low point of the blood pressure, with free breathing (4 mm. opening) and with the 3 mm. and 2 mm. openings in place, occurred during inspiration, and the high point occurred during the latter part of expiration.

Chart 5.

Fig. 1.—Preparation of the cat.

FIGS. 1-5.—Ab. R., abdominal respiration, mechanical; Tr. P., intratracheal pressure; B.P., blood pressure, carotid; Pl. P., intrapleural pressure; Time signal indicates five-second intervals and is at blood pressure zero.

When the 1 mm. opening was inserted, inducing marked respiratory obstruction, there was an immediate increase of the blood pressure fluctuation to 10 mm. Hg. This was raised still further to 15 to 20 mm. Hg when the 0.5 mm. opening was put in place. This smallest opening presented very marked obstruction to the respired air, causing the death of the cat from asphyxia eight or ten minutes later. The low point of the blood pressure still occurred during inspiration, and the high point occurred during expiration with both of these openings, although the exact location of these points cannot be precisely determined due to the wide swings and to the inertia of the water manometers used to record the intratracheal and intrapleural pressures.

Fig. 2.

With the two smallest openings in place there was a tremendous swing of the intratracheal air pressure during inspiration and expiration, and a correspondingly large swing of the intrapleural pressure. As indicated by these two respiratory tracings, the intrathoracic pressure is greatly reduced during inspiration, and greatly increased during expiration.

SUMMARY OF FINDINGS ON CATS

The normal respiratory fluctuation of blood pressure in the anesthetized cat was increased very little when slight or moderate obstruction was presented

to the respired air at the trachea. When greater degrees of obstruction were created, the amplitude of this fluctuation increased two to four times; i.e., beyond a certain point, the greater the obstruction, the greater the blood pressure fluctuation.

The maximum and minimum blood pressure fluctuations occurred in the same phases of the respiratory cycle, whatever the degree of respiratory obstruction; i.e., the low point occurred during inspiration, and the high point during expiration.

Fig. 3.

HUMAN EXPERIMENTS

In human beings fluctuations of the systolic blood pressure, synchronous with respiration, may be observed with considerable accuracy, using an ordinary sphygmomanometer. The 13 cm. cuff about the upper arm is inflated to above the systolic pressure. It is then slowly deflated (not over 2 or 3 mm. Hg per breath) while the respiratory movements are watched. At the high point of the systolic respiratory fluctuation a few arterial beats will be heard in the antecubital space by auscultation, followed by a trough of silence. If the cuff pressure is further lowered slowly, beats will come through more and more until they are heard throughout inspiration and expiration. The pressure reading where they are just heard throughout both phases of respiration marks

the low point of the fluctuation. On quiet breathing in normal persons, the fluctuation of the systolic blood pressure amounts to between 2 mm. and 6 mm. Hg, with the high point during expiration, and the low point during inspiration.

Healthy young medical students in their twenties were used for the following experiments, using the foregoing method for determining the fluctuation of the systolic blood pressure. The subjects were recumbent.

With the nose closed with a clip and a wide rubber mouthpiece, bearing a thumb-screw pinchcock, held tightly in the mouth, the respiratory fluctuations of the systolic blood pressure were determined, first on free breathing, then with the mouthpiece narrowed in successive stages.

With the smaller apertures there was marked obstruction to respiration, and the respiratory rate was slowed to permit the passage of the tidal air. In all three subjects the low point of the blood pressure fluctuation came during inspiration, and the high point during expiration, both in free breathing and with all degrees of obstruction.

Since the respiratory efforts in breathing through small apertures resembled those of hyperventilation, blood pressure readings were made on healthy subjects with unobstructed breathing, both during quiet respiration and during voluntary hyperventilation.

Fig. 4

As with the experiments with obstruction, likewise in hyperventilation, the low point of the systolic blood pressure fluctuation occurred during inspiration, and the high point during expiration.

Obstruction to respiration at the mouth caused an increase in the respiratory fluctuation of the systolic blood pressure roughly parallel to the degree of obstruction, as in the cat experiments. Hyperventilation alone, on the other hand, caused no increase in this blood pressure fluctuation in two subjects. In the third there was a moderate increase after hyperventilation had continued from one to two minutes.

DISCUSSION

Prinzmetal⁸ showed that the normal, slightly negative intrapleural pressure became more negative in asthmatic patients during the paroxysm, although he did not describe the fluctuations of this pressure during each respiratory cycle. In our cat experiments the intrapleural pressure fluctuated to an increasingly greater negativity during inspiration and showed an increasing, though less marked, movement toward the positive side during expiration, as the tracheal obstruction was increased.

Fig. 5.

It would seem, therefore, that the fluctuations of the systolic blood pressure under respiratory obstruction, observed in our experiments, are closely related to the concurrent changes of the intrathoracic pressure during the respiratory cycle, and that their amplitude reflects roughly the degree of respiratory obstruction.

It would be unsafe to apply directly the results of these animal and human experiments to an explanation of the respiratory fluctuations of the systolic blood pressure observed in asthmatic patients, since the site of the obstruction to respiration differs in the two cases. Nevertheless, there is obstruction to breathing in bronchial asthma; and it has been shown⁸ that the intrathoracic pressure deviates from the normal in this condition. Moreover, unpublished

observations which I have made show that the blood pressure fluctuations in asthma closely resemble those seen in our present experiments, both in their timing during the respiratory cycle, and in the parallelism between their amplitude and the degree of respiratory embarrassment. The assumption to be drawn, therefore, is that forces are in action in bronchial asthma, similar to those in the experiments here described and that these forces have a causal relationship to the observed blood pressure fluctuations.

CONCLUSIONS

Cat Experiments

1. The greater the obstruction at the trachea to passage of the respired air, the greater the fluctuation of the blood pressure during the respiratory cycle.
2. Whatever the degree of respiratory obstruction, the high point of the blood pressure occurs during expiration, and the low point during inspiration.

Human Experiments

1. Marked respiratory obstruction at the mouth induces greatly increased respiratory fluctuation of the systolic blood pressure.
2. With this obstruction in place the high point of systolic blood pressure occurs during expiration, and the low point during inspiration.

I wish to express my appreciation to Dr. Frederick Reece Griffith, Jr., Professor of Physiology, University of Buffalo School of Medicine, for much encouragement and advice, and for his hospitality in making available for this work the facilities and resources of the laboratories of his Department.

THE TREATMENT OF SEVERE PERIODIC HEADACHES WITH "DESENSITIZING" DOSES OF PROSTIGMINE*

A NEW CONCEPTION AND TREATMENT OF CERTAIN TYPES OF HEADACHES
INCLUDING THOSE DESIGNATED AS MIGRAINE AND HISTAMINE HEADACHES

LOUIS PELNER, M.D., AND M. E. AIBEL, M.D.
BROOKLYN, N. Y.

OF THE many ills to which humanity is heir, headache is one of the most common. Even after arbitrarily dismissing those types due to increased intracranial pressure (brain lesions and hypertension), sinusitis, anemia, and the so-called "nervous" headaches, there still exists an extremely large group of periodic headaches loosely termed "migraine."

Brickner¹ has described "migraine headache" as a severe periodically recurring, unilateral headache which lasts from a few hours to several days, and is often accompanied by nausea and vomiting. Not infrequently the attack is preceded by an aura, consisting of some form of visual disturbance, and in many instances a familial history of migraine or allergy is present. In women the attacks frequently occur at the menstrual periods.

A considerable number of these "migraine" headaches have recently been reclassified by Horton and others² as histamine cephalalgias because they can be reproduced by histamine injections and can be controlled by desensitizing the patient with small but increasing doses of histamine. Typically, this new class of headache is characterized by a very severe unilateral pain of a burning, boring nature, which may involve the same side of the face. The conjunctiva on this side is often injected and the face is usually flushed. In general, the attacks occur more frequently, but are of shorter duration than the migraine type—lasting from fifteen minutes to several hours. Further points of difference exist in that they are not preceded by auras, vomiting is rare, and they are usually confined to the older age group.

The present work has been motivated by the desire (1) to extend the group of vascular headaches described by Horton to all those manifesting a marked skin reaction to histamine or acetylcholine; (2) to demonstrate a new method of producing these headaches; and (3) to present a new, very simple and extremely encouraging method of treating them.

The original stimulus to the present study was supplied by a chance observation in a patient with a typical histamine headache, as described by Horton. Several weeks subsequent to the cessation of histamine desensitization therapy,

*From the Department of Medicine, Jewish Hospital of Brooklyn, and the Department of Surgery, Beth Moses Hospital of Brooklyn.
Received for publication, February 2, 1942.

this patient suffered an attack which was aborted with remarkable promptness by the administration of one tablet of prostigmine bromide. Some time later, when his desensitization had apparently lapsed and he was on the verge of another headache, similar treatment with prostigmine produced a typical, very severe, cephalalgia, accompanied by fullness in the back of the head, diarrhea, abdominal cramps, and a mild attack of wheezing. It would appear, therefore, that prostigmine was able to duplicate in this patient with a typical "histamine cephalalgia," the actions of histamine in both the desensitized and sensitive phases. This observation was deemed of particular significance in view of the fact that Horton and others,² in summarizing his excellent work, stated, "The spectacular manner in which patients respond indicates that histamine treatment is as specific for this syndrome as insulin is in the treatment of diabetes mellitus."

Another hint that histamine might not be the only factor involved in this type of headache was demonstrated by another patient who failed to respond—even after two hours—to epinephrine (0.5 c.c. of 1:1,000 solution), whereas 1 c.c. of bellafolin (atropine-like in action) promptly alleviated the attack. To further confuse the issue, a preparation of histaminase (torantil), which effectively served to decrease the incidence of attacks in this patient one year ago, proved to be valueless in recent months.

In the light of these observations it was decided to investigate the effect of prostigmine on headaches of the migraine and histamine types with a view toward expanding the present knowledge of the causal relationships and the etiologic factors underlying these headaches. Accordingly, a series of 60 cases of headaches were carefully analyzed, and for the purpose of convenience were divided, symptomatically, into four principal groups. Some variations existed within each group since, obviously, though the same neurobiochemical mechanism might conceivably be operative in every case, the symptomatology was dependent upon such variables as the psychic, somatic, and endocrinologic factors. The groups were divided as follows:

Group I consisted of 20 patients with more or less typical histamine cephalalgias, who frequently manifested, in addition, such symptoms as fullness in the head, ears, and back of the neck, pain in the muscles of the neck, and dizziness.

Group II consisted of 25 patients with the "migraine" type. The headaches in this group were of longer duration than those in group I and were frequently preceded by auras and accompanied by vomiting. The patients were of the younger age group with headaches since childhood and frequently with familial histories of allergy, migraine, or premature graying of the hair.

Group III consisted of 8 patients who complained of a constant tightness and fullness in the back of the neck which did not alternate with the headaches described by Horton. Dizziness was a prominent feature in these cases, and occasionally there were full-blown attacks of Ménière's syndrome. In 2 of these patients the headaches were previously ascribed to hypertension, although the systolic pressure was 150 to 160 mm.

Group IV consisted of 7 patients with hypertension of whom 3 had systolic blood pressure of 200 mm. or more, with pounding of the vertex of the skull and fullness or tightness in the neck muscles. The remaining 4 were in the

hypotensive phase without cardiac decompensation. In these, the fullness in the head and ears, and the tightness of the neck muscles were very marked.

The common denominator in all the above groups was a marked cutaneous sensitivity to histamine and/or acetylcholine. All patients reacted markedly to 0.01 mg. of histamine (0.01 c.c. of a 1:1,000 solution) injected intradermally, by exhibiting a large wheal, pseudopodia, and an erythematous flare of 2 or more inches.* Many also gave a marked reaction to 1 mg. of acetylcholine (0.02 c.c. of a 1:20 solution). Indeed, in some instances, sensitivity to acetylcholine was more pronounced than to histamine. Many patients were also allergic to some antigen.

TREATMENT

The notable sensitivity to acetylcholine was regarded as presumptive evidence of the possibility that acetylcholine might be a factor in the production of these headaches. It was hoped, therefore, that these patients could be "desensitized"—through a mechanism parallel to that operative in histamine "desensitization"—by the oral administration of increasing doses of prostigmine bromide, a parasympatheticomimetic drug, which is known to mobilize the acetylcholine reserves of the body by inhibiting the action of the acetylcholine esterase. Accordingly, a 15 mg. tablet of prostigmine bromide was dissolved in one ounce of water, and the resulting solution was administered as follows: On the first day, 1, 2, and 3 drops were given at morning, noon, and night, respectively. The increase of 1 drop per dose was maintained until 30 drops was reached, following which 30 drops were given each day for one week and then three times per week for an indefinite period. Occasionally, when it was felt that the results could be improved, the dose was increased to 40 drops. A few of the patients were given these drops in a slower fashion, e.g., the same dosage was given morning and night, and was increased by one drop each day until the dose of 30 drops was reached. Then the usual procedure was followed. This method was used when it was felt—on the basis of skin tests—that the patient was unduly sensitive to histamine or acetylcholine. For the purpose of uniformity in this experiment the majority of the patients were given identical dropper bottles containing previously prepared solutions.

The patients were initially skin tested with histamine before the institution of treatment, and repeat tests were made at approximately weekly or fortnightly intervals. Some were also tested with acetylcholine. Care was taken to swab the skin lightly with alcohol before the intradermal injection because vigorous rubbing in itself could produce a reaction in sensitive persons. A 26 gauge Schick needle with a tuberculin syringe was used for the test. The test was read arbitrarily five minutes after injection, traced on cellophane with a skin pencil, and retained for future records.

RESULTS

Significantly, in 40 per cent of the cases the skin reaction to injected histamine decreased, i.e., the size of the wheal was reduced, and the flare dimin-

Since nearly all persons give some reaction to intracutaneously injected histamine, it has been necessary to employ this criterion for a marked reaction. (Atkinson, M.: Observations on Etiology and Treatment of Ménière's Syndrome, J.A.M.A. 116: 1753, 1941.)

ished or disappeared by the treatment with "desensitizing" doses of prostigmine. Often in the initial histamine skin test there was marked localized itching, a symptom which was not evident in subsequent skin tests after the patients developed tolerance. There was no correlation, however, between the size of the wheal at a given time and the measure of relief. Of especial significance was the fact that the acetylcholine wheal and flare were always reduced in size following treatment. After one week the time taken for disappearance of the acetylcholine flare from the skin was usually halved.

TABLE I

GROUP	TYPE	LITTLE OR NO RELIEF	MODERATE RELIEF	MARKED TO COMPLETE RELIEF	TOTAL NUMBER OF CASES
I	"Histamine" headache	2	1	17	20
II	"Other migraine types" of headache	2	1	22*	25
III	Fullness in back of neck and dizziness + occasional attacks of Ménière's syndrome	0	0	8	8
IV	Hypertension with fullness in back of neck. Experimental	0	3	4	7

*Since the acceptance of this paper, 11 (50 per cent) of these patients have reverted to the "moderate relief" designation. The reason for this is not clear but is being investigated.

All the patients exhibiting definite periodic headaches, including those similar to the headache described by Horton, and those usually classed as migraine were relieved in large measure. The relief was definite, dramatic, and in many cases complete, for the duration of time so far observed. The results are recorded in Table I. The figures are based on patients' estimates of relief of their headaches, and are, therefore, rather arbitrary. Several persons independently observed that even though a mild headache did occur, it could be dispelled in a few minutes by taking 15 drops of the solution.

In the patients with hypertension, that part of the headache described as fullness in the head, with the complaint that the head was twice the normal size, and the feeling of tightness of the neck muscles were relieved in several cases. The part ascribable to the hypertension, i.e., the pounding of the vertex of the skull, was not improved. The blood pressure was not reduced by this medication, but some patients with hypertension had only the fullness of the head and felt well once this was gone. The patient with hypertension in the hypotensive phase was usually completely relieved of symptoms, although the blood pressure did not rise.

CASE REPORTS

CASE I.—C. M., male, aged 31 years, had a history of three years of severe, unilateral, burning and boring type of headaches, which lasted from several hours to a full day. These occurred about twice a week. There was no vomiting or aura. The patient's eyes teared, and his face appeared flushed on the side of the headache. For two months prior to treatment the headache appeared about four or more times a week and completely disabled him. The patient noticed that alcohol, even in slight quantities, could bring out a severe headache.

During the past year he has had three attacks of fullness in the back of the neck, coupled with dizziness that lasted all day. His previous history revealed a healed tuberculosis. His father has osseous tuberculosis. On May 25, 1941, the patient was put on prostigmine in desensitizing doses. On June 1 he had a slight headache over the whole forehead, but no unilateral headache. On June 8 he had one mild headache over the whole forehead, but again he had no unilateral headache. On June 15 he had one mild unilateral headache. The patient was last heard from on Oct. 1, 1941, at which time he stated that he had had no more unilateral headaches. Occasionally, after taking a drink of liquor, he developed a sensation as if a headache were about to come, but it never materialized. He was told to continue the medication. The histamine wheals are shown in Fig. 1.

Fig. 1.—Histamine wheals (one-fourth actual size). Case 1, C. M.

Fig. 2.—Acetylcholine wheals (one-fourth actual size). Case 2, L. P.

CASE 2.—L. P., female, aged 30 years, gave a history of severe unilateral headaches since childhood. The headaches usually lasted for about eight hours and culminated in vomiting. There was no lacrimation or flushing of the face. Occasionally there were some preheadache phenomena of slight blurring of vision. The only time in recent years that the patient has been free of headaches was during her two pregnancies, and a short interval when histaminase appeared to diminish the frequency of attacks. These severe headaches had been occurring at the rate of three to four times a week during the month previous to institution of treatment. They were especially frequent during shopping tours. The patient was also extremely reactive to soap, large blotches appearing on her skin after using any soap. The family history revealed that her brother has severe hay fever, and her sister has many attacks of vomiting and unilateral headaches that are not severe and last a short time. Her physical examination revealed a blood pressure of 120/90, normal eye grounds, normal refraction of the eyes, and normal ear, nose, and throat findings. On Sept. 24, 1941, following recovery from a very severe headache, she was skin tested with acetylcholine intradermally and prostigmine bromide was started in "desensitizing" doses. On September 31 she reported that

she had had no headache for a week, though at one time during this week she experienced some slight blurring of vision which did not, however, result in the usual severe headache. On October 5 she experienced a slight frontal headache, which did not last long and yielded readily to one aspirin tablet. When she was skin tested on October 10, she stated that she had had no severe unilateral headaches since the treatment. She also volunteered that she had ceased to be sensitive to soap. She was last seen on Dec. 1, 1941, and at that time she stated that she had not had the severe, unilateral type of headache that she had experienced before treatment. However, on two occasions she experienced an extremely mild unilateral fullness of the head but it did not incapacitate her. She was urged to continue the treatment. The acetylcholine wheals are shown in Fig. 2.

Fig. 3.—Histamine wheals (one-fourth actual size). Case 3, E. H.

Fig. 4.—Histamine wheals (one-fourth actual size). Case 4, F. C.

CASE 3.—E. H., male, aged 27 years, stated that for three years he had frequent attacks of fullness of the head, dizziness, and tinnitus. In addition, practically every day he had the feeling of a "clouded" head, that reached a maximum in the afternoon. He was previously told that his blood pressure was 160, and that his headache was due to this. No treatment seemed to be of any avail. He presented an endocrine problem because of a voluminous supply of hair all over his body, coupled with underdeveloped genital organs. The physical examination revealed a blood pressure of 140/90, the eye grounds were normal, and the refraction was normal. On May 25, 1941, prostigmine was started in "desensitizing" doses. On June 1 the patient reported that he had had no fullness of the head at any time during the preceding week. On June 8 he stated that slight fullness was present on two days during the past week. He was told to increase the dosage to 40 drops and then take 40 drops a day. The blood pressure was 142/90. On June 15 the patient reported no fullness of the head or dizziness and stated that he felt very well. The blood pressure was 134/90. The patient was last seen on Sept. 15, 1941, at which time he did not have any fullness or clouding of the head. Several times during the past month he had a slight ringing in one of his ears; this vanished within a few moments. He has been told to continue taking the medication. The histamine wheals are shown in Fig. 3.

CASE 4.—F. C., female, aged 36 years, had attacks of fullness in the back of her neck, dizziness, and ringing in both ears for many years. These attacks recurred about two times a week for a few years. Her anamnesis had a marked hysterical taint; she was in constant

conflict with her husband because she desired to become pregnant and he refused to consider it. Previous history revealed that she was on a Bradford frame for many months in an orthopedic hospital, but the x-ray examination and physical signs revealed no osseous tuberculosis. On May 23, 1941, the physical examination revealed a blood pressure of 120/80, normal eye grounds, normal refraction, and normal nose and throat findings. On the same day prostigmine was started in "desensitizing" doses. On May 31 there was neither fullness nor dizziness. On June 7 the patient was well. By August 5 the prostigmine had been stopped one and one-half months without return of the symptoms in her head. On October 5, when she had not taken medication for approximately three months, there was slight return of the fullness of the head and dizziness. She was put on the "desensitizing" dosage of prostigmine. On October 12, 1941, when she was last seen, there was no return of the fullness since taking medication. The histamine wheals are shown in Fig. 4.

Fig. 5.—Histamine wheals (one-fourth actual size). Case 5, F. B.

CASE 5.—F. B., female, aged 41 years, came to the Jewish Hospital Clinic on June 6, 1941, with a history of constant fullness in her head, especially in the back of it, for the past four weeks. She also had occasional fullness in her ears. The head felt as if it were twice the normal size. The previous history revealed that on April 30, 1936, the blood pressure was 204/130, and that the cardiac outline was enlarged. On March 22, 1941, the blood pressure was 175/125, and on May 31, 1941, it was 150/100. Her menstrual periods were irregular. The physical examination revealed that she had a blood pressure of 145/100 at this visit and that there were normal eye grounds and normal refraction. On May 31 prostigmine was started in "desensitizing" doses. On June 14 she reported no fullness in the head. The blood pressure was 140/100. On June 21 she reported that there still was no fullness in the head. On June 28 she reported occasional frontal headaches but no fullness or "large head." On Oct. 1, 1941, when she was last seen, she reported that she felt perfectly well and had none of her original symptoms. Her blood pressure at that time was 150/100. The histamine wheals are shown in Fig. 5.

COMMENT

The results obtained in this study serve to extrapolate the well-known parallelism between histamine and acetylcholine³ to the field of periodic headaches. Both of these substances are native to the body and both of them have been accused by different investigators of being the "allergic" substance. Histamine is produced by toxic or mechanical injuries of tissue cells, and acetyl-

choline results from the stimulation of the cell by the nerves. Acetylcholine would, therefore, appear to be the substance usually present unless some form of injury is presupposed. In addition, it would now appear that both histamine and acetylcholine may be causal factors in periodic headaches either at the same time or at different times. Certainly, both histamine and prostigmine are effective in the prophylactic treatment of these headaches.

These phenomena are of sufficient import to warrant the application of considerable thought to the question of the theoretical bases for the action of prostigmine. Admittedly, the data available are inadequate to permit the formulation, with any degree of certainty, of an all-embracing, coherent theory. Nevertheless, several explanations appear plausible enough to merit attention. The first of them is based on the known ability of prostigmine to liberate and to prolong the action of acetylcholine in the body by inhibiting the acetylcholine esterase. Thus the minute, controlled and ever-increasing quantities of acetylcholine liberated by the "desensitizing" doses of prostigmine may serve to administer mild repeated "shocks" to the hypersensitive organ responsible for the headaches, with the result that a relative tolerance or insensitivity is developed in this so-called "shock organ." This mechanism is sensibly analogous to that believed by many to be operative in histamine "desensitization." The analogy is perhaps best represented as follows:

Another explanation is based on the assumption that a person in the "sensitive" phase is in a state of autonomic or vasomotor imbalance with an ascendant parasympathetic system. This increased activity of the parasympathetic division accounts for the general hypersensitivity of the person toward both histamine and acetylcholine. Under such circumstances it may be postulated that prostigmine—though a para sympathetic stimulant in physiologic doses—may, in the minute desensitizing doses, increase the resistance of the parasympathetic division to both substances.

SUMMARY AND CONCLUSIONS

A series of 60 patients with periodic headaches with migraines and histamine cephalalgias predominating, were treated orally with gradually increasing doses of prostigmine. The extremely gratifying results which were obtained tend to prove (1) that in addition to histamine, acetylcholine is one of the factors involved in the production of these headaches; (2) that a similar neuro-biochemical mechanism is operative in many types of periodic headaches; (3) that prostigmine is as effective as histamine, and more convenient than it, in the treatment of these headaches.

We wish to express our appreciation to Hoffman-La Roche, Inc., for the materials used in this study.

OBSERVATIONS ON THE EFFECT OF HISTAMINE PHOSPHATE ON CAPILLARY PERMEABILITY AND INFLAMMATION*

R. H. RIGDON, M.D., MEMPHIS, TENN.

THE reactions of the skin to histamine are adequately described, and the observations of others are reviewed by Lewis.¹ When introduced into the skin in minute quantities, this poison "produces a characteristic series of independent phenomena comprising (a) local dilatation of the minute blood vessels by a direct action upon them; (b) a widespread dilatation of neighboring strong arterioles through the medium of a local reflex mechanism; and (c) increased permeability of the vessel walls by direct action."¹ Most investigators agree with these observations. In addition to these changes, Moon² has emphasized that there is stasis of blood with some diapedesis of red blood cells into the tissue spaces. The effects of histamine upon the systemic circulation are the same, and are due to the same mechanism as its local effects upon the capillaries of the skin.²

Bloom³ in 1922 advanced the idea that the migration of leucocytes into the tissues in areas of inflammation may be due to histamine. Grant and Wood⁴ were unable to demonstrate such an effect on the leucocytes of man, rabbit, and the frog. On the contrary, however, Wolf⁵ and Findlay⁶ showed that histamine acted as a positive chemotactic substance both in vitro and in vivo.

Best and McHenry⁷ in 1931, in reviewing the role of histamine in inflammation, state that "the very interesting and fundamental question of the role of histamine or a histamine-like substance in the production of the phenomena observed in inflammation is still controversial. A thorough investigation of the subject is needed."

Interest in the role of histamine in the development of the local inflammatory reaction has been stimulated by the recent work of Menkin.⁸ This investigator concludes from his experimental work that leucotaxine is the sub-

Received for publication, March 30, 1942.

stance responsible for the increase in capillary permeability and also for the localization of leucocytes in the local area. Menkin⁹ says "in regard to the statement that various products of protein metabolism, such as amino acids, are capable of inducing leucocytic migration, it is interesting to note that observations with a number of representative amino acids (as well as histamine) have failed to reveal leucocytic migration." Furthermore, there is no evidence according to Menkin to support the contention that the permeability factor in inflammation is histamine.⁹

It has been shown that trypan blue following an intravenous injection localizes and concentrates in areas of inflammation in the skin of the rabbit only during a specific interval following the application of xylol to the skin. The greatest quantity of dye localizes and concentrates in the area of skin where the xylol is applied for the shortest time before the dye is injected. It has also been shown that the localization of leucocytes in areas of skin in the rabbit, showing macroscopic evidences of inflammation, is not determined by the time that trypan blue localizes and concentrates in the same tissue.^{10, 11}

A problem is outlined to study the effect of histamine phosphate on capillary permeability and inflammation because there is some question as to the role that histamine may play in these processes. The technique is similar to that used in other studies on capillary permeability and inflammation.¹²⁻¹⁵ Varying dilutions of histamine phosphate are injected intradermally preceding the intravenous injection of trypan blue. Observations are made on the localization and the concentration of dye in the histamine-injected areas of skin. Histologic studies are also made on the areas of skin injected with the histamine. Data are given on the changes produced in the number of circulating leucocytes following an intravenous injection of histamine.

METHODS AND MATERIAL

Adult rabbits are used. The hair is carefully shaven from the sides and the abdomen several days before the experiment is begun. The following dilutions of histamine phosphate* are used: 1:1,000 (stock solution), 1:3,000, 1:5,000, 1:8,000, and 1:10,000. All dilutions are made in saline. Two-tenths cubic centimeter is injected intradermally. Several injections are made into different areas of the same animal. In some rabbits a single dilution is used while in others several dilutions are injected. Ten cubic centimeters of a 0.2 per cent solution of trypan blue in saline is injected intravenously following the last injection of the histamine. The time at which the histamine and the dye are injected is given in the individual experiments. Observations are made on the time of the localization and the concentration of the dye in the different areas of skin.

Areas of skin injected with the histamine are fixed in a 10 per cent solution of formalin immediately after the rabbits are killed. Paraffin sections are prepared and stained with hematoxylin and eosin.

Eight rabbits are used to study the effect of histamine on the number of circulating leucocytes. A standard technique is used for making these counts.

*Supplied by Parke, Davis & Company.

The white blood cells are counted in each rabbit immediately before 0.4 c.c. of a 1:1,000 solution of histamine phosphate is injected intravenously into the marginal ear vein. The white blood cells are counted after one, two, four, five, seven, twenty-three, and twenty-eight hours. These data are analyzed statistically.

EXPERIMENTAL

OBSERVATIONS ON THE LOCALIZATION AND THE CONCENTRATION OF TRYPAN BLUE IN AREAS OF SKIN INJECTED WITH HISTAMINE

A group of rabbits are injected intradermally with a series of different dilutions of histamine at the following intervals before 10 c.c. of trypan blue are injected intravenously: six hours, five hours, four hours, three hours, two hours, one hour, thirty minutes, fifteen minutes, and immediately. The concentration of histamine injected and the location of the dye in the skin are shown in Table I. It is evident from these data that trypan blue localizes and

concentrates for less than thirty minutes in areas of skin previously injected with dilutions of histamine less than 1:3,000. When a 1:1,000 dilution of histamine is injected, the dye may localize and concentrate in areas of skin injected as long as five to six hours previous to the injection of the dye. Some of these rabbits are injected with only a single dilution of the histamine.

The skin at the site of the injection of the histamine usually becomes blanched immediately following an intradermal injection. This color persists for varying periods of time. The skin around this blanched area becomes hyperemic and apparently edematous. The macroscopic size of the skin lesion is influenced by the concentration of the histamine. The lesions may persist for six hours when a 1:1,000 dilution of histamine is injected. There is only an insignificant amount of blanching when a 1:10,000 dilution of histamine is injected. The hyperemia persists for only a short time.

Fig. 1.—A, The subcutaneous tissue is slightly edematous. How much of the edema results from the fluid injected and how much from the effect of the histamine on the capillary walls cannot be determined histologically. This rabbit was injected intradermally with 0.2 c.c. of a 1:1,000 dilution of histamine phosphate for ten minutes before this section was removed.

B, In addition to some edema in the subcutaneous tissue there are few polymorphonuclear leucocytes. These are present especially around the small blood vessels. This is the same rabbit as shown in A. Two-tenths cubic centimeter of the 1:1,000 dilution of histamine phosphate was injected intradermally five hours before this section was removed.

C, Leucocytes and edema are present in the subcutaneous tissue. This is the same rabbit as shown in A and B. Two-tenths cubic centimeter of the 1:1,000 dilution of histamine phosphate was injected intradermally eight hours before this section was removed.

Trypan blue stains a ring of tissue blue around the blanched zone at the site of the intradermal injections. This dark blue zone may measure as much as 1 cm. The blue color then gradually fades as it extends peripherally. The entire area of skin becomes more or less uniformly blue when the most dilute solutions of histamine are injected. Trypan blue may fail to localize and to concentrate in areas of skin injected with a 1:3,000, 1:5,000, 1:8,000, and

1:10,000 dilution of histamine, although the skin is hyperemic. This occurs when the dye is given either thirty minutes or longer following the injection of the histamine.

HISTOLOGIC STUDIES UPON THE AREAS OF SKIN INJECTED WITH HISTAMINE

Sections of skin are removed from 5 rabbits injected with 0.2 c.c. of a 1:1,000 dilution of histamine at the following intervals before the animals are killed: 0 minutes, fifteen minutes, thirty minutes, one hour, two hours, three hours, four hours, five hours, and six hours. Sections of skin are also removed from 3 other rabbits injected with 0.2 c.c. of a 1:8,000 dilution of histamine at corresponding intervals before death.

Fig. 2.—Small, focal areas of degeneration occur in the fibers of the cutaneous maximus muscle following the intradermal injection of 0.2 c.c. of a 1:1,000 dilution of histamine phosphate. Polymorphonuclear leucocytes infiltrate the area about the necrotic tissue. The histamine was injected five hours before this section was removed.

The histologic changes are essentially the same when a 1:8,000 and a 1:1,000 dilution of histamine is injected. There may be some difference in the extent of the lesion, but this factor is difficult to determine from these sections. It is also difficult to separate the effect of the volume of fluid injected from the edema fluid that results from the direct effect of the histamine on the capillaries. Polymorphonuclear leucocytes are present in the extravascular tissue usually within an hour following the injection of the histamine. The number of these cells apparently increases during the following four to five hours. After this time apparently the number of leucocytes decreases. Leucocytes usually infiltrate the corium and the subcutaneous tissues down to the cutaneous maximus muscle (Fig. 1). Sometimes there is a pink stain material in the subcutaneous tissue. It is considered to be coagulated serum.

There are small focal areas of degeneration in the cutaneous maximus muscle. It is impossible to determine accurately the time at which this lesion begins; however, the sections removed two hours after the histamine is injected

show unquestionable necrosis. This lesion is characterized by a swelling of the muscle fiber and a loss of the striations. The area appears glossy and stains deeply with eosin. In some of the sections the muscle fibers are broken and the margins are irregular. Polymorphonuclear leucocytes are present in large numbers around such muscle fibers (Fig. 2).

Four rabbits are injected subcutaneously with 0.2 c.c. of a 1:1,000 dilution of histamine at the following intervals before they are killed and the sections are removed: seven, six, five, four, three, two, and one hours. An attempt is made to inject the histamine into the cutaneous maximus muscle in these animals. This technique is unsatisfactory. The sections from this material show the same histologic changes as those observed in the other animals, except there is a more extensive lesion in the muscle of these animals than there is in the former group of rabbits.

EFFECT OF HISTAMINE PHOSPHATE ON THE NUMBER OF CIRCULATING LEUCOCYTES IN THE RABBIT

The data from these counts are given in Table II. The number of leucocytes in the circulating blood increases during the seven hours following the intravenous injection of histamine. The number of leucocytes in the circulating blood, however, returns to within the range of normal twenty-four hours following the injection of the histamine.

TABLE II

EFFECT OF HISTAMINE PHOSPHATE ON THE NUMBER OF CIRCULATING WHITE BLOOD CELLS IN THE RABBIT

Value of t_{\dagger}		2.56	3.98	3.90	3.14	4.26		
Value of t_{\ddagger}				5.25	5.87	2.68		

*Differences in the mean leucocyte counts and the value of t for various hours.

t must equal 2.145 or more for the increase to be statistically significant.

Histamine injected at 9:00 A.M. immediately following the blood count.

\dagger : Value of t when the experimental animals are compared hour to hour—14 degrees of freedom.

\ddagger : Value of t when experimental animals are compared with 32 control animals—38 degrees of freedom.

The values of t are calculated for these samples of 8 rabbits in order to compare the counts at 9:00 A.M., 10:00 A.M., 11:00 A.M., 1:00 P.M., 2:00 P.M., and 4:00 P.M. of the day of injection; and counts are made again at 8:00 A.M. and 1:00 P.M. on the following day. t must equal for 14 degrees of freedom 2.145 or more if the increase in the mean leucocyte count is significant. The

mean counts at the specified hours and the values of t are given in Table II. The mean leucocyte counts of the experimental animals are also compared with the mean leucocyte counts of 32 control animals, and the values of t for these comparisons are also shown in Table II. For 38 degrees of freedom t must equal 2.02 for the differences to be statistically significant.

DISCUSSION

It is evident from this study that histamine phosphate, when injected intradermally in the rabbit, acts as a chemotactic substance. This observation is confirmatory of the studies of Wolf⁵ and Findlay;⁶ however, it does not support the opinion expressed by Bloom³ and Grant and Wood⁴ as to the effect of histamine on the attraction of leucocytes.

The presence of necrosis in the cutaneous maximus muscle, following the intradermal injection of 0.2 c.c. of a 1:1,000 and 1:8,000 dilution of histamine, indicates that this substance may produce not only an increase in capillary permeability, but also a severe injury that culminates in necrosis. Because of this necrosis it becomes more difficult to ascertain the role of histamine in inflammation.

Trypan blue following an intravenous injection localizes and concentrates in areas of skin previously injected with histamine. The localization and the concentration of trypan blue in these areas are influenced by both the interval between the injection of the histamine and the injection of the dye, and the concentration of histamine. The skin, where 0.2 c.c. of a 1:1,000 dilution of histamine is injected, becomes blue within a period of five minutes when the dye is injected intravenously as long as six hours after the intradermal injection of the histamine. In contrast to this the skin does not show a greater concentration of dye than that in the untreated area, when an interval of thirty minutes elapses between the injection of a 1:10,000 dilution of histamine and the intravenous injection of the trypan blue. These observations suggest that histamine, when injected intradermally in the rabbit, produces a disturbance in the metabolism of the regional cells. Trypan blue following an intravenous injection localizes and concentrates in this area of skin only during the time that this abnormal metabolic process is present. The cells may return to the "so-called normal" very quickly, as indicated by the failure of trypan blue to localize and to concentrate in the skin when a 1:10,000 dilution of histamine is injected thirty minutes before the dye is given. The cells remain abnormal for at least six hours when a 1:1,000 dilution of histamine is injected. This interval during which trypan blue may localize and concentrate in areas of skin previously injected with histamine may be influenced by the total quantity of histamine given to the animal.

A specific period during which trypan blue localizes and concentrates in an area is the same phenomenon as previously observed with a group of irritants and a variety of circulating substances. Trypan blue, India ink, a virus, staphylococci, and staphylococcus antitoxin each localizes and concentrates in the skin only within a period of three hours following the local application of xylol.¹¹ When staphylococci are injected intradermally and trypan blue is given intravenously, the largest amount of the dye localizes in the area where

the bacteria are injected within a period of three hours previous to the injection of the dye.¹⁷ In a discussion of these observations it has been suggested that "the process in inflammation referred to as increased capillary permeability represents a phenomenon well recognized in vital staining. The staining results from a metabolic disturbance in the epithelial cells, connective tissue cells, and endothelial cells of the small blood vessels."¹⁸

It is of interest to know that the polymorphonuclear leucocytes concentrate in areas of skin injected intradermally with histamine for a much longer period than that in which trypan blue localizes and concentrates in the same area. It has been pointed out in other studies that "the dye may localize and concentrate in tissue when there are no polymorphonuclear leucocytes and fail to localize and to concentrate when the subepithelial tissues are diffusely infiltrated with leucocytes."¹⁸

The data in this experiment show that there is a statistically significant increase in the leucocyte counts of rabbits injected intravenously with 0.4 c.c. of a 1:1,000 dilution of histamine phosphate. This increase occurs within one hour of the time of injection and continues for at least seven hours. These data are obtained by comparing the counts of the experimental animals with the counts from a group of 32 normal rabbits.

The demonstration of a leucocytosis following the injection of histamine phosphate corresponds to the observations of Moon.² He finds that histamine produces a leucocytosis in cats, monkeys, and human beings. Menkin,³ however, considers that histamine is essentially inactive for producing an increase in the leucocytic level in the blood of both dogs and rabbits.

It is obvious that the phenomena that occur in the local areas of inflammation and in the circulating blood are complex. These experimental observations with histamine may be an index of some of these changes; however, one must be careful in interpreting them, since there appears to be a variety of unrelated substances, each of which may produce an increase in capillary permeability and a localization of leucocytes in the skin of the rabbit.

SUMMARY

Histamine phosphate, when injected intradermally in the rabbit, produced a change in the tissue cells that permits the localization and the concentration of trypan blue in the local area. This localization and concentration of trypan blue are influenced by both the concentration of histamine and the interval between the intradermal injection of the histamine and the intravenous injection of the dye.

Polymorphonuclear leucocytes localize in the subcutaneous tissues of the rabbit following an intradermal injection of histamine phosphate.

Necrosis occurs in the fibers of the cutaneous maximus muscle following the intradermal injection of histamine phosphate.

The number of white blood cells increases in the circulating blood following an intravenous injection of histamine phosphate. The number, however, returns to normal within a period of twenty-four hours.

I am greatly indebted to Dr. F. L. Roberts, Professor of Preventive Medicine, University of Tennessee, for his assistance in the statistical problems concerned in this study.

CLINICAL CHEMISTRY

CHOLESTEROL STUDIES IN THE AGED*

HENRY A. RAFSKY, M.D., F.A.C.P., AND BERNARD NEWMAN, B.S., CH.E.,
NEW YORK, N. Y.

NUMEROUS investigators¹⁻¹¹ have studied the total cholesterol concentration and its partition, that is, the ratio of the free cholesterol, or the cholesterol esters, to the total cholesterol in the blood of persons below 60 years of age. Comparatively scant attention, however, has been paid to the cholesterol partition in the blood of normal persons past 60 years of age. A difference of opinion also exists as to whether advancing age affects the cholesterol values. In 1923 Parhon and Parhon¹² stated that the total cholesterol concentration in whole blood increased slightly with age. In 1924 Bing and Heckscher¹³ found that the blood lipids were relatively low in youth and increased with advancing age. These observers stated that the upper and lower limits for the total cholesterol in the blood of normal aged persons were 260 and 125 mg. per 100 c.c., respectively. On the other hand, Page, Kirk, Lewis, Thompson, and Van Slyke⁴ found that in a study of the lipids in the plasma of males of all ages there was no regular important change in any blood lipid fraction with advancing years. Similarly, Hunt¹⁴ stated that the age of the patient does not affect the blood cholesterol values. It was, therefore, thought of interest to make a study of the blood cholesterol and its partition in the serum and whole blood of normal aged males and females.

EXPERIMENTAL STUDY

The subjects chosen for this study comprised 76 males and 74 females. All were housed in the "Home" division of the institution, all were ambulatory, and all were on the normal institutional diet. Their ages ranged from 62 to 104 years and were distributed as outlined in Table I. The mean ages were found to be 77.1 years for males and 76.2 years for females.

Determinations were made of total and esterified cholesterol in both serum and in whole blood, using the method of Bloor and Knudson.⁷ All determinations were made after a fasting period of at least eight hours in order to rule out any temporary lipemia due to ingestion of fatty materials. The free cholesterol was computed in each case by subtracting the esterified cholesterol from the total cholesterol, and this value, divided by the total cholesterol, gave the fraction existing in the free state.

Table II shows the distribution of the total cholesterol concentration in milligrams per 100 c.c. for both whole blood and serum for both sexes. Table III shows the distribution of the free cholesterol percentages for both whole blood and serum for both sexes.

*From the Hospital and Home of the Daughters of Jacob, New York.
This study was aided by a grant from the Paul Hirsch Fund.
Received for publication, June 1, 1942.

The values for the total cholesterol concentration in the blood of the male subjects in our study ranged from 180 to 340 mg. per 100 c.c. in serum, and from 158 to 316 mg. per 100 c.c. in whole blood. The range of cholesterol concentration in whole blood for females was from 149 to 329 mg. per 100 c.c., and in serum the lower and upper limits were 168 and 320 mg. per 100 c.c., respectively.

TABLE I
AGE-FREQUENCY DISTRIBUTION OF SUBJECTS STUDIED

AGE GROUP (YEARS)	MALES	FEMALES	TOTAL
60-65	4	0	4
65-70	8	14	22
70-75	19	19	38
75-80	21	25	46
80-85	12	10	22
85-90	7	5	12
90-95	5	0	5
95-100	0	0	0
100-105	0	1	1

The free cholesterol in males was between 16 and 64 per cent in serum and between 14 and 75 per cent in whole blood. The free sterol for females showed a variation between 17 and 67 per cent in serum and between 11 and 75 per cent for whole blood. The average total cholesterol values in whole blood were computed to be 219 mg. per 100 c.c. for males and 227 mg. per 100 c.c. for females, and in serum the average total cholesterol values were found to be 246 mg. per 100 c.c. for males and 232 mg. per 100 c.c. for females. The average value for free cholesterol in whole blood was 39 per cent for males and 50 per cent for females, while in serum the average free cholesterol was 37 per cent for males and 42 per cent for females. The over-all average for total cholesterol in whole blood was 223 mg. per 100 c.c.; with the free sterol amounting to 46 per cent. Averaging all the values for serum gave a total cholesterol of 238 mg. per 100 c.c. of which 39 per cent existed in the free state.

COMMENT

The total cholesterol and cholesterol partition were studied in a group of 150 so-called normal aged persons. According to Todd and Sanford,¹⁵ the normal limits for total cholesterol estimated by the Bloor method were 165 to 200 mg. per 100 c.c. for plasma or serum with 30 per cent as the maximum normal free sterol. Bloor and Knudson⁷ found that the total concentration of cholesterol was from 180 to 200 mg. per 100 c.c., "little difference being noted between the results for whole blood and serum if the normal ratio of esters to free sterol is maintained." They further stated that in serum the maximum normal percentage of free sterol encountered was about 40 per cent, and in whole blood the free cholesterol ran to a maximum of 33 per cent. Pickhardt, Bernhard, and Kohn¹¹ regarded 30 per cent as the maximum normal percentage of free sterol in serum. Bodansky and Bodansky² stated that the concentration of total cholesterol in plasma was between 160 and 200 mg. per 100 c.c., with the free sterol around 30 per cent with very

slight variation. On the basis of these and other studies,^{1, 4, 6, 10} the maximum normal concentration of total cholesterol in either serum or whole blood may be regarded as 200 mg. per 100 c.c., with a maximum of 30 to 40 per cent existing as the free sterol.

TABLE II
FREQUENCY DISTRIBUTION FOR TOTAL CHOLESTEROL

TOTAL CHOLESTEROL MG./100 C.C.	WHOLE BLOOD		SERUM		TOTAL
	MALES	FEMALES	MALES	FEMALES	
140-160	2	2	0	0	4
160-180	9	7	0	3	19
180-200	14	9	4	6	33
200-220	6	10	3	4	23
220-240	8	2	5	5	20
240-260	2	5	3	2	12
260-280	5	3	2	1	11
280-300	4	3	4	1	12
300-320	4	0	1	4	9
320-340	0	3	0	1	4
340-360	0	0	1	0	1
360-380	0	2	0	0	2

TABLE III
FREQUENCY DISTRIBUTION FOR PERCENTAGE FREE CHOLESTEROL

FREE CHOLESTEROL %	WHOLE BLOOD		SERUM		TOTAL
	MALES	FEMALES	MALES	FEMALES	
10-15	1	1	0	0	2
15-20	1	0	4	1	6
20-25	3	1	1	1	6
25-30	6	2	3	5	16
30-35	5	2	5	2	14
35-40	6	3	1	1	11
40-45	6	9	2	5	22
45-50	6	3	3	3	15
50-55	7	9	2	4	22
55-60	1	2	2	3	8
60-65	4	8	1	1	14
65-70	3	2	0	1	6
70-75	2	3	0	0	5
75-80	1	2	0	0	3

In this study, as can be seen from Tables II and III, when whole blood was used, 29 males and 28 females, or 57 per cent of the subjects investigated, had a total cholesterol concentration of more than 200 mg. per 100 c.c.; 30 males and 38 females, or 68 per cent, had a free cholesterol of more than 40 per cent. When serum was employed, 19 males and 18 females, or 74 per cent of the subjects studied, had a total cholesterol of more than 200 mg. per 100 c.c.; 10 males and 17 females, or 54 per cent, showed a free cholesterol in excess of 40 per cent.

The question now arises as to whether the comparatively high total and free cholesterol in the normal aged person has any significance. Are these increased cholesterol values a natural concomitant of old age? The persons in this study did not present any clinical evidence of liver dysfunction, biliary tract disease, diabetes, or renal impairment, which conditions are often accompanied by a hypercholesterolemia and a disturbed cholesterol partition. Arteriosclerosis is a factor that must be taken into consideration in any per-

son past 50 years of age. Kilduffe¹⁶ stated that increased cholesterol values are often associated with arteriosclerosis. Leary¹⁷ thought that arteriosclerosis is probably the result of abnormal cholesterol metabolism. Best and Taylor¹⁸ stated that one of the means by which arteriosclerosis could be produced in rabbits was by feeding diets high in cholesterol. They also claimed that the administration of cholesterol is one of the most certain means of producing excessive deposition of neutral fats in the liver, with a resulting accumulation of cholesterol esters.

SUMMARY

Cholesterol studies were made in 150 normal aged persons. Of the 100 persons in whom whole blood was studied, 57 per cent had a total cholesterol concentration of more than 200 mg. per 100 c.c., and 68 per cent showed free cholesterol of more than 40 per cent. Of the 50 persons in whom serum was used, 74 per cent had a total cholesterol concentration of over 200 mg. per 100 c.c., and 54 per cent had an excess of 40 per cent free cholesterol.

We wish to thank Dr. Samuel Seidenberg for his cooperation.

SULFONAMIDE SOLUBILITY IN UREA*

SIDNEY S. SOBIN, PH.D., M.D.,† St. Louis, Mo.

SULFONAMIDE hematuria, well recognized in both clinic and laboratory, is closely associated with mechanical traumatic effects following precipitation of insoluble acetylated sulfanilyl derivatives within the urinary tract. Recent studies by Curtis and Sobin¹ have shown that the solubility of *acetylsulfapyridine* and *acetylsulfathiazole* is considerably enhanced by an alkaline pH and by increasing amounts of urea in solution. Both of these factors may well explain the difference in solubility of these substances in water and urine. The peptizing effect of urea is also seen with other more simple chemical substances.²

Analysis of the precipitated material found in the urinary tract of man and animals has shown that in sulfapyridine-treated cases more free drug is present than in the sulfathiazole-treated cases.³⁻⁶ To determine a possible mechanism for the differences in free sulfonamides in uroliths, the solubility of the *free acids* of sulfapyridine, sulfathiazole, and sulfadiazine in varying concentrations of urea have been studied.

It was further hoped that the solvent effect of urea on these sulfonamides might be sufficient to allow the preparation of a soluble form for parenteral use without the attendant dangers of a high pH of the alkaline salts.

METHOD

Urea solutions of varying concentrations from 0.1 to 10 per cent were incubated at 37° C. with an excess of sulfapyridine, sulfathiazole, and sulfadiazine, shaken at intervals, and filtered through two thicknesses of Whatman No. 42 filter paper. After appropriate dilution the free sulfonamide was determined by the method of Bratton and Marshall,⁷ using the Evelyn colorimeter and a No. 540 filter.

RESULTS

The results of this series of observations are shown graphically in Fig. 1. Solubility in milligrams per 100 c.c. is plotted on the ordinates, and concentration of urea in per cent on the abscissae. The order of increasing solubility is sulfadiazine, sulfapyridine, and sulfathiazole. The order of increasing solvent effect of urea is the same as their solubilities.

DISCUSSION

It has been previously shown that the solubility of acetylsulfathiazole is slightly increased by urea, and that of acetylsulfapyridine is more definitely increased.¹ In neither case is the total solubility in 10 per cent urea solution above 40 mg. per 100 c.c., as contrasted with the values of 133.0 mg. per 100 c.c. for sulfathiazole and 73.3 mg. per 100 c.c. for sulfapyridine in similar 10 per cent urea solution. The difference in solubility between the free acids them-

*From the Department of Internal Medicine, University of Michigan Hospital, Ann Arbor, Mich.

†Now at the Barnes Hospital, St. Louis.

Received for publication, June 18, 1942.

selves and between the free acid and their acetylated compounds is sufficient to explain the concentration of sulfapyridine and sulfathiazole in analyzed uroliths.

The solubility of sulfadiazine is quite low, and in 10 per cent urea the maximum solubility was found to be 31.5 mg. per 100 c.c. This figure approximates the solubility of acetylsulfapyridine and acetylsulfathiazole, and re-emphasizes a potential danger in the use of this drug—already experienced clinically.

Fig. 1.

The solvent effect of urea on these sulfonamides is not of sufficient degree to be adaptable to parenteral sulfonamide therapy.

CONCLUSIONS

1. Urea increases the solubility of sulfathiazole, sulfapyridine, and sulfadiazine.
2. The extent of such increase in solubility may explain some related problems of renal precipitation of sulfonamides.
3. Sulfonamide's solubility in urea-sulfonamide solutions is not sufficient to warrant its use in parenteral therapy.

LABORATORY METHODS

GENERAL

A STUDY OF THE PHENOMENON OF ERYTHROCYTE SEDIMENTATION*

III. ANTICOAGULATION AS A TECHNICAL SOURCE OF VARIATIONS

ROY E. NICHOLS, B.V.Sc., M.Sc., Ph.D.,† LAFAYETTE, IND.

IN A PREVIOUS publication a critical survey of considerable literature dealing with sedimentation was presented.¹ In another publication² a reliable technique for measuring sedimentation, a more practical "field technique" and evidence of the reproducibility and limitations of each were advanced. This paper includes evidence supporting my choice of the kind and amount of anticoagulant used, as well as the limitations of this choice and variations due to other kinds and quantities of anticoagulants.

The choice of a suitable means of anticoagulation for sedimentation studies in equine blood has been a perplexing problem. Many different concentrations of several kinds of anticoagulants were attempted, examples of results of which are to follow. Defibrination was also attempted but, because of varying degrees of hemolysis and somewhat variable results, was discarded. It is realized that Fahraeus³ employed this method of anticoagulation quite extensively with horse blood but used as a criterion of sedimentation a single reading at the end of one hour, a method of reading which because maximum sedimentation has passed will yield somewhat comparable results in practically all samples of equine blood having fairly close volume percentages. Fahraeus admitted that his method did not in reality measure sedimentation.

In defibrinated samples sedimentation is slower than in samples with added anticoagulants. In samples in which the process of defibrination caused the least cell damage, and plasma, although darker than anticoagulant plasma, was not reddish, volume percentages were closer to those of anticoagulant samples. Even in defibrinated samples where plasma was only slightly darker and volume percentages were quite uniform, sedimentation was much slower, as for example with potassium and ammonium oxalated aliquots of the same blood sample:

Aliquot No.	M_5 ‡	t_{M_5} ‡	$\angle^s M_5$	V%	Plasma
1	26 mm.	10-15 min.	30° 20'	35.5	Clear
2	25 mm.	10-15 min.	31° 30'	36	Clear
3	26 mm.	10-15 min.	30° 20'	36-	Clear

*From a thesis presented in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Graduate School of the Ohio State University, June, 1941.

†Comparative Physiologist, Department of Veterinary Science, Purdue University.

Received for publication, April 3, 1942.

‡Definitions:

M_5 = Maximum five-minute descent in millimeters of the line of demarcation between cells and plasma.

t_{M_5} = Times in minutes between which M_5 occurs. Since with the photographic apparatus one minute is the equivalent of 3 mm., this time-distance ratio is retained for the "field" technique.

With defibrinated aliquots of the same blood sample as the foregoing:*

Aliquot No.	M_s	t_{M_s}	$\angle^s M_s$	V%	Plasma
4	18 mm.	{ 5-10 min. 10-15 min.	40° 20'	34	Darker
5	19 mm.	10-15 min.	38° 50'	33.7	Darker
6	20 mm.	10-15 min.	37° 20'	33.7	Darker

Photographic recordings of sedimentation of aliquots of the same sample of blood, with hemolysis at a minimum, are like Fig. 1.

Fig. 1.—Sedimentation curves with the ammonium and potassium oxalate mixture (top) and defibrination (bottom).

*Definitions (cont'd):

\angle_{M_s} = Angle opposite the horizontal side of a right triangle having M_s as the perpendicular side and five minutes, or 15 mm., as the horizontal side.

V% = Volume per cent of packed cells.

t_{em} = The perpendicular distance from the estimated point of change between the vertical flexion and horizontal flexion of the photographically recorded sigmoid curve of sedimentation of a sample and the top line of the photograph representing 100 mm. of blood column height, i.e., estimated "fall" in millimeters at the point of change.

t_{em} = Time in minutes between the time of filling of the Wintrobe tube and the time that the point of change between the vertical flexion and horizontal flexion of the photographically recorded sigmoid curve of sedimentation of a sample occurs (one minute = 3 mm.)

\angle_s = The least angle between the steepest slope of the sigmoid curve of sedimentation of a sample and perpendicularity.

With potassium and ammonium oxalate:

Ex. No.	em*	t _{em} *	\angle°_g *	M _s	tM _s	$\angle^{\circ}M_s$	V%
1	31 mm.	9 min.	20°	30 mm.	5-10 min.	27°	34

With defibrination:

2	19 mm.	8 min.	29° 10'	25 mm.	5-10 min.	31° 20'	33.3
---	--------	--------	---------	--------	-----------	---------	------

It was found that, if careful measuring was employed, similar results could be obtained with similar quantities of anticoagulant. It was felt then that these anticoagulants should each be tested for the most suitable quantity and then these most suitable quantities compared. It was decided to choose that anticoagulant which had the least effect on both sedimentation and volume per cent over the widest range of concentration, and to use a minimal but safe quantity of it, realizing, of course, that there might be some individual differences in the minimal quantity.

Fig. 2.—Effects of varying quantities of lithium citrate upon sedimentation.

Accurate 2 per cent solutions of the following anticoagulants were prepared in double distilled water: potassium oxalate, sodium oxalate, lithium oxalate, ammonium oxalate, potassium citrate, sodium citrate, lithium citrate, ammonium citrate, and sodium fluoride.

Also a 2 per cent solution of a mixture of 3 parts ammonium oxalate and 2 parts potassium oxalate and a 0.05 per cent solution of heparin containing 110 units per milligram were prepared.

*See footnotes, page 1570, for definitions.

Collecting vials (0.5 ounce) previously graduated at 5 c.c. were prepared with the following concentrations of dry anticoagulants by introducing the proper quantity of the afore-mentioned solutions and allowing the water to evaporate in an incubator:

2, 4, 8, 12, 16, 20, 24 mg. for all the oxalates.

4, 8, 12, 16, 20, 24 mg. for the citrates and sodium fluoride.

5.5, 11.0, 16.5, 22.0, 27.5, 55.0 units of heparin.

Blood was collected as previously described² and divided into the 5 c.c. aliquots for each set. Blood and anticoagulant were vigorously shaken for two minutes by hand. While no specific check was made of the completeness of the mixture of anticoagulant and blood, it is felt that, since the anticoagulant was disbursed as much as possible in the collecting vial to facilitate its solution, error in this respect is probably at least minimized. Of course, previous to determination of sedimentation, each aliquot was uniformly agitated in the mechanical shaker previously described.²

Although there were minor variations in different samples, results which follow show at least trends. (In the following tabulated data *C* stands for clotting to the extent that measurements of sedimentation could not be made; *c* for evidences of small clots; *f* for what was thought to be fibrin precipitation observed in the plasma; *d* for slightly darker plasma; and *h* for plasma with a definite reddish cast.)

From the foregoing data one can see that, in general, sedimentation tends to decrease the more anticoagulant is used. Volume percentages tend to decrease with potassium, sodium, and lithium oxalates and citrates as the amount of anticoagulant is increased. With ammonium oxalate and ammonium citrate the reverse is true. With heparin and the potassium and ammonium oxalate mixture volume percentages tend to remain fairly close. With the ammonium salts, the potassium and ammonium oxalate mixture and heparin, sedimentation values tend to remain close over a wider range of concentrations than with the others. Since the volume percentages with ammonium oxalate and ammonium citrate vary considerably with concentration, they may be considered as less efficient than heparin and the potassium and ammonium oxalate mixture.

Sodium fluoride apparently cannot be used for equine blood.

Although heparin has many good features as an anticoagulant, it also has some which are disappointing. In practice it is less dependable than the potassium and ammonium oxalate mixture, there apparently being a wide variation in the minimal quantity necessary for anticoagulation. With some horse's blood as low as 11 units per 5 c.c. is sufficient for apparently complete anticoagulation, whereas with the blood of others three or four times that amount sometimes is not. Regardless of whether this is the result of poor solubility or not, or whether it is inherent in the action of the preparation itself or not, such variation seems to exist and naturally leads one to be a bit dubious of the results he obtains. The appearance of the plasma often is an aid in judging the degree of anticoagulation, since in equine blood with heparin the degree of what is apparently lipemia

is less than with the other anticoagulants. Any cloudiness of the plasma, where there are particles of various sizes, or a "flaky" appearance, is thought to suggest incomplete anticoagulation, especially since this phenomenon occurs only at concentrations nearest to clotting.

Fig. 3.—Effects of varying quantities of ammonium oxalate upon sedimentation.

In practice the ammonium and potassium oxalate mixture has been most satisfactory.

As photographic examples of the effects of those anticoagulants which decrease volume per cent as well as sedimentation consider the photographs in Fig. 2.

The amount of heparin used was found by previous trial to be sufficient for each particular experiment, at least as far as general appearance was concerned. Wherever any signs of clotting were apparent, or even strongly suspected, the amount of the particular anticoagulant used was increased, and the experiment was repeated. In practice it was found that even with blood from one and the same animal variations in the minimal quantity of anticoagulant occurred from time to time—this being true in both pathologic and apparently normal samples, even though perhaps more true in the pathologic blood. Realizing, of course, that large errors do occur in attempting to measure as small quantities of anticoagulants as were here used, and realizing that measuring exact small quantities of blood is also subject to large error, nevertheless in spite of these I feel that minimal quantities vary in the same animal, normal or not.

As an interesting adjunct to this problem various dilutions of these various anticoagulants were prepared and the *resistance of red blood cells* was tested in them. Results as listed are quite obvious (*h* signifies complete hemolysis; *p*, partial hemolysis; *s*, suspicious; and *o*, no hemolysis).

Consideration of the foregoing data is interesting in that the point of beginning hemolysis in all salts except one was in solutions of less than 2 per cent. In the oxalates, with the exception of ammonium oxalate, and in sodium fluoride beginning hemolysis was in solutions of less than 1 per cent, while in the citrates, including ammonium citrate, it began in solutions between 1 and 2 per cent. All dilutions of ammonium oxalate hemolyzed the red blood cells, although a saturated solution (approximately 8 per cent) offered some protection for a fraction of an hour.

Would it be incorrect to say that oxalates except ammonium oxalate offer greater protection against cell damage than the citrates?

The reaction of ammonium oxalate is indeed an interesting one, since in all dilutions up to saturation hemolysis occurs when 1 drop of fresh blood is added to 2 c.c. of the solution. No doubt, when used alone as an anticoagulant, the quantity necessary (about 8 to 12 mg.) for anticoagulation is so small in proportion to the amount of blood used (5 c.c.) that clinically at least evidence of hemolysis is not observed. The quantity necessary for the ammonium and potassium oxalate mixture is even less (6 mg.). Another factor must be considered, namely, the possibility that potassium oxalate may somewhat protect the red blood cells against the hemolyzing effects of ammonium oxalate. Concerning

the proportion of these two salts it may be said that a slight excess of ammonium oxalate (which according to previous observations swells the cells, as evidenced by volume percentages greater than those of heparinized samples) seems necessary to overcome the shrinkage effect of potassium oxalate, such shrinkage being evidenced by volume percentages less than those of heparinized samples.

Fig. 5.—Sedimentation curves of samples with incomplete anticoagulation.

A proportion of 6 parts of ammonium to 4 parts of potassium oxalate seems to produce volume percentages closer to those of heparinized samples than other proportions or even other single salts.

In practice, between 4 and 12 mg. of the mixture of ammonium and potassium oxalate per 5 c.c. of blood have been generally considered safe. Ten milligrams per 5 c.c. as a routine quantity so far has been satisfactory. No evidence of clot has been detected in any sample as yet; photographed curves have been smooth and not irregular, as sometimes occurs with heparin. Hemolysis has not

occurred in any normal sample, and in the few pathologic samples where it has occurred, it has also occurred with heparin, and volume percentages of replicate samples as well as curves of sedimentation have been very close.

The fourth and last publication of this series will include a discussion of the effects of variations in venous stasis, delay, temperature of sample, containers, agitation, and quantity of formed elements upon the measurement of sedimentation.

A SHAKING MACHINE AND CONTAINERS FOR SHAKING SPUTUMS AND OTHER BODY FLUIDS DURING THE PROCESS OF HOMOGENIZATION*

W. STEENKEN, JR., AND M. M. SMITH
TRUDEAU, N. Y.

LITTLE question can be raised that marked agitation of tuberculous sputum during homogenization breaks up tenacious matter and small caseous or pussy particles, and increases the distribution of the tubercle bacilli in the specimen, thereby making possible a more accurate count of bacilli by microscopic examination of the smear.

There are many types of agitating and shaking machines from which to choose, but from the standpoint of performance and durability, the Red Devil,† or a similar type, is the most satisfactory. The model described in this article will shake a can of paint of any size up to a gallon, and the rate of agitation is 760 three-dimensional shakes per minute.

For our work a special container had to be designed for holding more than one specimen bottle in place during agitation. Also, it had to be so constructed that the bottles or cans could be placed inside the container in a way that would allow for differences in height, size, and shape, and would keep stoppers or lids firmly in place during the shaking operation.

DESCRIPTION OF CONTAINER

Fig. 1 shows a vertical section taken on the center line through the large group container, and shows vertical sections through two of the individual containers.

Fig. 2 is a plan view looking down on the group container with the top section (1) removed, and shows the arrangement of the individual containers within the group container.

*From the Research and Clinical Laboratory, Trudeau Sanatorium, Trudeau.

†Made by Landon P. Smith, Irvington, N. Y.

Received for publication, April 15, 1942.

Fig. 3 shows a vertical section taken on the center line through an individual container.

Fig. 4 is a plan view looking down with the top section (1) removed, and shows the specimen container in place.

FIG. 4

FIG. 3

FIG. 2

FIG. 1

The group container consists of two sections, the top section (1) fitting over the bottom section (2). It is designed to hold a given number of smaller indi-

vidual containers. The size of the group container is determined by the size and number of individual containers to be accommodated.

A cushion of soft rubber, or some other resilient material (3), is placed inside each section, as shown, to allow for variation in height of individual containers and to prevent movement of such containers during the shaking operation.

The individual container consists of two sections, the top section (4) fitting partly or completely over the bottom section (5), and it is designed to hold a specimen container (7). A rubber sponge cushion (6) is placed in each section, as shown, to compensate for the variation in height of stopper (8), and to provide for resiliency during the shaking process.

Plate II shows the following:

- 1, A cross section of an individual container.
- 2, A cross section of an individual container with bottle in place.
- 3, A cross section of an individual container with bottle in place under pressure. Note rubber compression.
- 4, A group container.
- 5, A group container with lid removed. Note also the upper layer of individual containers.
- 6, Shows how the individual containers stack in the group container. Also, a cross section of an individual container with bottle in place.
- 7, The shaking machine mounted on a concrete base which, in turn, is mounted on four rubber sponge cushions.
- 8, Shaking machine with group container, with individual container inside fastened in clamp and ready for shaking.

Our experience has proved that the use of this shaking machine with its specially designed containers, results in a better homogenization of sputum. The concentration of sodium hydroxide can be reduced. Those specimens that usually require 4 per cent routinely, can be digested with 3 per cent, and with as little as 2 per cent, depending upon the appearance of the sputum, thus decreasing the loss of acid fastness, and lessening the chance of killing the tubercle bacilli by the digesting mixture.

The marked agitation and speed of the shaking process make possible a more even distribution of the tubercle bacilli, and this enables us to obtain an accurate count of bacilli in concentrated smear, especially in the Gaffky I and the so-called negative specimens. By this method of shaking we have raised our positive findings 11.0 per cent, particularly in the low Gaffky counts (I, II, and III).

A SIMPLE SURGICAL TECHNIQUE FOR DEVIATING THE ENTIRE URINE INTO THE BLOOD STREAM*

HANS SELYE, M.D., PH.D., D.Sc., MONTREAL, CANADA

IN CONNECTION with many problems of renal physiology it is of great importance to establish whether a change elicited by damage to renal tissue is caused by interference with the excretory functions of the kidney or whether it is due to a derangement of its endocrine and metabolic activities. In such instances the technique usually employed is to compare the results of complete nephrectomy with those caused by ligation of both ureters. It is then assumed that while nephrectomy eliminates all functions of the kidney, ligation of the ureters abolishes only renal excretion. It has often been emphasized, however, that after ligation of the ureters some urine is still produced so that hydro-nephrosis results. Hence this technique does not eliminate excretion completely. Furthermore, the often very high pressure which develops in the renal pelvis is transmitted to the kidney cells and damages them severely, so that not only the excretory, but also all the renal functions must suffer to some extent. It should also be borne in mind that a kidney, whose excretory function is gradually abolished by back pressure, is not normal, and that inhibition of excretory work may in itself interfere with other activities of the kidney cells.

The object of this study is to describe an experimental technique which makes it possible to eliminate the result of renal excretion completely, without actually interfering with the process of urine production or with any other kidney function. The fundamental principle of this method is to prevent urine elimination by ligation of the urethra, and then to establish a communication between the bladder and the vena cava. Thus the urine which continues to be formed and accumulates in the bladder is led back into the blood. The technique is readily adaptable to most laboratory animals, but up to the present it has mainly been used for experiments on the rat.

The procedure is as follows: The rat is anesthetized with ether and tied on its back to an operating board. An incision is made through the skin and muscle layers in the midline from the pubic region to the umbilicus. The intestines are pushed cranial and the rectum is pushed to the left by means of cotton pads which can be held in position by a retractor whose other end is hooked onto some heavy object on the table. This arrangement makes it possible to obtain perfect exposure of the vena cava between the pelvis and the kidney region without the help of an assistant. Now the peritoneal covering of the posterior abdominal wall is severed by mere traction between two fingers, and the vena cava

*From the Department of Anatomy, McGill University, Montreal.
Received for publication, April 15, 1942.

is carefully separated from its surroundings between its bifurcation into the two iliac veins and the right iliohumbar vein. This is accomplished by blunt dissection using two curved forceps, each of which holds a small cotton pad. With the help of these pads it is easy to crush and sever the numerous little venules which enter the cava from the psoas major and the ventral surface of the lumbar vertebrae. Some of these latter venules are very large, yet they can all be severed without ligature if they are first crushed with the pads. If they tend to bleed, the hemorrhage is readily stopped by pressing a minute piece of cotton on them until clotting occurs. After this the vena cava is completely occluded by a ligature placed above the junction of the iliac veins. Another ligature is laid loosely around the cava just underneath the iliohumbar vein. It should be emphasized here that in the rat ligature of the vena cava caudad from the renal veins produces no symptoms as there is an adequate collateral circulation.

Fig. 1.—First stage of the operation. The bladder is exposed and the blunt end of the curved cannula is tied into its cranial end with the ligature shown by arrow A. This ligature fits into one groove of the cannula, while the other groove is visible between the pointed end and the anatomical forceps which holds the cannula. Arrow B points to the ligature occluding the urethra. A curved forceps holds this ligature.

Now the urinary bladder is pulled forward and a ligature is tied around the urethra just caudad from the point where the ureters enter the bladder. In order to maintain a good blood supply to the bladder it is well to avoid any interference with the large veins which accompany the ureters. After loss of urine has thus been prevented by occluding the urethra, a small incision is made on the apex of the bladder, and the blunt end of a steel cannula is introduced into the lumen. This cannula may be fastened in this position by a single ligature, as shown in Fig. 1.

The cannula, which will connect the bladder with the vena cava, is made from gauge 16 or gauge 13 injection needles by cutting off about 1 to 1½ inches

near the pointed end, making one circular groove near the blunt and one near the pointed end to hold ligatures in place. It is well to bend the cannula slightly, as shown in Figs. 1 and 2, so as to adapt them better to the anatomy of the pelvic region. In order to prevent clotting it is advisable always to use the widest gauge that can be introduced into the vena cava. If this precaution is observed, and the inner surface of the needle is heparinized, thrombi do not form, and the passage of urine into the vein proceeds readily throughout the experiment. Reflux of blood from the vein into the bladder is rarely seen, since the pressure is usually greater in the bladder than it is in the vein. Both in order to avoid reflux and as a precaution against a delay in the re-entrance of urine into the blood, most of the bladder wall should be tied off with the ligature which fastens the cannula into the bladder. Only a small stump with the ureteral orifices needs to be left intact.

Fig. 2.—Dissection of the lower abdomen showing the position of the cannula after completion of the second stage of the operation. Arrow A designates the ligature which ties the vena cava to the pointed end of the cannula which is now inserted into the lumen of the vein. Arrow B points to the ligature fastening the blunt end of the cannula into the cranial end of the bladder. Arrow C points to the ligature occluding the urethra. Arrow D indicates the ligature occluding the vena cava above its bifurcation into the iliac veins.

The bladder is now washed with heparin which is introduced into it from a syringe armed with a fine injection needle that can readily be introduced into the free, pointed end of the cannula. It is important to aspirate into this syringe any air bubbles that may have entered into the bladder or the cannula in order

to prevent air embolisms. It is well to wipe off any excess heparin that may ooze out through the cannula, since a few drops of it suffice to prevent clotting, and an excess may lead to diffuse bleeding. Now follows the most dangerous part of the operation: The introduction of the pointed end of the cannula into the vena cava cranial from the place where the vessel was occluded and caudad from the loosely laid ligature underneath the iliolumbar vein. This is accomplished by firmly grasping the middle of the cannula with one forceps, and the vena cava with another, and then carefully pushing the point into the vessel until the circular groove underneath the pointed end is at the level of the loosely laid ligature. At this moment a few drops of blood usually escape from the vein, but bleeding is stopped immediately by pulling the ends of the loose ligature and thus fastening the wall of the cava to the cannula. A second knot fixes this ligature and thus a permanent anastomosis between urinary bladder and vena cava has been established. After removing the retractor and the cotton pads, which kept the intestines out of the way, the muscle and skin wounds are closed and the operation is finished. The intervention takes approximately fifteen minutes, and in the last series of fifty operations on rats, ranging between 105 and 275 Gm. of body weight, there was not a single case of death during the operation. Female animals are preferable because the uterus does not interfere with the cannula as much as the prostate and seminal vesicles, yet both sexes can be used.

After the animals recover from the anesthesia, they appear to be perfectly normal and readily take nourishment, showing no detectable signs of damage. Approximately twenty-four hours are required before the animals begin to show some tremor characteristic of uremia. The average survival time is thirty to forty-five hours.

Complete nephrectomy or ligature of the ureter is generally tolerated for a slightly longer time than the urinary-venous anastomosis. It is remarkable, however, that the continuous influx of urine into the blood is not accompanied by more rapidly developing signs of intoxication. It will be recalled that numerous investigators found urine to be rich in highly toxic substances, and workers who made a unilateral anastomosis between a ureter and a vein in the dog¹⁻⁴ concluded that introduction of the urine produced by one kidney suffices to elicit a rapidly developing fatal intoxication even if urine elimination through the other kidney proceeds normally. On the other hand, Geer and Dragstedt,^{5, 6} who used a similar surgical procedure, observed no toxic symptoms and no rise in blood nonprotein nitrogen after unilateral anastomosis of a ureter and a vein in the dog. In certain cases their animals survived several weeks and were still in good condition at the time they were sacrificed. From this it would appear that urine in itself is not a highly toxic product.

The only investigator who attempted to connect both ureters with veins was de Almeida^{7, 8} who, like all previous investigators, used the dog as an experimental animal. He employed a rather complicated method which involved the insertion of long tubes into the ureters, the tubes being led out of the peritoneal cavity and then introduced into the femoral vein. The procedure, which was successful only in a limited number of cases, led to the usual symptoms of

uremia and was fatal in a shorter period than complete nephrectomy. These experiments were also performed merely with the intent to study the toxicity of urine and, to our knowledge, the technique was never employed as a method for the selective differentiation between the excretory functions of the kidney on the one hand, and its endocrine and metabolic activities on the other hand.

The most striking pathologic changes, which we noted in our rats bearing a urinary-venous anastomosis, were a pronounced enlargement of the adrenal cortex, occasional lung edema, and a rise in the blood nonprotein nitrogen which was usually more pronounced than at a comparable period after complete nephrectomy. The marked decrease in blood hemoglobin, seen in the anastomosis-bearing animals, indicated, furthermore, that, owing to the continuous reflux of urine, blood dilution is more pronounced than after nephrectomy.

It is hoped that the use of this simple experimental technique, applicable even to small laboratory rodents, will prove useful in the study of the purely endocrine and metabolic functions of the kidney.

SUMMARY

A technique is described which permits the deviation of the entire urine into the inferior vena cava after ligation of the urethra by means of a cannula that connects the bladder with the vein. This technique permits the study of the endocrine and metabolic activities of renal tissue apart from its excretory function.

The expenses of this investigation were defrayed through a fund donated by the Des-Bergers-Bismol Co., Montreal, Canada.

THE USE OF A DETERGENT IN SOLUBILITY TESTS FOR THE IDENTIFICATION OF PNEUMOCOCCI*

ALBERT H. HARRIS, M.D., AND GEORGE Y. McCURE, M.D.
ALBANY, N. Y.

THEORETICAL considerations suggested that synthetic surface-active agents might affect pneumococci in a manner similar to that of bile and its salts. It is well known that lysis of pneumococci is activated by any process that destroys viability without impairing autolytic enzyme-activity, while it is inhibited by conditions unfavorable to such activity.¹⁻³ Agents that will induce the dissolution of pneumococci are legion. The principal ones, as listed by White,⁴ are bile acids and salts, dilute sodium hydroxide, unsaturated fatty acids, soaps, and saponin. The most satisfactory among these is the bile salt, sodium desoxycholate, which brings about the dissolution of pneumococci at room temperature in a very few minutes.

Most of the agents mentioned depress the surface tension of the solution in which they are dissolved. The recently developed surface-active agents, some of which are long-chain alcohol sulfates, are strong surface-tension depressants. Cowles⁵ showed that "duponols," in a concentration of only 0.03 per cent, prevent the growth of gram-positive bacteria. One such compound, duponol WA (flakes),† was employed by us in solubility tests.

EXPERIMENTAL WORK

A 0.2 per cent solution of duponol in distilled water was found to have exactly the same activity as a 1 per cent solution of sodium desoxycholate. When higher and lower concentrations were employed, the clearing of the solution was slower. A 0.2 per cent solution is opalescent, but when it is added to broth cultures, this property disappears. Sterilization before use is unnecessary. The solution has not been found to deteriorate, even if stored for several months. The microorganisms were cultivated in an infusion broth that contained 2 per cent peptone, but no serum, and only 0.02 per cent added dextrose. The addition of dextrose to the medium may be omitted. The dissolution of pneumococci in eighteen-hour-broth cultures was observed grossly and also by examination of films stained by Gram's method and prepared immediately after the addition of 0.1 ml. of duponol or sodium desoxycholate to 0.6 ml. of culture. Films were also prepared at the end of five minutes and of one hour.

*From the Division of Laboratories and Research, New York State Department of Health, Albany.

Received for publication, April 21, 1942.

Presented at the meeting of the New York State Association of Public Health Laboratories, Albany, November 1, 1940.

†A detergent manufactured by DuPont.

Twelve strains of pneumococci, comprising seven different types, dissolved completely in less than five minutes at room temperature under the influence of either duponol or sodium desoxycholate. All were insoluble when previously heated to 75° C. for twenty minutes. One type-specific type 14 strain and two degraded strains that had lost type specificity dissolved incompletely in both reagents, while two other strains, supposedly representing completely degraded pneumococci, appeared to be insoluble in both. Eleven strains of streptococci producing greenish discoloration of blood agar, and one strain each of hemolytic streptococcus, nonhemolytic streptococcus, and Friedländer's bacillus were insoluble in both reagents.

The pH of an eighteen-hour broth culture of pneumococcus is about 7.0 or 7.2. It is not influenced appreciably by adding the bile salt. It is lowered slightly when duponol is added, but remains well within the range of optimal enzymatic activity. The surface tension of the broth used was found to be 47.1 dynes per centimeter. The addition of sodium desoxycholate lowers the tension to approximately 44; and of duponol, to approximately 36.

Duponol was used in parallel tests with sodium desoxycholate during a four-month period in the routine examination of specimens received for pneumococcus typing. Its activity was found to compare very favorably with that of the bile salt. Broth cultures of fishings of colonies surrounded by a zone of greenish discoloration were tested; eighty-five individual strains were soluble in both reagents, two were partially soluble in both, and 78 were insoluble in both. In no instance was a discrepancy observed.

The low cost of duponol WA (flakes) compared with that of sodium desoxycholate is its principal advantage. The method has now been adopted as an alternative standard procedure in solubility tests for pneumococci in this laboratory.

SUMMARY

A detergent, duponol WA (flakes), in 0.2 per cent aqueous solution, has been found to have the same activity as 1.0 per cent sodium desoxycholate in solubility tests for differentiating pneumococci from other microorganisms producing greenish discoloration on blood agar. It has the advantage of being very inexpensive.

CHEMICAL

THE NORMAL VALUE FOR THE HIPPURIC ACID LIVER FUNCTION TEST*

OPAL E. HEPLER, PH.D., M.D., AND HELEN GURLEY, M.S.
CHICAGO, ILL.

QUICK¹ first described the hippuric acid liver function test in 1933. He stated that under the conditions of the test the normal excretion of benzoic acid as hippuric acid is 3 to 3.5 Gm. In 1936 he² suggested that the efficiency of the liver be expressed as a percentage, using 3 Gm. of excreted benzoic acid as normal. On this basis he gave the normal range as 85 to 110 per cent. In 1940 he³ improved the original method by the addition of 5 Gm. of ammonium sulfate for each 10 c.c. of urine to decrease the solubility of the hippuric acid. At this time he gave 90 to 120 per cent as normal excretion, and suggested that an excessive excretion, i.e., over 120 per cent, might be abnormal.

After we started using the ammonium sulfate method routinely, we noticed that many of our values were over 120 per cent. Some were as high as 150 per cent. Several patients who had previously been tested by the old method gave consistently higher results with the new method. In some cases the variation between the two methods amounted to 20 per cent. Theoretically, the difference between the additive corrective factors (0.33 Gm. in the old method and 0.1 Gm. in the new), used for the amount of hippuric acid remaining in solution in the urine, should make the results by the two methods essentially identical. Since this was not found to be the case, it seemed desirable to investigate the normal excretion of hippuric acid and the factors that may influence it.

PROCEDURE

Hippuric acid tests were run on 30 men and 25 women, all presumably normal, and between the ages of 20 and 30 years, the majority being between 20 and 25 years of age. The subjects were either students or laboratory technicians. Six grams of sodium benzoate were dissolved in 30 c.c. of water and taken after breakfast. This was followed by one-half glass of water. The bladder was emptied immediately before the test, and hourly urine specimens were collected for four hours. Each specimen was measured and, if over 100 c.c., it was acidified with a few drops of acetic acid and concentrated over a water bath to about 50 c.c. The four specimens were pooled, as recommended

*From the Department of Pathology, Northwestern University Medical School and the Clinical Laboratory, Passavant Memorial Hospital, Chicago.
Received for publication, June 10, 1942.

by Snell and Plunkett.⁴ The pooled specimen was measured and divided in equal parts. To one portion 5 Gm. of solid ammonium sulfate were added for each 10 c.c. of urine. When the salt was dissolved, the urine was filtered and then acidified with concentrated hydrochloric acid until the urine was distinctly red to Congo red paper. After vigorous stirring, the specimen was allowed to stand for thirty minutes in the icebox before separating the crystalline hippuric acid by filtration through a Buchner filter. The crystals were washed with ice cold water, then dissolved in hot water. The amount of hippuric acid was determined by titrating with 0.2 N. sodium hydroxide, using phenolphthalein as an indicator. One cubic centimeter of 0.2 N. sodium hydroxide equals 0.0358 Gm. of hippuric acid. This method checked very well with the gravimetric method. We had adopted the titration method, since most clinicians in hospitals like their reports the same day the test is performed; and with the gravimetric method it was necessary to let the hippuric acid dry overnight in order to obtain uniform results. The aliquot portion was treated in a similar manner except that no ammonium sulfate was added. The calculation for the two methods is identical except for the addition of the amount of hippuric acid remaining in solution in the urine. With the method using ammonium sulfate, 0.1 Gm. of hippuric acid is added for each 100 c.c. of urine, and 0.33 Gm. per 100 c.c. is added in the method not using ammonium sulfate. These are the amounts assumed by Quick to remain in solution. The amount of hippuric acid was multiplied by 0.68 to change it to benzoic acid.

DISCUSSION

Not all the hippuric acid excreted in the urine is precipitated by the methods used. Quick, therefore, corrected his results by adding 0.33 Gm. per 100 c.c. of urine to the value found without the addition of ammonium sulfate, and 0.1 Gm. to the value obtained when the sulfate was added. The results with each method are stated as a percentage, obtained by dividing the "corrected" amount of benzoic acid excreted as hippuric acid by the arbitrarily chosen normal excretion of 3 Gm., and multiplying by 100.

The estimated amount of benzoic acid excreted as hippuric acid in the group of women ranged from 75 to 149 per cent with the old method, that is, the method not using ammonium sulfate. In the group of men the amount ranged from 110 to 156 per cent. With the new method, using ammonium sulfate, the range of the estimated amount for women was 95 to 155 per cent and, for men, 114 to 166 per cent. The difference between the two methods for each person varied greatly. The greatest increase of the ammonium sulfate method over the old method was 33 per cent. In four cases results by the old method were greater than those obtained by the use of ammonium sulfate. However, the uncorrected value in each case was greater by the latter method, the difference being due to the larger quantity (0.33 Gm.) added to "correct" the value by the method not using ammonium sulfate. The variation in the two methods can be explained on the basis of the variability in the precipitation of the hippuric acid in the urines without the addition of ammonium sulfate. The addition of ammonium sulfate to the urine gives a more con-

Fig. 1.—Per cent of excretion of hippuric acid as benzoic acid in relation to weight.

○—○ Men.

sistent and accurate estimation of the hippuric acid. Weichselbaum and Probstein⁵ demonstrated that, with Quick's original method, the amount of hippuric acid that remained in solution was greater than 0.33 Gm. per 100 c.c. and showed a large range of variability with different urine specimens. They suggested using sodium chloride to decrease the solubility of hippuric acid. However, Marron⁶ found that ammonium sulfate was the best salt to use for reducing the solubility of hippuric acid.

The statistical analysis of the data obtained in these tests is shown in Table I. From this table it is seen that the mean body weight, the mean surface area, and the mean per cent excretion is much greater in men than in women. The coefficients of correlation between body weight and per cent excretion (+0.873) and between surface area and per cent excretion (+0.834) in the women of this group was much higher than in the men (+0.545 and +0.429, respectively). The coefficient of correlation between body weight and per cent excretion in the men, in the women, and in the combined group was higher than that between surface area and per cent excretion in the same groups.

TABLE I
STATISTICAL ANALYSIS OF DATA

	MEN	WOMEN	MEN AND WOMEN
Body weight and per cent excretion*			
Body weight			
Mean	172.60 \pm 2.57	125.80 \pm 2.12	152.60 \pm 2.71
Standard deviation	21.00 \pm 1.84	16.48 \pm 1.57	29.74 \pm 1.91
Per cent excretion			
Mean	140.86 \pm 1.60	124.60 \pm 2.04	137.60 \pm 1.47
Standard deviation	12.44 \pm 1.08	15.86 \pm 1.51	16.10 \pm 1.09
Correlation coefficient	+0.545 \pm 0.095	+0.873 \pm 0.032	+0.677 \pm 0.049
Surface area and per cent excretion*			
Surface area			
Mean	1.99 \pm 0.02	1.62 \pm 0.016	1.892 \pm 0.022
Standard deviation	0.147 \pm 0.02	0.12 \pm 0.011	0.229 \pm 0.015
Per cent excretion			
Mean	140.86 \pm 1.60	124.80 \pm 2.12	137.60 \pm 1.47
Standard deviation	12.44 \pm 1.08	16.48 \pm 1.57	16.10 \pm 1.09
Correlation coefficient	+0.429 \pm 0.110	+0.834 \pm 0.041	+0.613 \pm 0.058

*Per cent excretion = $\frac{\text{Number of grams excreted as benzoic acid}}{3 \text{ Gm.}} \times 100$.

The relation of excretion to body weight is also shown in Fig. 1. These curves were made from weighted averages for each 10 pounds of weight for the men and women separately. None of these persons were obese. The variations in weight were due to differences in general build, muscular development, and stature. In such a group the size of the organs may be assumed to vary directly with the size of the body as a whole. A person with a large well-developed body will have a larger liver. This being true, it may be assumed that the liver forms hippuric acid from benzoic acid in proportion to its size. It is not surprising, therefore, to find that the per cent of benzoic acid excreted as hippuric acid is greater in larger built persons than in smaller built ones. For this reason, the normal standard for such excretion should not be fixed within even fairly wide limits but should be related to the body weight of the patient.

It is interesting to note that the coefficient of correlation between per cent of excretion and both the body weight and the surface area was much higher in the women of this group than in the men. This is also shown in Figs. 1 and 2. The curve for the women is much steeper and straighter in each case than that for the men. This may be due in part to wider range of weights of the men (135 to 220, or 85 pounds) as compared with the range in the women (103 to 167, or 64 pounds). However, while the actual surface areas of the men were, in general, greater than in women, the spread between the extremes in each sex was almost identical—for women, 1.43 to 1.87, or 0.44 sq. m.; for men, 1.78 to 2.26, or 0.48 sq. m.

We do not agree with Rosenberg and Soskin⁷ that a hypersecretion of hippuric acid is pathologic, at least in all cases. We believe that the weight of the patient must be taken into consideration. Although Quick⁵ definitely stated in one of his early articles that the quantitative results indicated that the excretion of hippuric acid depended on the size of the person, that is, on the surface area, this has not been emphasized in the routine use of the test. Consequently high values have been misinterpreted.

CONCLUSIONS

1. The addition of ammonium sulfate to the urine to decrease the solubility of hippuric acid makes the hippuric acid liver function test more accurate and consistent in results.
2. The lower limit of normal when ammonium sulfate is used in the test should be 90 per cent.
3. There should be no upper limit for normal because there is a correlation between body weight and the benzoic acid excreted as hippuric acid.

DETERMINATION OF ALUMINUM IN BIOLOGICAL MATERIAL WITH THE EVELYN PHOTOELECTRIC COLORIMETER*

JACQUELINE S. FRONT, M.A., AND JOSEPH B. KIRSNER, M.D.
CHICAGO, ILL.

ALTHOUGH numerous quantitative tests for aluminum have been described in the literature, no method has proved entirely satisfactory. A major technical problem has been the development of a stable, colored lake free of interfering substances and suitable for colorimetric analysis. In the course of a study on the effect of aluminum hydroxide and aluminum phosphate on mineral excretion in man, an improved colorimetric technique for the determination of aluminum was developed which overcomes this difficulty and permits the rapid and accurate quantitative measurement of aluminum in biological material.

PRINCIPLE OF PROCEDURE

The material to be tested for aluminum is put into solution and brought to a pH of 4.9. Aurintricarboxylic acid is added, and the mixture is heated to from 70° to 78° C. until a red color develops, the intensity of which is measured in a colorimeter.

Rapid and reproducible reading of samples for their aluminum content is further facilitated by a chart which converts the values obtained from the colorimeter into milligrams of aluminum. This chart may be prepared by plotting the readings of light intensity obtained from solutions of known aluminum content on semilogarithmic paper, and interpolating from the standard curve.

DEVELOPMENT OF A STANDARD CURVE

Reagents:

1. *N/10 HCl*—8.3 ml. of 37 per cent (concentrated) HCl (reagent grade) diluted to one liter with distilled water.
2. *Aluminum standard*—3.5018 Gm. of $\text{K}_2\text{SO}_4 \cdot \text{Al}_2(\text{SO}_4)_3 \cdot 24\text{H}_2\text{O}$ are dissolved and diluted to one liter with *N/10 HCl* (stock solution). Dilute 1:20 with *N/10 HCl* to give a solution containing 0.01 mg. Al per milliliter.
3. *Phthalate buffer*—*M/5* potassium acid phthalate ($\text{KHC}_8\text{H}_4\text{O}_4$). 20 Gm. of potassium biphthalate in 500 ml. of water.
250 ml. of *M/5* phthalate and 238 ml. of *N/10 NaOH* made up to one liter with water. The pH should be 4.9 to 5.1.

*From the Frank Billings Medical Clinic, Department of Medicine, University of Chicago. This work was supported by a grant from John Wyeth & Brother, Inc., Philadelphia, Pa. Received for publication, May 18, 1942.

4. *0.1 per cent aurintricarboxylic acid*—(Eastman Kodak P 4468.)
1 Gm. of aurin and 2.5 ml. of concentrated NH_4OH diluted to one liter with water. Keep in a brown bottle. A good quality of aurin gives a straw-yellow color in a dilution of 1:100 ml.
5. *1:50 NH_4OH* —1 ml. of concentrated (28 per cent) NH_4OH made up to 50 ml. with water.
6. *Methyl red*—0.2 per cent alcoholic solution.
7. *Ammonium thiocyanate* (or potassium thiocyanate)—60 per cent. Keep in a brown bottle.
8. *Ether*—exposed to light or containing some alcohol.

Standards:

Ten standards of varying concentrations of aluminum are prepared from the stock solution to contain from 0.005 mg. per milliliter to 0.05 mg. per milliliter.

Blank:

Since the pH affects the color of the aurin itself without the addition of aluminum, it is important to have the blank at the same pH as the standards or unknowns. Accordingly, the blank contains all the reagents except the aluminum.

PREPARATION OF A STANDARD CALIBRATION CURVE

0.42 ml. of 1:50 NH_4OH ^a
5.00 ml. of phthalate buffer
1.0 ml. of standard
1.0 ml. of aurin

Three such tubes are prepared for each dilution of standard in addition to three blanks. The blank contains 1 ml. of tenth-normal hydrochloric acid in place of a standard solution. After the addition of the aurin the tubes are shaken gently to mix the contents and placed in the test tube rack. When all tubes are set up and stoppered, the rack is placed in a water bath for exactly five minutes at a temperature between 70° and 78° C. The rack with the tubes is then removed from the bath and immersed in a deep pan of cold water for five minutes, or until the tubes reach room temperature. The water level in the pan should extend at least to the level of the solution inside the tubes. The solution is then diluted to the final volume of 25 ml. The first few milliliters are used to wash down any solution condensed on the walls of the tube into the main body of the liquid, and then the remainder is allowed to run freely into the middle of the tube to aid in mixing the solution. The tube is then moved in a circular motion until the color is evenly distributed throughout. Inverting the tube to mix the contents is faster, but any loss of fluid introduces an error in the reading. The standards are then ready to be read in the colorimeter. The reading of the "blank" is subtracted from that of each standard. The galvanometer readings, indicating the amount of light transmitted, are then plotted against the concentration of aluminum, using semilogarithmic paper. The values from this prepared chart can be used indefinitely to determine the concentration of aluminum in any unknown solution prepared under identical conditions.

^aOne milliliter of standard requires 0.42 ml. of 1:50 NH_4OH for neutralization to methyl red.

CENTER POINT

The colorimeter is adjusted to read 100 per cent light transmission with the tube containing water in the path of the light. The tube is then removed and the galvanometer reading taken as the "center point." The same "center point" is kept throughout the reading of all the unknowns prepared at the same time.

TABLE I

RECOVERY OF ALUMINUM IN THE FECES DURING ORAL ADMINISTRATION OF ALUMINUM HYDROXIDE AND ALUMINUM PHOSPHATE

ANTACID GIVEN	CASE I		CASE II	
	4-DAY INTAKE Al (MG.)	4-DAY OUTPUT Al (MG.)	4-DAY INTAKE Al (MG.)	4-DAY OUTPUT Al (MG.)
Aluminum hydroxide	4,716	4,866	4,716	4,986
Aluminum phosphate	2,625	2,787	2,625	2,697
Control		13		15

TABLE II

RECOVERY OF ALUMINUM CHLORIDE ADDED TO SAMPLES OF FECES

	ALUMINUM ADDED (MG./ML.)	ALUMINUM FOUND (MG./ML.)
2 Gm. of feces	0.0120	0.0123
2 Gm. of feces	0.0120	0.0122
2 Gm. of feces	0.0120	0.0122

Blank determinations on diluted urines, plasma, feces and distilled water, known to be free of aluminum but ashed, extracted, and treated with the reagents, gave values of 0.0002 to 0.0003 mg. per milliliter.

PREPARATION AND ANALYSIS OF UNKNOWN

Feces.—The quantity of feces used for analysis depends upon the conditions of the clinical experiment. A patient on an ordinary diet excretes a very small amount of aluminum in the stool, so that it is advisable to use 10 Gm. (wet weight) of feces for an analysis. During aluminum therapy 2 Gm. of feces are sufficient.

For *ashing*, 2 Gm. of fresh, moist, well-mixed feces are weighed into a vitreosil silica beaker and 0.2 ml. of nitric acid, and 0.2 ml. of sulfuric acid are added. The water is driven off by heating at 100° C. in a drying oven. It is then ashed in an electric muffle furnace for about twenty-four hours at a temperature of 400° to 500° C. The heat should be started slowly to avoid spattering of the material. When a fluffy white ash is obtained, 10 ml. of tenth-normal hydrochloric acid are added to the ash, which is transferred to a centrifuge tube where the insoluble material is separated by centrifuging. According to the expected concentration of aluminum, aliquots of the supernatant fluid are further diluted 25 to 50 times.

If iron is present in the solution, it can be removed after bringing it to volume by adding 60 per cent ammonium thiocyanate and ether to a portion and shaking it several times in a separatory funnel or centrifuge tube. The colored ether extract is siphoned off, and the aluminum is determined on 1 ml. aliquots of the colorless substrate, exactly as in the calibration of the standard curve.

Urine.—One hundred grams of urine are weighed into a vitreosil beaker, 0.2 ml. of concentrated sulfuric acid and 0.2 ml. of nitric acid are added, and the solution is evaporated to dryness, charred in a drying oven, and then ashed in a muffle furnace for about twenty-four hours at a temperature between 400° and 500° C. Five milliliters of tenth-normal hydrochloric acid are added to the ash. The solution is then centrifuged. Two milliliters duplicate samples of the clear supernatant liquid are placed in colorimeter tubes and evaporated to dryness in an oven at 100° C. One milliliter of tenth-normal hydrochloric acid is then added to the dried residue in the tubes, and the color is developed exactly as for feces. It is sometimes advisable to combine the ash of several samples to increase the concentration of aluminum. Another method is to add a known amount of aluminum to bring the color into a better range for reading.

The concentration of aluminum in the urine is extremely low (0.005 to 0.15 milligrams per liter) even during aluminum therapy, and there are large variations from day to day in the same person on a constant intake of aluminum.

TABLE III

RECOVERY OF ALUMINUM IN URINE DURING ORAL ADMINISTRATION OF ALUMINUM HYDROXIDE AND ALUMINUM PHOSPHATE

Blood.—Fresh oxalated blood is mixed well and centrifuged. Ten to 15 ml. of plasma are placed in a vitreosil silica beaker, 0.2 ml. of nitric acid and 0.2 ml. of sulfuric acid are added, and the solution is dried in an oven at 100° C. The sample is then ashed in a muffle furnace for twenty-four hours at 400° C., or until the ash is white. The ash is dissolved in 5 ml. of tenth-normal hydrochloric acid and transferred to a centrifuge tube. It is then centrifuged to remove the insoluble material. Two milliliter duplicates of the clear super-

natant liquid are placed in colorimeter tubes and evaporated to dryness in an oven at 100° C. When dry, 1 ml. of tenth-normal hydrochloric acid is added, and the other reagents, as for the urine and feces.

Amounts of aluminum recovered from the blood of patients excreting about 2 to 4 mg. per twenty-four hours in the feces vary from 0.0113 to 0.0984, with an average of 0.045 mg. per 100 ml.

Recovery Experiment.—A solution containing a known amount of aluminum was added to samples of plasma and ashed, as described above. The results are recorded in Table V.

EXPERIMENTAL CONSIDERATIONS

1. *Influence of pH and temperature on the color of the lake formed by the aluminum-aurin complex.* Eveleth and Myers concluded,³ after a critical review of the colorimetric analyses for aluminum currently in use, that the lake formed with aurintricarboxylic acid as a chromatogenic agent was superior to that formed with alizarin, or with 1, 2, 5, 8-hydroxyanthraquinone. On the basis of their work, aurin was used in this test. It is not an ideal reagent for colorimetric work, however, since it is not colorless and varies with the pH and temperature. Thus, in a solution of pH 7.0 or above, it is yellow; at a pH of 3 to 5 it has a faint orange-pink color. Various investigators have sought to overcome this difficulty by suggesting a final adjustment of the solution to a pH 7.2, using ammonium chloride for the purpose of removing any excess color. This procedure is difficult to control, since the lake is readily decomposed or its color progressively fades.

In the present test the pH of the aluminum solution was adjusted before the color was developed and maintained at a constant hydrogen-ion concentration by means of a buffer. The acid solution of digested biological material was made neutral to methyl red with a small amount of ammonium hydroxide. A phthalate buffer at pH 4.9 to 5.1 was used because potassium biphthalate was easier to handle than the hygroscopic ammonium acetate used by some investigators for an acetate buffer. By the foregoing procedure a solution was obtained which had a final pH of 5.1. At this pH a definite red lake formed in the presence of aluminum. The color, however, developed slowly at room temperature. When heated in a water bath at 70° to 78° C., it developed a maximum intensity in five minutes.

2. *Prevention of the precipitation of the colloidal color complex at high concentrations of aluminum.* Previous investigators reported precipitation of the lake when the concentration of aluminum exceeded 0.015 mg.²² To obtain a curve for the photoelectric colorimeter, it was desirable to keep the lake in a

dispersed phase well beyond a concentration of 0.05 mg. The stability of the lake was not increased by changes in pH after the development of color; it was less stable when large amounts of ammonium salts were added. Attempts to peptize the precipitate by adding large amounts of water were unsuccessful. Using organic solvents in diluting the colored lake did not prevent it from precipitating. Heating above 80° C. increased the tendency of the lake to precipitate. When more than 1 ml. of aurin was used, it was less stable.

Chart 1.—Comparison of methods for sensitivity.

This problem was solved by the following procedure: The aluminum-aurin lake was allowed to form in a volume of solution not exceeding 10 ml., and was heated at 70° to 78° C. for five minutes. After cooling, it could be diluted with water to any desired volume without danger of precipitation. A solution containing as much as 0.063 mg. of aluminum in 25 ml. remained stable for an indefinite period of time (Chart 1).

3. *Optimum quantity of aurin reagent for developing a color with aluminum.* Amounts of aurin reagent, varying from 0.16 ml. to 2.0 ml., were tested. One milliliter yielded the best results. An amount of aurin less than 1 ml. was insufficient to contrast differences in concentration of aluminum; more than 1 ml. gave too much color to the blank.

4. *Elimination of interfering substances.* Yoe,²³ after investigating certain metallic ions which might form colored lakes similar to that of aluminum with aurin, found that all except iron were decolorized by ammonia.

A qualitative test to determine whether iron is present in the sample should be made before the development of color. Sixty per cent of ammonium thiocyanate, followed by an ether extraction, completely removed the interfering substance when present.

5. *The final dilution.* For the greatest accuracy in photoelectric colorimetry, the intensity of light transmitted by the colored solution should cause a deflection of the galvanometer needle within the most sensitive range of the instrument. Most of the galvanometer readings should fall, therefore, between 80 and 20 on the galvanometer scale. The final volume of 25 ml. was found, experimentally, to meet this requirement.

6. *Selection of filter.* The filter was selected from a spectrophotometric analysis of the colored solution. The characteristic peak of maximum transmission was between 520 and 540 $m\mu$, at about 530 $m\mu$. The Evelyn filter No. 520 was slightly more sensitive than No. 540.

COMMENT

Analyses of feces, urine, and plasma for aluminum before and after the administration of aluminum phosphate and aluminum hydroxide indicate that the aluminum is excreted entirely by way of the gut and that there is very little, if any, absorption into the blood stream. Kehoe and co-workers⁷ found "the daily output in the feces . . . practically equivalent to daily intake in the diet," when speaking of the trace metals, such as aluminum, normally found in the body. In agreement with this observation the figures in Table I show a quantitative recovery of aluminum in the feces during aluminum therapy.

These same authors⁷ report the concentration of aluminum in normal urine as 0.052 mg. per liter \pm 0.025 mg. The values given for control urines in Table III of the present study are 0.015 mg. and 0.052 mg. Since the concentration of aluminum in the urine varies from day to day in the same person on a constant diet, sharp margins of normal are not easily established.

Grasinov⁴ reported 0.068 to 0.0708 mg. of aluminum in 100 Gm. of whole blood. Kehoe⁷ found 0.015 mg. \pm 0.012 mg. of aluminum per 100 Gm. of whole blood "occurring almost entirely in the plasma." The values in Table IV of this present study, based on analyses of plasma, range from 0.015 to 0.050 mg. per 100 c.c.

From these comparisons it may be concluded that the results of the present method are in agreement with those of previous investigators.

CONCLUSIONS

1. An improved method for the quantitative determination of aluminum in biological material, using the Evelyn photoelectric colorimeter, is described. The use of a phthalate buffer, a smaller volume of reaction mixture, and careful control of the pH and temperature of the solution, as well as of the time of dilution, contribute to the formation of a stable-colored solution. The procedure is easily performed and yields accurate and reproducible results.

2. There is no significant increase in the aluminum content of the blood or urine after the oral administration of aluminum hydroxide or aluminum phosphate.

MEDICAL ILLUSTRATION

THE BASIC TECHNIQUE OF KODACHROME PHOTOGRAPHY OF FLUORESCENCE PHENOMENA*

FRANK H. J. FIGGE, PH.D.,† AND CARL DAME CLARKE, PH.D.
BALTIMORE, MD.

UNTIL recently the photography of fluorescence phenomena was seriously handicapped since it was unable to reproduce accurately a variety of colors. It was possible to record some of these color differences by means of black-and-white film.^{1, 3, 4} However, this method is truly colorless and falls flat when compared with the spectacular and delicate shades of color that have been observed and described as a result of fluorescence in near-ultraviolet radiations. The relatively recent development of practical, efficient sources of near-ultraviolet radiations has given a great impetus to fluorescence studies in many fields, and especially in the field of medical examinations and diagnosis.^{1, 2, 4, 5} An accurate method of reproducing colors is the result of the development of Kodachrome film. These two developments of suitable lighting and film have gone hand in hand and each serves to amplify the utility of the other.

The simple efficient apparatus and filters necessary to extend the limited range of visual perception by means of fluorescence phenomena has been reported previously.² It is the purpose of this paper to describe and discuss equally simple methods and apparatus for accurately and faithfully recording fluorescence phenomena by means of Kodachrome photography.

Fluorescence is the term applied to the phenomenon which certain substances or bodies show when illuminated with ultraviolet light. It usually involves the absorption of the invisible near-ultraviolet radiations and the emission of visible light of longer wave length. For a more complete discussion, the reader is referred to other literature on this subject.^{1, 2, 4}

One of the difficulties that had to be overcome in the photography of fluorescence was the fact that the ordinary film or plate is less sensitive to the rays of visible light caused by fluorescence than it is to the reflected rays of the near-ultraviolet or so-called actinic rays used to excite the fluorescence. The problem was to find a filter to place either in front or in back of the lens of the camera to absorb the reflected near-ultraviolet radiations and to transmit fully the relatively feeble rays of visible light caused by fluorescence. The photography of fluorescence must be done in a dark room. No extraneous or stray light can

*From the Departments of Anatomy and Art, University of Maryland School of Medicine.

†One of us (F. H. J. Figge) is indebted to Dr. C. N. H. Long and the staff of the Physiological Chemistry Department at Yale University School of Medicine, who first demonstrated the feasibility of Kodachrome photographs of porphyrin incrustations in rats.

This work was aided by a grant from the Anna Fuller Fund for Cancer Research. The reproduction of the Kodachrome photographs was made possible by the J. A. Cox Fund.

Received for publication, December 6, 1941.

be tolerated because of the long exposures necessitated by the low intensity of the light emitted by fluorescent objects. The light source must be intense, especially in the near-ultraviolet range (3,000 to 4,000 A.U.). The primary filter should exclude visible light from the fluorescent object. It should also exclude the far-ultraviolet or tanning and bactericidal rays. This is desirable from the point of view of safety for the photographer and others who may be present.

The photography of fluorescence thus requires, in addition to an ordinary camera, a lamp radiating only ultraviolet or invisible radiations, and a secondary filter which transmits visible light. The desirable characteristics of each of these requirements will be discussed in the course of a description of the apparatus and technique used to take the Kodachrome fluorescence photographs shown in Plate I.

The light source for Kodachrome fluorescent photography may be any type of quartz mercury arc or even carbon arc. Both of these are strong in the near-ultraviolet wave lengths. The primary filter must be applied in such a way as to prevent the leakage of visible light. For this reason the mercury arc is more convenient to use. There are numerous lights on the market today that are designed particularly for fluorescence studies. These have filters built into the lamp, either as close fitting lenses or as an envelope which almost completely surrounds the quartz mercury arc. It is, therefore, advisable to discuss the light source along with the primary filter.

These lamps, with the attached filter, which are designed for fluorescence studies are decidedly superior to many others for photographic utility.* Two of these lamps were used to irradiate the object with near-ultraviolet light in order to obtain the fluorescence photograph in Plate I. One was fixed at a distance of 20 inches from the object, and the other was held in the hand at the same distance and moved from side to side to avoid deep shadows. The bulb of the lamp used consisted of a quartz mercury arc surrounded by a primary filter or envelope of filter glass. This was screwed into a socket on an alzac aluminum reflector. One of the excellent features of this lamp is that it may be moved from side to side or fastened to a ring stand to illuminate the object from any desired angle. It is absolutely necessary to irradiate all sides of an object to be photographed. Due to the mobility of this lamp only one is required, but in order to decrease the exposure time two lamps are advantageous.

The only undesirable feature is that the arc light is enclosed with filter glass similar to No. 587 Corning filter, and this filter is not interchangeable. It transmits a small amount of violet, green, and a trace of red light. Even this almost negligible amount of visible light interferes with the recording of purely fluorescent light. When the light from this lamp was examined with a diffraction grating spectroscope, the violet band at 4,100 A.U. was easily discernible. The red was dim and the green line of the mercury spectrum was only observed when the arc was in line with the slit on the spectroscope. In this connection the Corning filter No. 586 might be more desirable as a primary filter. This is more nearly monochromatic since it transmits no visible light. The near-ultraviolet transmission is, however, much lower than in glasses which transmit traces of visible light. Other Corning filters which are usually recom-

*Detailed specifications will be furnished on request.

mended for fluorescence studies are the red-purple ultra No. 597, red ultra No. 584, blue-purple ultra No. 585, and red-purple corex A No. 986. While these filters are suitable for some studies in fluorescence, they are not suitable for color photography of fluorescence because of the visible light which they transmit.

The secondary filter used to photograph the fluorescence (Plate I) was a Corning glass filter No. 306 Noviol shade O. This has been referred to as the lens filter because it is placed either in front or in back of the lens. The perfect camera lens filter or secondary filter for fluorescence photography has not been found. The ideal filter for this would be one that absorbed all ultraviolet radiations and transmitted all the visible light. The Corning filter No. 038 Noviol shade A was almost ideal, but was itself highly fluorescent. However, this filter has been used successfully by placing it behind the lens inside the bellows where it is protected from most of the near-ultraviolet rays. The Corning filter No. 306 Noviol shade O, although almost ideal, transmits a negligible amount of near-ultraviolet and absorbs a trace of violet and blue. The Wratten No. 2A gelatin filter, which is used most frequently and is recommended by Walter Clark³ for fluorescence photography, is also good. This does transmit some near-ultraviolet, but absorbs less violet and blue in the visible spectrum than the Corning No. 306. The Wratten No. 2 Aesculine gelatin filter also absorbs ultraviolet radiations shorter than 3,800 to 3,900 A.U. but this, like the Corning No. 038 Noviol A, is intensely fluorescent. When the primary filter is a glass with characteristics of the Corning No. 587 red-purple ultra, the Corning No. 306 is superior to all other secondary filters since it absorbs a part of the purple light transmitted by the primary filter.

The photograph illustrated was taken with a 5 by 7 inch extension bellows camera equipped with a lens having a focal length of $6\frac{1}{2}$ inches. Kodachrome film, $3\frac{1}{4}$ by $4\frac{1}{4}$ inches, was used in a reducing back. Similar pictures have also been taken with several other cameras, including a Leica. In general, it may be said that almost any ordinary camera may be used for fluorescence photography. A quartz lens is not required and, as a matter of fact, would be a disadvantage because this would readily transmit the ultraviolet radiations. The glass lens in an ordinary camera also transmits some of the longer wave lengths or near-ultraviolet, but less than the quartz lens would transmit. The camera lens filter is thus necessary to absorb the reflected near-ultraviolet radiations (so-called actinic rays) which are not absorbed by the glass lens.

There is little information available with regard to the fluorescence of camera lenses. It is known, however, that the fluorescence characteristics of glass change with age, and that optical glasses or lenses from different manufacturers show unmistakable variations in fluorescence.⁴ The differences in the color of the fluorescent light emitted by various lenses range from pale yellow to violet, blue, and brilliant white. The differences in shade have been described as subtle but so characteristic that glasses from numerous sources almost never fluoresce similarly, and this fact has been used by one manufacturer to distinguish between his own and other products.⁴

The discussion of the fluorescence of glass has been introduced to emphasize the importance of checking this feature in every camera lens before attempting to use it for fluorescence photography. During the long exposure necessary for

FIG. 1 A and B.—Illumination. Visible light. A. Normal rat with the harderian gland exposed by removal and displacement of the eyeball. B. Rat maintained on a diet deficient in pantothenic acid. Note the incrustation of material that resembles dried blood. Illumination, incandescent tungsten filament (500 watt) at 5 feet. Camera, 5 by 7 inch extension bellows with a lens having a focal distance of $6\frac{1}{2}$ inches. Kodachrome type B film. Exposure time, $2\frac{1}{2}$ minutes at $f:45$.

FIG. 2 A and B.—Same as Fig. 1 A and B, but with near-ultraviolet illumination. Note the red fluorescence of the harderian gland and the porphyrin incrustations. Illumination, two 100 watt G. E. BH4 mercury arc lamps with an envelope of Corning No. 557 filter glass at 20 inches from the rats. Camera, same as above, 18 inches from rats to camera lens. Kodachrome daylight type film. Secondary filter, Wratten No. 2A for entire exposure. Corning No. 12 blue-green filter for last 4 minutes of exposure. Exposure time, 12 minutes at $f:5$.

Kodachrome photography a camera lens that fluoresced appreciably would cause fogging of the film or plate. This point was checked before making the color photograph in Plate I. The lens was not fluorescent so the filter to absorb the near-ultraviolet was placed between the lens and the plate. Had the lens been found to fluoresce, the filter would have been mounted in front of the lens. This would, therefore, have served a double purpose. It would have prevented ultraviolet radiation from reaching either the lens of the camera or the photographic plate. To test a lens for fluorescence irradiate it with near-ultraviolet light. If it is distinctly fluorescent, the lens will be seen to glow. Slight fluorescence may be detected by intermittently shielding the lens from the ultraviolet radiations by an ultraviolet-absorbing filter. If there is a glow which disappears when the lens is shielded, the lens is fluorescent. Shielding the lens with a hood or filter decreases the intensity of the fluorescence and the possibility of objectional effects.

There is great variation in the intensity as well as the wave length of the fluorescent light emitted by different materials. These widely varying conditions make it impossible to recommend specific types of Kodachrome film for recording fluorescence. In general, it may be stated that Kodachrome professional daylight type film is superior for objects which fluoresce a blue white, or blue and green with a little red. For objects that fluoresce more intensely in the red or yellow end of the visible spectrum, the type B professional Kodachrome gives the best color balance. Likewise, no specific rule can be given for the exposure time, except that it must always be relatively long in comparison to exposures with reflected light, because the intensity of the visible light resulting from the fluorescence is low and varies in different objects. Several factors will influence this variable fluorescence intensity in a definite way. The intensity of the light and its distance from the object regulate the intensity of fluorescence. The distance of the object from the camera or film must also be taken into account in estimating the exposure time.

As a preliminary procedure to determine the proper exposure, a series of test exposures of five, ten, twenty, and forty minutes at $f:8$ may be made and from these results the proper exposure is approximately estimated. It is imperative in Kodachrome photography to have the proper exposure, since this determines the accuracy of the method of recording the colors.

The fluorescence of the background is also an important feature. The background should be either nonfluorescent or should fluoresce a color that will set off or emphasize the color of the fluorescent object. A dull blue or black (nonfluorescent) background is best for red fluorescent objects. A white or red fluorescent background almost completely masks the fluorescence of red fluorescent objects.

The wide variation in the intensity of fluorescent light from different materials makes it impractical to try to photograph more than one specimen at a time. If this becomes necessary, groups of specimens should be chosen that exhibit a uniform fluorescence with regard to brightness. If this is impossible, it would be better to try to photograph the objects individually and to combine the photographs. In the case of the photograph of the fluorescence of rat fur

and the harderian gland, both objects fluoresce brightly. The red fluorescence of the harderian gland is relatively more intense than the blue-green fluorescence of the fur. It was found that when the proper exposure (twelve minutes) was given for the fur, the intense red of the gland and porphyrin incrustations was overexposed. To avoid this the exposure was made in the usual way for eight minutes. At the end of that time a Corning No. 430 dark shade blue-green filter was introduced between the object and the lens for an additional four minutes. This filter transmits the blue-green light from the fur but practically none of the red from the gland and porphyrin. In other words, the blue-green light from the fur acted on the film for twelve minutes, while the red of the gland and porphyrin incrustations acted only eight minutes. This yielded a more nearly perfect exposure for both materials. Accordingly, it may be seen that it is possible to compensate for differences in the brightness of the fluorescence of two objects by means of colored filters applied during a certain fraction of the exposure. It should be emphasized, however, that this is possible only for two or three different materials or colors, and in cases where the fluorescence spectra do not overlap too much. A number of attempts to compensate for the variations in brightness by means of illuminating the objects with filtered visible light of low intensity proved unsuccessful.

SUMMARY

A Kodachrome photographic method is outlined for recording the more delicate shades of colors caused by the fluorescence of objects when subjected to near-ultraviolet radiation. Some form of quartz mercury arc is recommended as the light source. This light must have a primary filter (Corning glass filter No. 586 or No. 587) transmitting the near-ultraviolet light, and absorbing all or almost all of the visible light. Only two of the secondary or lens filters mentioned in this discussion are suitable and practical. They are the Corning No. 306 Noviol O and the Wratten No. 2A. These may be mounted either in front of or in back of the camera lens. When it is necessary to photograph objects exhibiting the fluorescence of different colors and intensities, a more nearly perfect exposure is attained by means of a colored filter which absorbs the color emitted by the object which fluoresces most intensely. Such a filter would transmit the colors emitted by the materials which fluoresce less intensely. This filter is applied only during the last third of the exposure. Some of the requirements of the camera and lenses are also discussed.

Through the use of these methods and principles, it is possible to record faithfully on Kodachrome film some of the striking color effects brought to light by fluorescence studies.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

RESPIRATORY INFECTIONS, A Medium for Blood Cultures in, Humbert, C. R. Am. Rev. Tuberc. 45: 456, 1942.

The following formula has been found very serviceable:

	Bouillon	
Peptone		10 Gm.
Sodium chloride		5 Gm.
Lung infusion		1,000 c.c.
	Solid Medium	
Agar-agar		15 Gm.
Sodium chloride		5 Gm.
Lung infusion		1,000 c.c.

If the powdered lung is used, 120 Gm. in 1,000 c.c. of water are soaked overnight in the ice chest. It is then boiled and filtered. This filtrate is used as described above. The reaction is set at 7.8 pH.

This medium has been useful in obtaining blood cultures in respiratory infections where others have failed. It is also used for many other organisms by adjusting the reaction suitable for their growth.

TUBERCULOSIS, Vitamin K in, With Special Reference to Pulmonary Hemorrhage, Levy, S. Am. Rev. Tuberc. 45: 377, 1942.

Vitamin K and its relation to pulmonary tuberculosis and pulmonary hemorrhage are discussed.

Bleeding time, coagulation time, clotting power, and liver function tests were carried out in four groups of patients with pulmonary tuberculosis and in one control group.

Of the patients with pulmonary tuberculosis 32 per cent had a more or less marked degree of hypoprothrombinemia, while there was no evidence of this condition among the subjects of the control group. Hypoprothrombinemia is a frequent finding in pulmonary tuberculosis and reaches the lowest values among the group of patients with pulmonary hemorrhage.

Parenchymal liver damage was found to be present in 87 per cent of patients with pulmonary tuberculosis, while 33 per cent of the control subjects showed a slight degree of liver dysfunction.

The effect upon the clotting power of drugs routinely used in pulmonary hemorrhage was studied. It was found that sodium pentobarbital causes a lowering of the clotting power. Morphine, koagamen, and calcium also have a slight beneficial effect on the clotting power, although inferior to that of vitamin K.

It is suggested that vitamin K be used routinely as a prophylactic measure in patients whose x-ray films show cavity formation and who are shown to have a hypoprothrombinemia.

Vitamin K, together with the administration of morphine, appears to be the therapy of choice in the prevention and treatment of pulmonary hemorrhage due to tuberculosis.

BLOOD VELOCITY, An Objective Method of Determining (Fluorescein Method), Fishback, D. B., Gullman, S. A., and Abramson, E. B. Am. J. M. Sc. 203: 535, 1942.

A new objective circulation time is described, using fluorescein.

The data obtained indicate that the method is reasonably simple, not harmful to the patient, and reliable as indicated by comparison with other methods.

This method is of particular advantage in determining the blood velocity in small children, and in comatose, anesthetized, mentally ill, and moribund patients.

In patients with normal hearts or with fully compensated cardiac disease, the circulation time varied from 7 to 15.6 seconds. In another group of patients with cardiac disease undergoing decompensation, the circulation time varied from 16 to 25 seconds, one being 45 seconds.

The test for circulation time is done as follows: Using sterile precautions, an 18 gauge needle attached to a syringe containing 4 c.c. of a 10 per cent, or preferably 3 c.c. of a 20 per cent, sodium fluorescein solution is inserted into the antecubital vein of the arm. The room is then darkened, and the fluorescein is injected rapidly into the vein. The assistant, using a portable ultraviolet source with a Wood's filter, directs the light to one of the eyes of the patient, observing the palpebral conjunctiva. The first appearance of a brilliant yellow color in the lower palpebral conjunctiva is the end point. The end point is sharp, especially if the room is dark. The time elapsed from the moment of injection to the appearance of the dye in the eye is recorded.

Thus, the circulation time from the antecubital vein of the arm to the conjunctiva of the eye is accurately determined.

SYPHILIS, Value of Complement Fixation and Agglutination With Spirochetal Antigens and Relation of Spirochetal Antibody to the Wassermann Reaction, Kolmer, J. A. Arch. Dermat. & Syph. 45: 455, 1942.

Complement fixation tests conducted with antigens of cultivated *S. pallida*, especially of the Reiter and Kazan strains, compare favorably in sensitivity with the Wassermann and flocculation tests in the serologic diagnosis of syphilis of human beings and rabbits, but their practical value in the diagnosis of the disease in its different stages and in relation to treatment has not been sufficiently defined.

Spirochetal complement fixation tests in syphilis of human beings and rabbits are not as specific as the Wassermann and flocculation tests, largely because of the presence in normal serum of natural spirochetal antibody.

This natural antibody, as well as that produced in syphilis, is of a group character reacting not only with cultivated *S. pallida* but with *S. macrodentium*, *S. microdentium*, and other spirochetes.

Spirochetal complement fixing antibody is increased in malaria and in leprosy, with a high incidence of positive complement fixation reactions in both diseases, especially in the former. Under the conditions it is improbable that the spirochetal complement fixation test will identify as biologic false reactions the positive Wassermann and flocculation reactions observed in nonsyphilitic persons with leprosy and malaria.

Normal human and rabbit sera also contain a natural group agglutinin for cultivated *S. pallida* and other spirochetes. The agglutinin undergoes some increase in syphilis but not sufficient for rendering the spirochetal agglutination test with cultivated spirochetes of diagnostic value in syphilis.

The results of agglutination and complement fixation tests with suspensions of virulent *S. pallida* obtained from acute testicular syphilomas of rabbits have indicated more definitely the production of these antibodies in syphilis of human beings and rabbits than tests employing suspensions of the cultivated spirochetes, which suggests that the latter have undergone dissociation into variants with a change in antigenic structure associated with a loss of virulence.

Complement fixation and agglutination tests with cultivated spirochetes have indicated the possible existence of serologic strains of *S. pallida* and also their biologic relation to *S. macrodentium*, *S. microdentium*, and *S. refringens*.

Largely on the basis of absorption of syphilitic human serum with tissue lipids and suspensions of cultivated *S. pallida*, the preponderance of evidence is in favor of regarding the Wassermann reagin and spirochetal antibody as separate entities which may coexist in serum.

Undoubtedly the lipids of *S. pallida* are important in complement fixation by the Wassermann reagin. Whether spirochetal antibody reacts with them is unknown, but it

has been suggested that it fixes complement with some other constituent of spirochetes of a nonprotein nature.

The practical value of antigens of cultivated *S. pallida* in the serologic diagnosis of syphilis and in relation to the treatment of the disease cannot be stated at present, but they are worthy of further study. If such strains are employed, antigens of whole spirochetes in phenolized saline solution appear to be advisable. The Reiter or Kazan strains are preferred, and a mixture of the two may be advisable. The amount employed should be the minimum, giving positive reactions with human syphilitic serum, in order to avoid falsely positive reactions with natural spirochetal antibody as much as possible. Suspensions of virulent tissue spirochetes are preferred, but owing to technical difficulties in their preparation they probably cannot be employed.

CULTURE, Differential, Simple Method of Using Penicillin, Tellurite and Gentian Violet for, Fleming, A. Brit. M. J., May 2, p. 547, 1942.

By the simple method of spreading a small quantity of gentian violet over half of the culture plate of blood agar after it has been planted, it is possible to isolate a few streptococci from the midst of a multitude of staphylococci, just as it has been shown to be if the gentian violet is incorporated in the medium.

Whatever chemical is used with this technique, it is necessary, when spreading it over half the plate, to start where the inoculum is lightest and proceed toward where it is heaviest; otherwise there may be so many resistant bacteria that a confluent sheet of growth results.

Three chemicals can be used in this way with great advantage in the clinical bacteriological laboratory. They are penicillin, potassium tellurite, and gentian violet.

The great advantages of this simple method of spreading the chemical over half the culture plate after inoculation are (1) special media need not be prepared; (2) one-half of the culture plate is an ordinary culture and the other half a selective culture, thus really giving the effect of two culture plates in one.

GLUCOSE, The Assimilation Rate of Intravenously Injected, in Hospital Patients, Cain, J. C., and Belk, W. P. Am. J. M. Sc. 203: 359, 1942.

The assimilation rate of intravenously administered glucose in hospital patients was found to be correlated with the rate of injection. The assimilation of 5.77 Gm. per kilogram of body weight per hour was observed.

In all cases some glucose was lost in the urine, the amounts varying from approximately 0.3 to 30 per cent of the total given. The average loss was 12.2 per cent.

The proportion of injected glucose lost in the urine was not correlated with the rate of injection, nor with the total amount given within the limits studied. This "spill" is conditioned by factors within the individual patients.

For practical purposes the rate for the intravenous administration of glucose may be determined solely on two considerations; first, the hydrodynamics of the patient's circulation; second, technical convenience.

SYRINGE, Removing "Frozen" Plungers by a Hydraulic Pressure Method, Novak, M., and Lacy, A. M. Am. J. Technol. 8: 42, 1942.

A 1 inch No. 22 Yale hypodermic needle is telescoped into a No. 19 (1½ inch) Yale needle so as to make a firm connection. One needle is attached to the frozen syringe, and the other to the tuberculin syringe which is filled with water. By forcing water into the "frozen" syringe, pressure is exerted on the "frozen" plunger and almost always it will be forced out. Air in the system should first be displaced with water for best results.

This simple device may be made in a minute from old needles, and kept on hand for use when needed. Any combination of needles may be used as long as they fit together firmly. The use of the two needles in this manner makes a flexible connection and diminishes the chances of breaking the ends of the syringes.

TISSUE, Combined Frozen and Paraffin Method for Rapid Sections, Thomlinson, B. C.
Arch. Path. 33: 35, 1942.

Technique

1. The tissue, if not already fixed, is placed in hot dilute formaldehyde solution (10 c.c. of solution of formaldehyde U.S.P. in 90 c.c. of water) for three minutes. The solution should be steaming (about 65° C.) but not boiling, and the pieces of tissue may be large, but not over 3 mm. in thickness.

2. Frozen sections, as thin as possible (10 to 15 microns), are prepared by the usual method. Overfreezing should be avoided since it causes an unnecessary delay.

3. Sections are transferred from the knife to a dish of warm (40° C.) 0.2 per cent gelatin solution, from which a section is then floated carefully onto a clean slide, and any wrinkles which may form are teased out.

4. The excess fluid around the section is wiped off, and the slide is dried cautiously over the pilot flame of a Bunsen burner. Overheating is to be avoided.

5. When the section is thoroughly dried, it is cooled and placed in formaldehyde alcohol (10 c.c. of solution of formaldehyde U.S.P. in 90 c.c. of 95 per cent ethyl alcohol) for one-half minute.

6. It is then dehydrated in 95 per cent ethyl alcohol, followed by absolute alcohol, one-half minute in each.

7. After being cleared in xylene for one-half minute, it is transferred to a beaker of melted paraffin in an oven at 60° C. for three minutes.

8. The slide is then removed from the beaker of paraffin and returned to the oven for five minutes. This assures attachment of the section to the slide during the staining process and apparently produces a mordant effect on the tissues.

Various staining methods may now be employed. The technique for the hematoxylin-eosin method is as follows:

1. Remove paraffin with xylene for 30 seconds.

2. Place in 95 per cent alcohol for 15 seconds.

3. Place in 70 per cent alcohol for 15 seconds.

4. Wash quickly in tap water for 10 seconds.

5. Stain in fresh Harris hematoxylin for one minute.

6. Wash in water, and decolorize in 0.5 per cent aqueous solution of hydrochloric acid. Wash and intensify in a weak solution of ammonia water and again wash for 30 seconds.

7. Counterstain with eosin and rinse in water for one minute.

8. Dehydrate in 70 per cent, 95 per cent, and absolute alcohol for 10 seconds each.

9. Clear in xylene.

10. Mount in Canada balsam.

HEMOSIDERIN, A New Modification of Perls's Reaction for, in Tissues, Highman, B.
Arch. Path. 33: 937, 1942.

It is suggested that one volume of a 2 per cent aqueous solution of potassium ferrocyanide be mixed with an equal volume of a 4 to 6 per cent aqueous acetic acid, heated in a test tube until beads of gas appear on the inner surface of the glass (about 60° to 80° C.), poured on the section, and allowed to remain thereon for from forty-five seconds to five minutes.

After being washed in water, the section is counterstained for five minutes with a 1:6,000 to 1:10,000 solution of basic fuchsin in 2 per cent aqueous acetic acid.

SUBJECT INDEX

Abstracts are indicated by (Abst.) after the page number; book reviews by (B. Rev.) after the page number.

A

- Abdominal surgery in experimental animals, sodium pentothal anesthesia for, 1199
wall, local rigidity of, demonstration of, 1122
- Abscess, lung, postoperative, 1510
radioactive substance in, detection of, 50
- Abscesses and tumors, detection of, 50
- Absorption, enteral, of pollen antigen, 32S
from esophagus, 51
from stomach, 51
of stilbestrol and theelin from cysts of sesame and peanut oils, 622
of undigested protein, studies in, 51
- Acacia in treatment of nephrotic syndrome, 567 (Abst.), 551 (Abst.)
- Accessories, laboratory, blood lancet assembled from, 92
- Acetate, desoxycorticosterone, in Addison's disease, 1117
syndrome simulating diabetes insipidus in dogs induced by, 1009
- Acetylcholine esterase in blood serum, 619
- Acid, adenylic, muscle, effect of, in malnourished persons, 527
ascorbic, tolerance test, oral, 51S
citric, determination of, 267
glacial acetic, method for Cabot ring bodies in erythrocytes, 996
hippuric, from urine, effect of added salts on recovery of, 10S
liver function test, 1593
- Acid-fast bacilli, examination for, 806
technique for detection of, 531
- Acidosis, diabetic, blood volume produced by, changes in, 1169
- Acute diarrhea in infants and children, 347
postoperative lung abscess, 1510
- Adapter for microcentrifuge shields, 839
- Addison's disease, desoxycorticosterone acetate and sodium in, 1117
- Adenylic acid, muscle, effect of, in malnourished persons with pellagra and peripheral neuritis, 527
- Adhesive materials, 124
- Administration, intravenous, of oxygen, 223
- Adsorption analyses, chromatographic, 1229 (B. Rev.)
- Adtevac process, mass production methods based on, 812
- Advancing front of medicine, 981 (B. Rev.)
- Aerobic, gram-negative sporulating bacillus, used by, 41
- Ag of *Neisseria*, 656
- Agar, *Neisseria* *flexneri*, isolation of *Flexner* dysentery bacilli, use of, 1051
- Age incidence of positive tuberculin reactions (Mantoux), 322
- Aged, cholesterol studies in, 1563
vital capacity studies in, 737
- Agglutination reactions in rheumatoid arthritis, 765
slide, in detecting pertussis antibodies, 792
- Agglutinin response to skin tests with brucellergen and Brucella vaccine, 1244
- Air, embalmed specimens exposed to, dehydration in, 1078
- Albumin, determination of, 1446
plasma, in healthy individuals, 471
- Alcohol, amphetamine sulfate-ethyl, antagonism in rabbit, 131
perchlorate method for determining concentration of, 1225 (Abst.)
- polyvinyl, injections, effects of, on blood and tissues, 1131
- Alkalinization of urine, 12S (Abst.)
- Allergic asthma, 321
- persons, blood magnesium in, 1367
- Allergy in clinical practice, 982 (B. Rev.)
iodine, 1150
serum, multiple, in atopic individuals, 187
synopsis of, 982 (B. Rev.)
- Alum precipitated, tetanus toxoid, sensitization induced by, 26
- Aluminum in biological material, 159S
- American and his food, 1109 (B. Rev.)
- Amino acid mixtures, peptone in, 260
plasma levels, 1491 (Abst.)
- acids, parenterally administered, results of treatment with, 1400
- Amphetamine sulfate-ethyl alcohol antagonism in rabbit, 131
- Amyl nitrite, pulmonary cerebral effect time as determined by, 1111
- Amylase on digestion, supplemental, effect of, 30S
- Amyloidosis, Benhold's test for, 934
Congo red, test for, 1225 (Abst.)
primary, of lungs, 882
- Anaerobic atmospheres in Petri dishes, exposing cultures to, 1431
- "Anagrams," electrocardiographic, 1063
- Anal canal, gonorrhea of, treatment of, 1046
- Analytical chemistry of industrial poisons, hazards and solvents, 1230 (B. Rev.)
- Analyzer, oxygen, for oxygen tents, 1346
- Anaphylactic shock, effect of, upon blood potassium and concentration, 206
in guinea pigs, protection against, by histaminase, 337
- Androgenic substances in urine of eunuchoid and castrate men, 917
- Anemia, acute hemolytic, 139
pernicious, hypoprolthrombinemia in, 1226 (Abst.)
patients with, under treatment, red blood cell counts and hemoglobin determinations in, 937
target cells in, 1105 (Abst.)
- Anemic rabbits, hematopoiesis in, 890
- Anesthesia, sodium pentothal, for abdominal surgery in animals, 1199
- Anesthetic steroid hormones and pentamethylenetetrazol, antagonism between, 1051
- Animal compression chamber, 237
- Animals, experimental, abdominal surgery in, anesthesia for, 1199
small, method for stomach tubing, 352
- Antagonism between anesthetic steroid hormones and pentamethylenetetrazol, 1051
- Antibacterial property in diphtheria, 1491 (Abst.)
- Antibodies, pertussis, slide agglutination in detecting, 792
- Anticoagulation as technical source of variations in erythrocyte sedimentation, 1569
- Antifogging effect of soap on eyeglasses and diagnostic mirrors, 798
- Antigen for Eagle flocculation test, 660
pollen, 328
- Antihemorrhagic activity of extract of European mountain ash berry, 897
- Antiseptics, toxicity of, 1432
- Antithrombin, quantitative studies on, 1493 (Abst.)
- Antitoxin, staphylococcus, in areas of rabbit's skin, 37
- Apical scars, silicon in relation to, 1023
- Apparatus facilitating preparation of tissues for paraffin sections, 673
- Application and wearing of facial prostheses, 123
- Aqueous solution, extraction of proteins from, 941

- Art and science of nutrition, 1108 (B. Rev.)
 Arterial obstruction, peripheral, 19
 pressure, systolic, indirect determination of,
 in rats, 1192
 Artery occlusions, coronary, 418 (Abst.)
 Arthralgia, menopause, 297
 Arthritis, atrophic, chronic, peripheral nerves
 in, 1256
 pathology of, 435
 brucellosal, chronic, atrophic type of, 168
 by electroparalysis, treatment of, 1135
 rheumatoid, Mester's test in, 81
 Ascorbic acid tolerance test, oral, 518
 Aspergillosis, pulmonary, 740
 Assay of heparin, 820
 microbiological, method for six B vitamins,
 1086
 Assembly trays, 676
 Assimilation rate of intravenously injected
 glucose, 1613 (Abst.)
 Asthma, allergic, 321
 experimental, 319
 histamine, 323
 Atopic individuals, multiple serum, allergy
 in, 187
 Atrophic arthritis, chronic, peripheral nerves
 in, 1256
 pathology of, 435
 Auscultatory blood pressure method for dogs,
 371
 percussion with a new instrument, 602
 Australian tiger snake (*Notechis scutatus*),
 venom of, coagulant from toxic
 principles of, 45
 Auto-antibodies in serodiagnosis of syphilis,
 720
 Automatic pipette washer and rinser, 381
 quadruple pipetting machine, 244
- B
- Bacilli, acid-fast, technique for detection of,
 531
 Flexner dysentery, isolation of, from feces,
 1081
 Bacillus dysenteriae (Flexner), medium for,
 1350 (Abst.)
 tellurite rosolic acid medium for, 977
 (Abst.)
 sporulating, aerobic, gram-negative, bac-
 teremia produced by, 41
 Bacteria, production of pyrogen, 569
 Bacterial flora of nose, 1105 (Abst.)
 Bacteriemia produced by an aerobic gram-
 negative sporulating bacillus, 41
 secondary, septicemia complicated by, 176
 Bacteriologic check on residual dental infec-
 tions, 1154
 , 275 (Abst.)
 use of thioglycollate
 medium, 1
 Bacterium coli anaerogenes septicemia, 1048
 Balancing rack, hematocrit tube, 928
 Basal metabolic rates, effect of cigarette
 smoking upon, 787
 metabolism data, variability of, effect of
 operator on, 1328
 Basophilia, diffuse and punctate, 992
 Bottle, suspending, method of, 1336
 Benhold's test for amyloidosis, 934
 Benzene poisoning in industry, 1517
 β (3,5 di-iodo-4-hydroxyphenyl) α propionic
 acid, pharmacology of, 1376
 Bile, calcium in, determination of, 113
 salts, toxicities and choleric activities of,
 181
 Bilirubin in body fluids, qualitative studies
 of, 1447
 Biliselectan, 1376
 Biochemistry, practical methods in, 1110 (B.
 Rev.)
 Biological diagnosis of pregnancy, 547
 fluids choline content of, 103
 , in, meth-
 (Abst.)
 of, 391
 material, aluminum in, 1598
 symposia, 1228 (B. Rev.)
 Bipolar electrodes, shielded, 364
 Biuret method for determination of serum
 proteins, 840
 "Black line" in hematocrit determinations,
 1034
- Blastomycoides histolytica in infections of
 central nervous system, 58
 Blood, 704 (Abst.)
 bromide determinations, 680
 cell, radio-phosphorus on, effects of, 1291
 cells in healthy young infants, 586 (Abst.)
 red, human, in disease, type hemolytic
 reactions of, 542
 chloride in diagnosis of dehydration, 1174
 citrate, effect on stools, 1491 (Abst.)
 clotting, 701 (Abst.)
 in circulation studies, method for pre-
 venting, 75
 coagulation of, fibrinolysis in, 1119
 simple method of timing, 1226 (Abst.)
 cultures in respiratory infections, medium
 for, 1611 (Abst.)
 diseases of, 981 (B. Rev.)
 donors, response of, to iron, 128 (Abst.)
 for transfusion, collection of, 1070
 from ear lobe, 487
 fusospirochetes in, recovery of, 417 (Abst.)
 human, cholesterol and cholesterol ester
 values in, effect of standing on, 1208
 infusion of, via bone marrow, 703 (Abst.)
 in human feces, 1212
 in lungs of dogs, 1144
 inulin in, colorimetric determination of, 115
 iodine, 703 (Abst.)
 fractionation of, 613
 lancet assembled from common laboratory
 accessories, 92
 loss, response of normal subjects to, 567
 (Abst.)
 magnesium in allergic persons, 1367
 of rabbit, nonprotein nitrogen in, retention
 of, 779
 pattern in diagnosis of malignant disease,
 1522
 peripheral, sulfaguanidine in, 785
 picture in chickenpox, 276 (Abst.)
 platelets, method of evaluating, 1069
 polyvinyl alcohol injections on, effects of,
 1131
 postmortem, dextrose and nondextrose re-
 ducing substances in, 568 (Abst.)
 potassium, effect of anaphylactic shock up-
 on, 206
 pressure fluctuations in respiratory obstruc-
 tion, 1536
 in unanesthetized rat, plethysmographic
 method for, 240
 methods, auscultatory, for dogs, 371
 proteins, adsorption of bromides by, 683
 serum, acetylcholine esterase in, 649
 desiccated, 277 (Abst.)
 pycnometer for, 1096
 specific gravity of, 1463
 vitamin D in, 557
 "stored," glucose in preservation of, 129
 (Abst.)
 stream, multiple invasion of, 173
 surgical technique for deviating entire
 urine into, 1586
 sugar and structure of pancreas of rat,
 influence of a parotid extract on,
 510
 curves, intravenous, measurement of, 491
 sulfanilamide in, micro test for, 852 (Abst.)
 sulfonamide determination, micromethod
 for, 1355
 sulfonamides in, method for determining,
 827
 urea, determination of, clinical micromethod
 for, 1222
 micromethod for determination of, 1222
 velocity, 1611 (Abst.)
 volume produced by diabetic acidosis,
 changes in, 1169
 whole, cholesterol in, 1439
 Bodansky and Fiske-Subbarow methods, com-
 parison of, for determination of in-
 organic phosphorus, 554
 Bodies, Cabot ring, of erythrocytes, 983
 Body fluids, bilirubin in, 1447
 bromides in, methods for determining, 680
 shaking machine for, 1582
 trypsin as digestant of, 866
 Bone marrow, infusions of blood and other
 fluids via, 703 (Abst.)
 Bowel, large, sulfaguanidine in, 785
 Brain, recovery of rabies virus from, 1263
 Bromide, blood, determinations, 680

Bromides, adsorption of, 683
 Brucella, 1259
 vaccine, skin tests with, 1244
 Brucellergen, skin tests with, 1244
 Brucellosis, chronic, atrophic type of, 168
 Brucellosis, 1259
 Bulb, duodenal, acidity, 1501

C

Cabot ring bodies of erythrocytes, 983
 Calcium in bile, determination of, 113
 Calibration curve, standard, preparation of, 1599
 Cancer, 1368
 magnesium content of blood in, 1370
 Capacity, vital, studies in the aged, 737
 Capillary and venous red blood cell counts, comparison of, 937
 permeability, effect of histamine phosphate on, 1554
 in skin of sensitized rabbits, 598
 serum, protein content of, 1457
 Caps, protective, for glass tissue grinders, 1337
 Carbon dioxide, exposing cultures to, 1431
 disulfide poisoning in cats, 1107 (Abst.)
 Cardiac depression by mercurial diuretics, 303
 Cardiospasm, 102
 Cardiovascular syphilis, 17
 Carotene, comparative physiologic value of, injected, 502
 parenteral administration of, 504
 Castrate men, androgenic and estrogenic substances in urine of, 917
 Cell, blood, effects of radio-phosphorus on, 1294
 counts, capillary and venous red blood, in patients with pernicious anemia, 937
 Center point, 1600
 Central nervous system, Blastomycoides histolytica in infections of, 58
 Centrifugation, tube for, in four-place centrifuge, 252
 Centrifuge, 252
 Cephalin-cholesterol flocculation test, 777
 Cerebral, pulmonary, effect time, 1111
 Cerebrospinal fluid, 416 (Abst.)
 Chamber, animal compression, 237
 Chemical factors of erythrocyte sedimentation, 1319
 solutions, 1229 (B. Rev.)
 studies in delirium tremens, 63
 Chemistry, analytical, of industrial poisons, hazards and solvents, 1230 (B. Rev.)
 of infectious diseases, 213
 Chemotherapeutic studies of 2-sulfanilyl-3-5 dihydrothiazole, 1276
 Chest Lead CF₂, P wave in, following spontaneous pneumothorax, 465
 Chickenpox, blood picture in, 276 (Abst.)
 Children, acute diarrhea in, 347
 Chloride, blood, in diagnosis of dehydration, 1174
 Chloroform, emulsification with, extraction of proteins by means of, 941
 "Chocolate agar" for isolation of Neisseria and hemoglobinophiles, 656
 Choleretic activities of bile salts, 181
 Cholesterol ester values in human blood, 1208
 in whole blood, serum, or plasma, determination of, 1439
 spectrophotometric determination of, 1349
 studies in the aged, 1563
 urinary, determination of, 1093
 Cholesterol-cephalin flocculation test, 777
 Choline content of biological fluids, 103
 Choline-esterase, serum, regional and seasonal variations in, 640
 Chorio-allantoic membrane of developing hen egg, cultivation of Spirochaeta pallida on, 232
 Chromatographic adsorption analysis, 1229 (B. Rev.)
 Chronic atrophic arthritis, peripheral nerves in, 1256
 type of brucellosis arthritis, 168
 syphilis, serologic diagnosis in histologically proved, 15
 Cigarette smoking, immediate effect of, upon basal metabolic rates, 787

Cinemicography, dark-field, apparatus for, 1187
 Circulation, renal, effect of pitressin on, 1013
 studies, blood clotting in, method for preventing, 75
 time, pulmonary cerebral, 1111
 venous, lesions which interfere with, 908
 Circulatory system, diseases of, 1365
 Cirrhosis, hepatic, serum proteins in, 1101 (Abst.)
 of liver, 1400
 Citrated blood in man, oral administration of, 1491 (Abst.)
 Citric acid, determination of, 267
 Clinical micromethod for determination of blood urea, 1222
 practice, allergy in, 952 (B. Rev.)
 significance of serum proteins, 1457
 studies with aid of radio-phosphorus, 1294
 use of cephalin-cholesterol flocculation test, 777
 Clostridium welchii, identification by Nagler reaction, 417 (Abst.)
 Clot retraction time, measuring, 1492 (Abst.)
 Clots, plasma, 1333
 Clotting, blood, in circulation studies, method for preventing, 75
 time, relation of, to prothrombin concentration in human plasma, 197
 Coagulate human plasma, ability of staphylococci to, 603
 Coagulation, blood, simple method of timing, 1226 (Abst.)
 from toxic principles of venom of Australian tiger snake (Notechis scutatus), 45
 of blood, fibrinolysis in, 1119
 time, plasma, 1492 (Abst.)
 Cobaltinitrite, silver, method, adaptation of, for potassium to photoelectric colorimeter, 960
 Collection of blood for transfusion, 1070
 Color in wax-resin compositions, 1102
 index, hemoglobin-red cell ratio to replace, 128 (Abst.)
 plate, 272, 1608
 Colorimeter, Evelyn, determination of trypsin in duodenal contents with, 835
 photoelectric, 1598
 photoelectric, adaptation of Marshall's micro sulfonamide method to, 1218
 of silver cobaltinitrite method for potassium to, 960
 direct diazo reaction by, 1447
 phosphorus determination for use with, 955
 Colorimetric determination of inulin in blood and urine, 115
 phosphorus determination, 955
 Colorimetry, photoelectric and visual, determination of serum proteins as applied to, 840
 Colostrum cutaneous test for pregnancy, 1494 (Abst.)
 Coma, hypoglycemic, temperatures in, statistical study of, 11
 Comparative effects of propylene glycol and some other agents on oxygen consumption of the organism, 770
 physiologic value of injected carotene and vitamin A, 502
 Comparator, 1338
 Complement fixation and agglutination with spirochetal antigens in Wassermann reaction, 1612 (Abst.)
 Complement-antigen combination for use in Kolmer complement fixation test, 97
 Compositions, agar, for molding, 966
 wax-resins, for moulage-making, 1098
 Compounds, sulfonamide, in treatment of poliomyelitis of mice, ineffectiveness of, 1166
 Compression chamber, animal, 237
 Concentration of staphylococcus in areas of rabbit's skin, 37
 methods, demonstration of tubercle bacilli by, factors influencing, 84
 Congenital absence of gall bladder and cystic duct, 594
 Congo red test for amyloidosis, 1225 (Abst.)
 Convulsant drug therapy, electrocardiogram in epilepsy and in seizures following, 1249

- Corn germ sterol, deterioration of, 83
 Coronary artery occlusions, 418 (Abst.)
 Corpuscle, red, life of, 448
 Corynebacterium diphtheriae, serological classification of, 1360 (Abst.)
 Cottonseed protein from stomach, absorption of, 55
 Counting spermatozoa, method of, 660
 Creatinine clearance and urine flow of dog during fever, 1306
 Cryptococcus hominis in mice, immunity studies of, 751
 Culture, differential, using penicillin, tellurite and gentian violet for, 1613 (Abst.)
 Cultures, bacteria, under paraffin oil, 1491 (Abst.)
 method of exposing to carbon dioxide or anaerobic atmospheres in Petri dishes, 1431
 Cutaneous diagnosis of gonococcal infections, 128 (Abst.)
 Cystic duct, congenital absence of, 594
 Cysts of sesame and peanut oils, absorption of stilbestrol and theelin from, 622
- D
- Daily variations in toxicity of neoparsphennamine in rabbits, 715
 in white rats, 719
 Dark-field cinematography, apparatus for, 1487
 Dehydrating and clearing iron-hematoxylin stained fecal smears, 251
 Dehydration, diagnosis of, value of blood chloride and sodium in, 1174
 in embalmed specimens exposed to air, 1078
 Delayed typing of pneumococcus, 805
 Delirium tremens, chemical studies in, 63
 Delivery, bilirubin values and prothrombin in umbilical artery and vein at, 1227 (Abst.)
 Demonstration of tubercle bacilli by concentration methods, factors influencing, 84
 Dental infections, residual, bacteriologic check on, 1154
 Dermatology, introduction to, 1229 (B. Rev.)
 "Desensitizing" doses of prostigmine, treatment of severe periodic headaches with, 1546
 Desiccated plasma for national defense, 812
 Desiccator, "lyophile," 799
 Desoxycorticosterone acetate in Addison's disease, 1117
 syndrome simulating diabetes insipidus in dogs induced by, 1009
 Destruction of human leucocytes, toxicity of antiseptics measured by, 1432
 Detection of abscesses and tumors, studies on, 50
 Detergent in solubility tests for identification of pneumococci, 1591
 Deterioration of corn germ sterol, 83
 Device for protection of thermostats in water baths, 797
 Dextrose, hypertonic solution of, intravenous injections of, in rabbit, 779
 in postmortem blood, 568 (Abst.)
 Diabetes insipidus, syndrome simulating, in dogs induced by desoxycorticosterone acetate, 1009
 Diabetic acidosis, blood volume produced by, changes in, 1169
 Diagnosis, biological, of pregnancy, 547
 of intestinal parasites, food remnants as cause of confusion in, 1036
 and chronic
 Diagnostic bacteriology, use of thioglycollate medium in, 671
 mirrors, antifogging effect of soap on, 798
 1109 (B. Rev.)
 test in, 347
- Digestant of sputum, trypsin as, 806
 Digestion, amylase on, supplemental, effect of, 308
 procedure for microgasometric determination of nitrogen, Hengar selenized granules in, 266
- Digestive mixture for protein determinations, use of, 1444
 system, diseases of, 1108 (B. Rev.)
 Dihydrotachysterol in parathyroid tetany, use of, 497
 β (3, 5 di-iodo-1-hydroxyphenyl) α propionic acid, pharmacology, 1376
 Diphtheria, antibacterial property in, 1491 (Abst.)
 tellurite test for, 702 (Abst.)
 Disease, Addison's, desoxycorticosterone acetate and sodium in, 1117
 Hodgkin's, sedimentation rate in, 1200
 human red blood cells in, type hemolytic reactions of, 542
 malignant, blood pattern in diagnosis of, 1522
 peripheral vascular, vasodilatation tests in, 878
 serum magnesium in, variations in, 1361
 Diseases, acetylcholine esterase in blood serum of patients with, 649
 infectious, chemistry of, 213
 of blood, 981 (B. Rev.)
 of digestive system, 1108 (B. Rev.)
 of eye, 1108 (B. Rev.)
 of liver and gall bladder, 1371
 Dithionite method, aid in, 269
 Diuresis, use of sucrose-Ringer's solution to produce, 606
 Diuretics, mercurial, cardiac depression by, 303
 Dog, creatinine clearance and urine flow of, during fever, 1306
 effect of pitressin on, 1015
 Dogs, blood pressure methods for, 371
 lungs of, amount of plasma and whole blood in, 1114
 serum choline-esterase of, variations in, 640
 syndrome simulating diabetes insipidus in, 1009
 Dosage-mortality ratio of pentothal sodium with sulfanilamide, 749
 Doucil, removal of interfering substances by, 1442
 Drawings, water color, for screen projection, 271
 Drip method, intravenous, 1268
 Drop recorder, Hanike-Gibbs, modification of, 802
 Drug therapy, convulsant, electrocardiogram in epilepsy and in seizures following, 1249
 Drying serum, method and procedure for, 558
 Duodenal bulb acidity in fasting normal people, 1501
 contents, trypsin in, 835
 Duponol WA (flakes), 1591
 Dysentery bacilli, Flexner, isolation of, from feces, 1081
- E
- Eagle flocculation test, antigen for, 660
 Ear lobe, blood from, 487
 Effect time, pulmonary cerebral, 1111
 Egg, hen, chorio-allantoic membrane of developing, Spirochaeta pallida on, 232
 yolk, production of diffuse and punctate basophilia with, 993
 Electrocardiogram in epilepsy following convulsant drug therapy, 1249
 in seizures following convulsant drug therapy, 1249
 Electrocardiographic "anagrams," 1063
 changes in malignant hypertension, 1156
 Electrocardiography, essentials of, 1109 (B. Rev.)
 method of teaching, 1063
 Electrodes, bipolar, 364
 scalp, 1344
 Electroencephalography, application of scalp electrodes in, 1344
 Electropyrrexia, treatme
 Embalmed specimens,
 Emulsification with ch
 proteins by means of, 941
 adaches, 150
 of, 278 (B. Rev.)
 ollen antigen, 328

- Enzymes, 219
 Eosinate, methylene blue, polychrome, 552
 Eosinophilia, extreme, 418 (Abst.)
 Erythroblastic leucemia, 506 (Abst.)
 Erythrocyte fragility changes produced by
 sulfanilamide, 418 (Abst.)
 human, surface area of, 1280
 mature, structure of, 989
 sedimentation, equipment for measuring,
 1410
 measurement of, 1410
 phenomenon of, 1317
 anticoagulation as technical source of
 variations, 1509
 Erythrocytes, Cabot ring bodies of, 983
 human, 994
 of citrated human blood, survival time of,
 129 (Abst.)
 Esophagus, absorption from, 54
 Essentials of electrocardiography, 1109 (B.
 Rev.)
 of endocrinology, 278 (B. Rev.)
 Ester, cholesterol, in human blood, effect of
 standing on, 1208
 Esterase, acetylcholine, in blood serum, 649
 Estrogenic substances in urine of eunuchoid
 and castrate men, 917
 Eunuchoid men, androgenic and estrogenic
 substances in urine of, 917
 European mountain ash berry, investigations
 on extract of, 837
 Evelyn colorimeter, determination of trypsin
 in duodenal contents with, 835
 photoelectric, determination of aluminum
 with, 1598
 Experimental animals, anesthesia for abdom-
 inal surgery in, 1199
 asthma, 319
 hypertension, and indirect determination of
 systolic arterial pressure in rats,
 1192
 polycythemia, recovery from, 874
 production of hypoalbuminemia by fasting,
 1183
 study of lymphocytic response in thyrotoxi-
 cosis, 1
 Experimentally induced hematopoiesis in ane-
 mic rabbits, 800
 Exposure time in photomicrography, deter-
 mination of, 846
 Extract of European mountain ash berry,
 investigations on, 837
 splenic, effect of, from cases of essential
 thrombocytopenic purpura on rab-
 bits, 754
 Extraction of proteins from aqueous solution,
 941
 Eye, diseases of, 1108 (B. Rev.)
 Eyeglasses, antifogging effect of soap on, 798

F

- Face, agar mold for, 972
 Facial prostheses, application and wearing of,
 123
 Factors influencing Weltmann serum coagula-
 tion reaction, 368
 Fasting, experimental production of hypoal-
 buminemia by, 1183
 normal people, duodenal bulb acidity in,
 1501
 Fatigue, vitamin B complex on recovery from,
 influence of, 1396
 Fecal smears, iron-hematoxylin stained, 254
 Feces, Flexner dysentery bacilli from, isola-
 tion of, 1051
 human, blood in, quantitative determination
 of, 1212
 Feeding device, mechanical, 931
 Ferrithemochromogen, insulin, 774
 Fever, creatinine clearance and urine flow of
 dog during, 1306
 therapeutic, plasma proteins in, 1054
 therapy, physiologic studies during, 1135
 Fibrinogen in healthy individuals, 471
 Fibrinolysis in coagulation of blood, 1119
 Fibroblast in vitro, effect of lowered temper-
 atures upon growth of, 460
 Filter, Seitz, pressure, for laboratory use, 79
 Fluke-Subbarow and Bodansky methods, com-
 parison of, for determination of in-
 organic phosphorus, 551

- Fixation, formaldehyde, measurement of, 666
 meter, 667
 Flexner dysentery bacilli, isolation of, from
 feces, 1081
 Flocculation test, cephalin-cholesterol, 777
 Eagle, antigen for, 660
 Flora, vaginal, in children, 1107 (Abst.)
 Fluctuations, blood pressure, in respiratory
 obstruction, 1536
 Fluid, pipetting machine for delivery of, 244
 Fluids, biological, choline content of, 103
 estimation of sulfanilamide and sulfapy-
 ridine in, 978 (Abst.)
 body, bilirubin in, 1447
 method of examining, 507 (Abst.)
 trypsin as digestant of, 806
 intravenous, temperature studies on, 1164
 Fluorescein method, 1611 (Abst.)
 Fluorescence microscopy detection of tubercle
 bacilli by, 274 (Abst.)
 demonstration of tubercle bacilli by, 416
 (Abst.)
 simplification of, 188
 phenomena, kodachrome photography of,
 1606
 Fluorescent screen, light-producing power of,
 407
 staining technique for detection of acid-
 fast bacilli, 531
 Fluorography, 399
 Food, the American and his, 1160 (B. Rev.)
 remnants in diagnosis of intestinal para-
 sites, 1036
 Forensic medicine, 568 (Abst.)
 Formaldehyde fixation, measurement of, 666
 sulfoxylate, sodium, treatment of mercury
 poisoning with, 1357
 Formalin-fixed tissues, staining technique for,
 1342
 Formol-gel test in rheumatic fever, 1226
 (Abst.)
 Formulary, University of California Hospital,
 1169 (B. Rev.)
 Fractionation of blood iodine, 643
 Frog kidney, effect of pitressin on, 1013
 Frozen and paraffin method, combined, for
 rapid sections, 1614 (Abst.)
 sections, staining method for gram-positive
 and gram-negative organisms in, 977
 (Abst.)
 "Frozen" plungers, removing, by hydraulic
 pressure method, 1613 (Abst.)
 Funnels, separatory, mechanical shaker for,
 269
 Fusospirochetal angina, mouth spirochetes
 from, 1473
 Fusospirochetosis, 417 (Abst.)

G

- Gall bladder, congenital absence of, 594
 Gastric analysis, use of Töpfer's reagent in,
 111
 digestion, effect of taka-diastase on, 309
 Gastro-enteritis, acute, 348
 Genital functions and their hormonal regula-
 tion, 278 (B. Rev.)
 Gentian violet, 1613 (Abst.)
 Georges Hayem, 855
 Gibbs-Hanike drop recorder, modification of,
 802
 Glacial acetic acid method for Cabot ring
 bodies in erythrocytes, 996
 Gland, harderian, 1455
 Glass tissue grinders, protective caps for,
 1337
 Globulin in healthy individuals, 471
 Glomerular circulation in frog kidney, effect
 of pitressin on, 1013
 Glucose, intravenously injected, assimilation
 rate of, 1613 (Abst.)
 Glycerinated red blood cells, laking of, by
 physiologic salt solution, 253
 Glycol, propylene, comparative effects of, 770
 Gonococci, isolation and identification of, 276
 (Abst.)
 Gonococcal infections, cutaneous diagnosis of,
 125 (Abst.)
 Gonococcus, preservation of, 129 (Abst.)
 Gonorrhea of anal canal, sulfanilamide for
 treatment of, 1046

- Gonorrheal urethritis in male, treatment of, 1001
- Gout, sedimentation rate in, 725
- Gram-negative sporulating bacillus, aerobic, bacteremia produced by, 41
- Grinders, tissue, 1337
- Growth of fibroblast in vitro, effect of lowered temperatures upon, 460
- *Guinea pigs, mouth spirochetes in exudate from, 1475
- protection against histamine and anaphylactic shock in, 337
- systemic histoplasmosis produced in, 419
- H
- Hair, tensile strength of, 235
- Hanke-Gulbs drop recorder, modification of, 502
- Harderian gland ablation, prevention of porphyrin incrustations on pantothenic acid-deficient rats, 1495
- Hawaiian islands, hematologic values for normal healthy men, 1231
- Hayem, Georges, 855
- Headaches, endocrine aspects of, 150
- periodic, severe, treatment of, 1546
- Healthy individuals, plasma albumin, globulin, and fibrinogen in, 471
- Heart records, stethoscopic, 981 (B. Rev.)
- Hematocrit determinations, "black line" in, 1084
- tube balancing rack, 928
- Hematologic values for normal healthy young men, 1231
- Hematology, father of, 855
- Hematopoiesis in anemic rabbits, 890
- Hematopoietic organs of rabbits, effect of splenic extracts from cases of essential thrombocytopenic purpura on, 754
- Hemoglobin determinations in patients with pernicious anemia, 937
- Hemoglobin-red cell ratio to replace color index, 128 (Abst.)
- Hemoglobinometry, 1358 (Abst.)
- Hemoglobinophiles, isolation of, 656
- Hemolytic reactions, type, of human red blood cells in disease, 542
- Hemophilia, diagnosis of, 128 (Abst.)
- Hemophilus pertussis, 851 (Abst.)
- Hemorrhagic chicks, effect on coagulation time in, 897
- Hemosiderin, Perls's reaction for, in tissues, 1614 (Abst.)
- Hemostatic, rabbit thrombin as, use of, 704 (Abst.)
- Hengar selenized granules, use of, 266
- Heparin, assay of, 820
- Hepatic deficiency, 1493 (Abst.)
- Hinton tests, evaluation of Laughlen test based on, 374
- Hippuric acid from urine, added salts on recovery of, effect of, 108
- liver function test, 1593
- test in hepatic deficiency, 1493 (Abst.)
- Histaminase, 628, 635
- anaphylactic shock in guinea pigs by, protection against, 337
- laboratory studies, 628
- treatment of asthma with, 319
- by intramuscular injection, results of, 635
- Histamine asthma, 323
- headaches, 1546
- phosphate, effect of, on capillary permeability and inflammation, 1554
- protection against, in guinea pigs by histaminase, 337
- trypan blue in areas of skin injected with, 1556
- Histologically proved chronic syphilis, serologic diagnosis, 15
- Histoplasmosis, systemic, 419
- Hodgkin's disease, sedimentation rate in, 1200
- Homogenization, shaking sputums and body fluids during, 1582
- Hormonal regulation, genital functions and their, 278 (B. Rev.)
- Hormones, anesthetic steroid, and pentamethylenetetrazol, antagonism between, 1051
- Human beings, serum choline-esterase of, variations in, 640
- erythrocyte, surface area of, 1280
- feces, blood in, 1212
- plasma, ability of staphylococci to coagulate, 663
- Hydraulic pressure method, removing "frozen" plungers by, 1613 (Abst.)
- Hydrolysates, protein, peptone in, 260
- Hyperplasia, lipomelanotic reticular, of lymph nodes, 343
- Hypertension, experimental, in rats, 1192
- malignant, electrocardiographic changes in, 1156
- Hypoalbuminemia by fasting, production of, 1183
- Hypoglycemic coma, temperatures in, 11
- Hypoprote thrombinemia in pernicious anemia, 1226 (Abst.)
- Hypothyroidism, findings in patients with, 643
- I
- Identification of pneumococci, 1591

- studies of *Cryptococcus hominis* (Torula histolytica) in mice, 751
- Immunology, 982 (B. Rev.)
- Inanimate object, agar mold for, 969
- Indoxyl compounds in urine, quantitative determination of, 949
- Industrial poisons, hazards and solvents, analytical chemistry of, 1230 (B. Rev.)
- Industry, benzene poisoning in, 1517
- Infant nutrition, 1108 (B. Rev.)
- Infants, acute diarrhea in, 347
- blood cells in, 566 (Abst.)
- Infections, dental, residual, bacteriologic check on, 1154
- streptococcus, sulfonamide therapy of, 1268
- Infectious diseases, chemistry of, 213
- lymphocytosis, 275 (Abst.)
- mononucleosis, 417 (Abst.)
- Inflammation, effect of histamine phosphate on, 1554
- Ingestion of large doses of vitamin D, 557
- Injections, intravenous, of hypertonic solution of dextrose in rabbit, 779
- polyvinyl alcohol, on blood and tissues, 1131
- Inoculation, intranasal, of mice, micropipette for, 1197
- Inorganic phosphorus, determination of, comparison of methods for, 554
- Insulin ferrihemochromogen, 774
- Intestinal parasites, diagnosis of, food remnants as cause of confusion in, 1036
- vascular sclerosis, 576
- Intramuscular administration of sodium sulfapyridine to children, 712
- pressure, apparatus for measurement of, 1339
- Intranasal inoculation of mice, micropipette for, 1197
- Intraperitoneal drip of anesthesia for abdominal surgery in animals, 1199
- Intravenous administration of oxygen, 223
- of phosphate solution in normal rabbits, 68
- blood sugar curves, 491
- drip method, sulfonamide therapy of streptococcus infections by, 1268
- fluids, temperature studies on, 1164
- injections of hypertonic solution of dextrose in rabbit, 779
- use of sucrose-Ringer's solution to produce maximal diuresis, 606
- Introduction to dermatology, 1228 (B. Rev.)
- Inulin in blood and urine, 115
- Inverted microscope, improvised, 809
- Iodine allergy, 1150
- blood, 703 (Abst.)
- fractionation of, 643
- Iron, response of blood donors to, 128 (Abst.)
- Iron-hematoxylin stained fecal smears, dehydrating and clearing, 254
- Isolation of Flexner dysentery bacilli from feces, 1081
- of *Neisseria* and hemoglobinophiles, 656
- Item, meeting of scientific photographers, 1357
- urology award, 418

J

Jaundice, nonprotein nitrogen in, 271 (Abst.)

K

Kahn verification test, 1105 (Abst.)

Kodachrome photography of fluorescence phenomena, 1606

Kolmer complement fixation test, complement-antigen combination for use in, 97

L

Laboratory accessories, blood lancet assembled from, 92

shaking machine, 1330

use, pressure Seltz filter for, 79

Lactobacillus casei, microbiological assay method for six B vitamins using, 1086

Laking of glycerinated red blood cells by physiologic salt solution, 253

Lancet, blood, assembled from common laboratory accessories, 92

Larvae, *Trichinella spiralis*, in tissues, 1354

Laughlin test for syphilis, 77, 374

Lecithinized venom on prothrombin clotting time, 830

Lecture on spirochetes, 1470

Leptospira biflexa, 1480

canicola, 1484

icterohaemorrhagiae, 1480

Lesions, malignant, multiple primary, 588

in man, *Treponema pallidum* from, 1478

in superior mediastinum, 908

Leucemia, erythroblastic, 566 (Abst.)

Leucemoid reaction, 139

Leucocytes, human, destruction of, toxicity of antiseptics measured by, 1432

Leucocytosis 418 (Abst.)

Lewis, Dean De Witt, In memoriam, December, 1941

Life of red corpuscle, 448

Lipomelanotic reticular hyperplasia of lymph nodes, 343

Liver, cirrhosis of, 1400

hippuric acid, function test, 1503

Lobar pneumonia, sodium sulfapyridine monohydrate in treatment of, 443

Local rigidity of abdominal wall, demonstration of, 1422

Localization and concentration of staphylococcus antitoxin in areas of rabbit's skin, 37

Lung abscess, postoperative, 1510

Lungs of dogs, plasma and whole blood in, 1144

nonsilicotic, silicon in, 1623

primary amyloidosis of, 852

Lymph nodes, lipomelanotic reticular hyperplasia of, 343

Lymphatics, lymph, and lymphoid tissue, 1228 (B. Rev.)

Lymphocytic response in thyrotoxicosis, study of, 1

Lymphocytosis, infectious, 275 (Abst.)

Lymphoid tissue, lymphatics, lymph and, 1228 (B. Rev.)

ascorbic acid tolerance test, 518

cavity, pathology of, 1110 (B. Rev.)

Organism, oxygen consumption of, comparative effects of propylene glycol on, 770

Origin and nature of Cabot ring bodies of erythrocytes, 983

Oscillometry, 22

Oxidation test in serum, direct diazo reaction by, 1447

Oxygen analyzer for oxygen tents, 1346

consumption of organism, comparative effects of propylene glycol on, 770

intravenous administration of, 223

tents, analyzer for, 1346

P

Pain, sensitivity to, determination of, 248

Pancreas, structure of, and blood sugar of rat, influence of parotid extract on, 510

Pantothenic acid-deficient rats, prophylin incrustations on, prevention of, 1495

Paraffin for imbedding purposes, preparing, 932

oil, bacteria cultures under, 1491 (Abst.)

sections, apparatus facilitating preparation of tissues for, 673

Parasites, animal, immunity against, 1110 (B. Rev.)

intestinal, diagnosis of, food remnants in, 1036

Parasitic spirochetes, 1470

Parathyroprivic tetany, use of dihydrotachysterol in, 497

Parotid extract, influence of, on blood sugar and structure of pancreas of rat, 510

Pathogenic spirochetes, 1470

Pathologic patients, serum magnesium in, variations of, 616

tissue changes produced by sulfathiazole and sulfathiazoline in rabbits, 1043

Pathology of atrophic arthritis, 435

of oral cavity, 1110 (B. Rev.)

Peanut oils, cysts of, absorption of, stilbestrol and theelin from, 622

Pellagra, malnourished persons with, 527

Penicillin, 1613 (Abst.)

Pentamethylenetetrazol and anesthetic steroid hormones, antagonism between, 1051

Pentothal, sodium, anesthesia, for abdominal surgery in animals, 1199

with sulfanilamide, dosage-mortality ratio of, 749

Peptone in protein hydrolysates and amino acid mixtures, 260

Perchlorate method for determining concentration of alcohol, 1225 (Abst.)

Percussion with a new instrument, 602

Percutaneous potency of progesterone, 746

Perineum, rubber, 1429

Periodic headaches, severe, treatment of, 1546

Peripheral arterial obstruction, diagnosis of, 19

blood, concentration of sulfaguanidine in, 785

nerves in chronic atrophic arthritis, 1256

neuritis, malnourished persons with, 527

vascular disease, vasodilatation tests in, 878

Perls' reaction for hemosiderin, in tissues, 1614 (Abst.)

Permeability, capillary, effect of histamine phosphate on, 1554

in skin of sensitized rabbits, 598

Pernicious anemia, patients with, under treatment, red blood cell counts and hemoglobin determinations in, 937

Pertussis antibodies, slide agglutination in detecting, 792

hemophilus, 851 (Abst.)

Petri dishes, anaerobic atmospheres in, exposing cultures to, 1431

- Pharmacology of β (3, 5 di-iodo-1-hydroxy-phenyl) a phenyl propionic acid, 1376
of thymoxyethyldiethylamine, 289
Phosphate, histamine, effect of, on capillary permeability, 1554
solution in normal rabbits, intravenous administration of, 68
Phosphorus determination, colorimetric, 955
inorganic, determination of, comparison of methods for, 554
spectrophotometric determination of, 1349
Photoelectric colorimeter, adaptation of Marshall's micro sulfonamide method to, 1218
colorimetric phosphorus determination for use with, 955
direct diazo reaction by, 1447
Evelyn, determination of aluminum with, 1598
colorimetry, 840
Photographers, scientific, meeting of, 1357
Photography, kodachrome, of fluorescence phenomena, 1606
Photomicrography, 1228 (B. Rev.)
exposure time in, method for determination of, 846
Physical and chemical properties of sputum, 1106 (Abst.)
factors of erythrocyte sedimentation, 1318
medicine, 1110 (B. Rev.)
Physician, social revolution and, 279
Physiologic saline injected intravenously, 157
studies during fever therapy, 1135
value of injected carotene and vitamin A, 502
Physiological factors of erythrocyte sedimentation, 1320
Pipette washer and rinser, automatic, 381
Pipettes, mechanical manipulator for, 1354
specific gravity, 695
Pipetting machine, automatic quadruple, 244
Pitressin, effect of, on renal circulation and urine secretion, 1013
Plasma albumin in healthy individuals, 471
amino acid levels, 1494 (Abst.)
cholesterol in, 1439
clots, tensile strength and stretch of, 1333
coagulation time, 1492 (Abst.)
desiccated, for national defense, 512
human, ability of staphylococci to coagulate, 663
relation of clotting time to prothrombin concentration, 197
hypertonic, 813
in lungs of dogs, 1144
proteins and cirrhosis of liver, 1400
in therapeutic fever, 1054
method for estimating, 701 (Abst.)
relationship of, to corrected sedimentation rate, 1072
prothrombin, 1494 (Abst.)
Plaster method, closed, specimens from wounds treated by, 275 (Abst.)
Platelet factors, quantitative and qualitative, estimation of, 255
Platelets, blood, method of evaluating, 1069
of rabbits, effect of splenic extracts from cases of essential thrombocytopenic purpura on, 754
Plethysmographic method for determining blood pressure in unanesthetized rat, 240
Pleural shock—a reflex, 145
Pleximeter, 603
Pneumococci, identification of, detergent in solubility tests for, 1591
sensitivity of, to sulfapyridine, 127 (Abst.)
Pneumococcus, delayed typing of, 505
infected dog sera, polarographic studies of, 213
Pneumonia, lobar, sodium sulfapyridine monohydrate in treatment of, 443
Pneumothorax, spontaneous, P wave in chest Lead CF₂ following, 465
Poisoning, benzene, in industry, 1517
mercury, acute, treatment of, 1357
Polarographic studies of behavior of normal and pneumococcus infected dog sera, 213
Pollomyelitis of mice, ineffectiveness of sulfonamide in treatment of, 1166
Pollen antigen, enteral absorption of, 328
Polychrome methylene blue eosinate, 552
Polycyte, 806
Polycythemia, experimental, recovery from, 571
Polyvinyl alcohol injections on blood and tissues, effects of, 1131
Porphyrin incrustations on pantothenic acid-deficient rats, prevention of, 1495
Postoperative lung abscess, acute, 1510
Potassium, blood, effect of anaphylactic shock upon, 206
Potency, percutaneous, of progesterone, 746
Practical methods in biochemistry, 1110 (B. Rev.)
Pregnancy, biological diagnosis of, 547
colostrum cutaneous test for, 1494 (Abst.)
Pressure Seitz filter for laboratory use, 79
Primary amyloidosis of lungs, 882
malignant lesions, multiple, 588
Principal nervous pathways, 1169 (B. Rev.)
Priodol, 1376
Procedures and reagents, diagnostic, 1169 (B. Rev.)
Processing assembly, 673
Production of pyrogen by some bacteria, 569
Progesterone, percutaneous potency of, 746
Projection, screen, water color drawings for, 271
Propolycytes in infection, 867
Propylene glycol, comparative effects of, on oxygen consumption of organism, 770
Prosthesis, facial, application and wearing of, 123
Prostigmine, "desensitizing" doses of, treatment of severe periodic headaches with, 1546
observations and use of, 162
Protection of thermostats in water baths, 797
Protective caps for glass tissue grinders, 1337
Protein concentration of blood serum, specific gravity of, 1463
cottonseed, absorption of, from stomach, 55
determinations, digestive mixture for, use of, 1444
hydrolysates, peptone in, 269
serum, determination of, 693
undigested, studies in absorption of, 54
Proteins, extraction of, from aqueous solution, 941
plasma, in therapeutic fever, 1054
method for estimating, 701 (Abst.)
relationship of, to corrected sedimentation rate, 1072
serum, clinical significance of, 1457
direct biuret method for determination of, 840
in hepatic cirrhosis, 1104 (Abst.)
Prothrombin, 1227 (Abst.)
clotting time, effect of lecithinized on, 820
concentration in human plasma, relation of clotting time to, 197
deficiency, 1226 (Abst.)
in pulmonary tuberculosis, 978 (Abst.)
plasma, 1494 (Abst.)
studies using Russell viper venom, 197, 820
tests, thromboplastins for, 255
Pucher-Sherman-Vickery method for determination of citric acid, modification of, 267
Pulmonary aspergillosis, 740
cerebral effect time as determined by amyl nitrite, 1111
Purpura, 139
thrombocytopenic, essential, effect of splenic extracts from, on rabbits, 754
P wave in chest Lead CF₂ following spontaneous pneumothorax, 465
Pyelitis with septicemia caused by *S. paratyphosiae*, 1607
Pyknometer for blood serum, 1666
Pyridoxine hydrochloride, relief of muscular weakness by, 763
Pyrogen, production of, by some bacteria, 569

Q

- Qualitative platelet factors, estimation of, 235
studies of bilirubin in body fluids, 1447
 Quantitative determination of blood in human feces, 1212
 of indoxyl compounds in urine, 949
 micropipette for intranasal inoculation of mice with virus suspensions, 1197
 platelet factors, estimation of, 235
 studies on antithrombin, 1493 (Abst.)

R

- Rabbit, amphetamine sulfate-ethyl alcohol antagonism in, 131
 nonprotein nitrogen in blood of, retention of, 779
 plasma, 704 (Abst.)
 skin, staphylococcus antitoxin in areas of, 37
 Rabbits, anemic, hematopoiesis in, 890
 effect of splenic extracts from cases of essential thrombocytopenic purpura on, 754
 neoarsphenamine in, variations in toxicity of, 715
 normal, phosphate solution in, intravenous administration of, 68
 pathologic tissue changes produced by sulfathiazole and sulfathiazoline in, 1043
 sensitized, capillary permeability and inflammation in skin of, 598
 Rabies, error in diagnosis of, by microscopic search for Negri bodies, 71
 virus, recovery of, from brain, 1263
 Rack, balancing, hematocrit tube, 928
 test tube, 1338
 Radioactive substance in abscess, concentration and detection of, 50
 Radio-phosphorus, clinical studies with, 1294
 Rapid section of tissue, 1014 (Abst.)
 Rat, blood sugar and structure of pancreas of, influence of parotid extract on, 510
 hypertension and systolic arterial pressure in, production of, 1192
 pantothenic acid-deficient, prevention of incrustations on, 1495
 unanesthetized, plethysmographic method for determining blood pressure in, 240
 Rate, microsedimentation, 355
 sedimentation, in gout, 725
 in Hodgkin's disease, 1200
 relationship of plasma proteins to corrected, 1072
 Ratio, dosage-mortality, of pentothal sodium with sulfanilamide, 749
 Reaction, direct diazo, 1447
 Takata-Ara, diagnostic value of, 1359 (Abst.)
 Weltmann micromethod of, 94
 serum coagulation, factors influencing, 366
 xanthoprotein, in renal insufficiency, 201
 Reactions, agglutination, in rheumatoid arthritis, 705
 toxic, to sulfapyridine, 139
 tuberculin, age incidence of, 332
 type hemolytic, of human red blood cells in disease, 542
 Reagent, Nessler's, by use of mercuric oxide, 118
 Töpfer's, use of, in gastric analysis, 111
 Reciprocal activity of desoxycorticosterone acetate and sodium in Addison's disease, 1117
 Recovery of rabies virus from brain, 1263
 Red blood cell counts in patients with pernicious anemia, 937
 cells, glycerinated, laking of, 253
 in disease, type hemolytic reactions, 542
 corpuscle, life of, 448
 Reducing substances in postmortem blood, 568 (Abst.)
 Reflex, 148
 Regional and seasonal variations in serum choline-esterase of human beings and dogs, 640
 Regulation of reciprocal activity of desoxycorticosterone acetate and sodium in Addison's disease, 1117

- Relationship of plasma proteins to corrected sedimentation rate, 1072
 Relief of muscular weakness by pyridoxine hydrochloride, 703
 Remnants, food, in diagnosis of intestinal parasites, 1036
 Renal circulation, effect of pitressin on, 1013
 disorders, 1363
 insufficiency, xanthoprotein reaction in, 201
 Residual dental infections, check on, 1151
 Resin, 1102
 Resin-wax compositions for moulage-making, 1098
 Respiration tambour, 722
 Respiratory amplitudes, differences between, apparatus for observation of, 1425
 infections, medium for blood cultures in, 1611 (Abst.)
 obstruction, blood pressure fluctuations in, 1536
 Response, lymphocytic, in thyrotoxicosis, study of, 1
 venous pressure, to physiologic saline injected intravenously, 157
 Retina, 982 (B. Rev.)
 Retraction time, clot, 1492 (Abst.)
 Revolution, social, and the physician, 279
 Rheumatic fever, formol-gel test in, 1226 (Abst.)
 Rheumatoid arthritis, agglutination reactions in, 705
 Mester's test in, 81
 Rigidity, local, of abdominal wall, demonstration of, 1422
 Ring bodies, Cabot, 983
 Ringer's-sucrose solution, use of, to produce diuresis, 606
 Rocky mountain spotted fever, 127 (Abst.)
 Roots, hair, tensile strength of, 235
 Rubber perineum, 1429
 Russell viper venom, prothrombin studies using, 197, 830

S

- Salt, bile, toxicities and choleretic activities of, 181
 effect of, on recovery of hippuric acid from urine, 108
 solution, physiologic, laking of glycerinated red blood cells by, 253
 Salyrgan, 304
 Sarcoidosis, 1284
 Scalp electrodes, application of, in electroencephalography, 1344
 Scars, apical, etiologic conception of, 1023
 Schizophrenic patients, application of oral ascorbic acid tolerance test to, 518
 Scientific photographers, meeting of, 1357
 Sclerosis, intestinal vascular, 576
 Screen projection, water color drawings for, 271
 Seasonal variations in serum choline-esterase, 640
 Secretion, urine, effect of pitressin on, 1013
 Sedimentation, erythrocyte, 1317, 1569
 measurement of, 1410
 rate in gout, 725
 in Hodgkin's disease, 1200
 relationship of plasma proteins to corrected, 1072
 Seitz filter for laboratory use, 79
 Seizures, electrocardiogram in, following convulsant drug therapy, 1249
 Selenized granules, Hengar, use of, 266
 Senile patients, application of oral ascorbic acid tolerance test to, 518
 Sensitivity to pain, determination of, 248
 Sensitization induced by tetanus toxoid, alum precipitated, 26
 Sensitized rabbits, capillary permeability and inflammation in skin of, 598
 Senses, 249
 Septicemia, *Bacterium coli anaerogenes*, 1045
 pyelitis with, caused by *S. paratyphenteriae*, 1007
 spurious mixed, 178
 true mixed, 174
 Sera, dog, pneumococcus infected, polarographic studies of, 213

- Serodiagnosis of syphilis, auto-antibodies in, 729
- Serologic diagnosis in histologically proved chronic syphilis, 15
- reactions in tests for syphilis, 1101 (Abst.)
- testing, strain variation in, 1259
- Serological classification of *C. diphtheriae*, 1360 (Abst.)
- Serum allergy, multiple, in atopic individuals, 187
- blood, acetylcholine esterase in, 619
- pycnometer for, 1096
- specific gravity of, 1183
- vitamin D in, 557
- chloride, 1178
- cholesterol in, 1439
- choline-esterase, variations in, of human beings and dogs, 610
- coagulation reaction, Weltmann, factors influencing, 366
- drying, method and procedure for, 558
- magnesium in health and disease, 1361
- variations of, 616
- protein, determination of, 693
- in wound disruption, 276 (Abst.)
- proteins, clinical significance of, 1457
- direct biuret method for determination of, 810
- sodium, 1175
- Sesame, cysts of, absorption of stilbestrol and theelin from, 622
- Shaker, mechanical, for separatory funnels, 269
- Shaking machine and containers for shaking sputums and body fluids, 1552
- laboratory, 1330
- Shields, microcentrifuge, adapter for, 539
- S. paratyphosa*, pyelitis with septicemia caused by, 1007

- Thrombic activity of globulin fraction derived from rabbit plasma, 704 (Abst.)
- Thrombin, rabbit, as local hemostatic, 704 (Abst.)
- Thrombocytopenic purpura, essential, effect of splenic extracts from, on rabbits, 754
- Thromboplastins for prothrombin tests, 385
- Thymoxyethylidethylamine, pharmacology of, 289
- Thyroid function, findings in patients with normal, 643
- relation of blood iodine to, 703 (Abst.)
- Thyrotoxicosis, lymphocytic response in, study of, 1
- Time, influence of, on venous pressure responses to physiologic saline, 157
- Tissue, formaldehyde-fixed, stain for, 701 (Abst.)
- for microscopic examination, method of preparing, 537
- grinders, glass, 1337
- method for rapid sections, 1614 (Abst.)
- pathologic, changes in rabbits, 1043
- polyvinyl alcohol injections on, effects of, 1131
- staining method for gram-positive and gram-negative organisms in frozen sections, 977 (Abst.)
- technique for formalin-fixed tissues, 1342
- washer, multiple, 673

Titration and standardization of antigen for Eagle flocculation test, 660
 of soybean meal, 112
 T.N.T. derivative in urine, test for, 853 (Abst.)
 Töpfer's reagent in gastric analysis, use of, after test meals of milk, cream, or soybean biscuits, 111
 Torula, dead, immunity from injections of, 752
 histolytic in mice, immunity studies of, 751
 Toxic principles of venom of the Australian tiger snake *Notechis scutatus*, coagulant from, 45
 reactions to sulfapyridine, 139
 Toxicities and choleric activities of bile salts, 181
 Toxicity of antiseptics, 1432
 of neoparsphenamine in rabbits, daily variations in, 715
 in white rats, daily variations in, 719
 of neoprontosil by intravenous administration, 1268
 Toxoid, tetanus, alum precipitated, 26
 Transfusion, blood for, collection of, 1070
 Transfusions, 703 (Abst.)
 "Transparent chocolate agar," 656
Treponema buccale, 1474
 cuniculi, 1480
 microdentium, 1475
 pallidum, 1476
 pertenuis, 1480
 recurrentis, 1473
 vincenti, 1474
Trichinella spiralis larvae in tissues, 1384
 Trichinosis, 127 (Abst.)
 precipitin test for, 1106 (Abst.)
 Trypan blue in areas of skin injected with histamine, 1556
 Trypsin as digestant of sputum, 806
 determination of, in duodenal contents, 835
 Tube agglutination, comparison of slide with, 792
 for centrifugation, 252
 Tubercle bacilli, 416 (Abst.)
 concentration of, 1494 (Abst.)
 culture of, 130 (Abst.)
 demonstration, 130 (Abst.)
 factors influencing, 84
 detection of, 274 (Abst.)
 sedimentation of, factors influencing, 88
 Tubercular lesion of color and abdominal wall, 272
 Tuberculin reactions, age incidence of, 332
 Tuberculosis, criteria differentiating sarcoidosis from, 1284
 pulmonary, prothrombin deficiency in, 978 (Abst.)
 vitamin K in, 1611 (Abst.)
 Tubing, stomach, small animals, 352
 Tubo-ovarian abscess, 272
 Tularemia, 701 (Abst.)
 Tumors, detection of, 50
 Type hemolytic reactions of human red blood cells in disease, 542
 Typing, delayed, of pneumococcus, 805
 Tyrosine equivalent method, protein values determined by, 416 (Abst.)

U

"Ulcer-bearing area," 1501
 Ultrafiltration, mercury vacuum release for, 1206
 University men and women, effect of cigarette smoking upon basal metabolic rates of, 787
 of California Hospital formulary, 1109 (B. Rev.)
 Unknown, preparation and analysis of, 1600
 Urea, blood, micromethod for determination of, 1222
 clearance test, Van Slyke, nomogram of, 264
 nitrogen in biological fluids, 391
 sulfonamide solubility in, 1567

Urethritis, gonorrheal, in male, treatment of, 1001
 Urinary cholesterol, determination of, 1093
 Urine, androgenic and estrogenic substances in, of eunuchoid and castrate men, 917
 flow of dog during fever, changes in, 1306
 hippuric acid from, effect of added salts on, recovery of, 108
 indoxyl compounds in, 949
 inulin in, colorimetric determination of, 115
 method for rapid alkalization of, 128 (Abst.)
 secretion, effect of pitressin on, 1013
 surgical technique for deviating, into blood stream, 1586
 T.N.T. derivative in, 853 (Abst.)
 urobilinogen in, 977 (Abst.)
 Urines and broth, frozen, preservation of gonococcus in, 129 (Abst.)
 Urobilinogen in feces and urine, 977 (Abst.)
 Urology award, 418

V

Vaccine, brucella, skin tests with, 1244
 Vacuum release, mercury, 1206
 Vaginal flora in children, 1107 (Abst.)
 smears, method of staining, 1104 (Abst.)
 Values for acetylcholine esterase in blood serum of normal persons and patients with various diseases, 640
 Van Slyke urea clearance test, nomogram of, 264
 Variability of basal metabolism data, effect of operator on, 1328
 Variation, strain, in serologic testing, 1259
 Variations, anticoagulation as a technical source of, 1569
 in toxicity of neoparsphenamine, 715, 719
 of serum magnesium in health and disease, 1361
 in normal and pathologic patients, 616
 Vascular and cellular dynamics of shock, 1227 (Abst.)
 disease, peripheral, vasodilatation tests in, 878
 sclerosis, intestinal, 576
 Vasodilatation tests in peripheral vascular disease, 878
 Venom of Australian tiger snake (*Notechis scutatus*), 45
 Russell viper, prothrombin studies using, 197, 830
 Venous circulation, lesions which interfere with, 908
 pressure, apparatus for measurement of, 1339
 response to physiologic saline, 157
 red blood cell counts in patients with pernicious anemia, 937
 serum, protein content of, 1457
 Viper venom, Russell, prothrombin studies using, 197, 830
 Virus, rabies, recovery of, from brain, 1263
 suspensions, micropipette for intranasal inoculation of mice with, 1197
 Visual colorimetry, 840
 Vital capacity studies in the aged, 737
 Vitamin A, comparative physiologic value of injected, 502
 parenteral administration of, 506
 B complex, influence of, on recovery from fatigue, 1396
 microbiological assay method for, 1086
 C and senility, 524
 and serum protein in wound disruption, 276 (Abst.)
 D in blood serum, 557
 K, effect of, on patients with prothrombin deficiency, 1226 (Abst.)
 in tuberculosis, 1611 (Abst.)
 Volume, blood, produced by diabetic acidosis, changes in, 1169
 influence of, on venous pressure responses to physiologic saline, 157

W

- Wassermann reaction, relation of spirochetal antibody to, 1612 (Abst.)
Water baths, protection of thermostats in, 797
color drawings for screen projection, 271
Wax, 1102
Wax-resin compositions for moulage-making, 1098
Webster test for T.N.T. derivative in urine, 853 (Abst.)
Weltmann reaction, micromethod of, 94
serum coagulation reaction, factors influencing, 366
Wetting agents, 219
Whole blood, cholesterol in, 1439
in lungs of dogs, 1144
Wilson and Blair medium, 1359 (Abst.)

- Wound healing, effect of lowered temperatures upon growth of fibroblast in vitro in, 466
Wright's solution, staining with, 351

X

- Xanthoprotein reaction in renal insufficiency, 201

Y

- Yeast, effect of, in malnourished persons with pellagra and peripheral neuritis, 527

Z

- Ziehl-Neelsen stain, sulfonamides and, 1106 (Abst.)
